DR. R. W. TAYLOR'S CASE OF PRIMARY MELANO-SARCOMA OF THE VULVA.

A SECTION OF THE LESS PIGMENTED PORTION.

# THE NEW YORK MEDICAL JOURNAL, JULY 6, 1889.

## Original Communications.

### PRIMARY MELANO-SARCOMA OF THE VULVA.\*

BY R. W. TAYLOR, M. D.,  
SURGEON TO CHARITY HOSPITAL, NEW YORK.

ALL forms of malignant new growths—epithelioma, carcinoma, and sarcoma—upon the external genitals of the female are of exceedingly rare occurrence. When found on these regions, they are usually primary lesions, and exceptionally they occur as secondary deposits, or, still more rarely, by extension downward from the internal genital tract. While epithelioma of the uterus is far from common, it has been noted that from thirty-five to forty cases of it occur to one of the same disease of the external parts, yet epithelioma takes first place in the order of frequency of malignant new growths of the vulva. In medical literature the histories of so many cases of epithelioma of the vulva are given that its history and course are tolerably well known, and it has ceased to be a clinical rarity. Carcinoma and sarcoma of the vulva are exceedingly rare, and an extended study of the meager statistics relating to them seems to warrant the conclusion that the former is more frequent than the latter in the proportion of two to one. An attentive study of the literature of these cases is exceedingly disappointing, since their history is given in a very fragmentary manner, and a sharp definition of the nature of the cases is not made. In truth, much has yet to be added to our stock of knowledge of primary carcinoma of the vulva, and the same may be said, in the main, of primary sarcoma of this region, of which there are less than six indifferently recorded cases. Coming now to melano-sarcoma, the occurrence of which primarily in the eye, upon the skin, and in the viscera, can hardly be called common, we find but six satisfactory cases on record (and very vague mention of the subject in a few text-books) in which this new growth began upon the vulva. Primary melano-sarcoma of the vulva, therefore, may be considered as among the rarest of all forms of malignant new growths of these parts.

In this connection it is necessary to emphasize the fact that a number of cases of melanosis of the vulva have been reported which are really instances of melanotic carcinoma. The result is that confusion exists in the minds of many who have not clear ideas of these two forms of malignant new growths. The word "melanosis" should, therefore, be discarded since it is so misleading. Melanotic carcinoma has its origin in the epithelial structures; melano-sarcoma, like simple sarcoma, is a disease of the connective tissue.

In this essay I shall give the history of a personal case of primary melano-sarcoma of the vulva, and a synopsis of the cases of Göth, † Terrillon, ‡ Müller, # Haeck-

el,\* Baily, † and Fischer, ‡ all thus far reported, with the hope of throwing light upon the subject.

Melano-sarcoma of mucous membranes should be studied with the aid of our knowledge of similar conditions in the skin, since between the course of the two there are many analogies, though the disease of the mucous membranes is lacking in the rich objective symptomatology of its dermal congeners. It is important in this study to remember the following primary modes of development of melano-sarcoma:

1. The primary melano-sarcoma of the skin, which begins as one nodule, or as several small ones, on a pigment, mole or freckle, a vascular nævus, or on any congenital abnormality of the skin, or cutaneous outgrowth, upon or in consequence of any chronic hyperplastic process of the skin or as a result of mild or severe injury to a part. In all of these instances irritation or traumatism seems to be an important and essential factor.

2. The primary local melano-sarcoma, which may or may not become disseminated, which, from a want of knowledge of the causes which produce it, may be called idiopathic, and is sometimes of congenital origin. This form is akin to the first type.

3. The simultaneous multiple idiopathic melano-sarcoma, which, as a rule, begins upon the hands and feet, and from these regions invades the body, which has been called "Kaposi's" type, and is regarded by that observer as a general morbid affection from the very outset. In exceptional cases the disease begins, in unique form, elsewhere than upon the extremities, particularly on the various parts of the face and the trunk.

4. Melano-sarcoma originating in the uveal tract (the choroid and its duplicatures).

5. Melano-sarcoma beginning in any of the viscera or in lymphatic ganglia (unusual).

6. Melano-sarcoma of the mucous membranes, conjunctiva, mouth, vulva, and penis. # This type is most frequent-

\* "Ueber melanotische Geschwülste der weiblichen Genitalien," "Arch. f. Gynäk.," xxxii, 1888, pp. 400 *et seq.*

† "Tumeurs mélanotiques de la vulve," "Gaz. hebd. de méd. et de chir.," 1868, No. 47, pp. 740 *et seq.*

‡ "Ueber die Ursachen der Krebskrankheit und ihre Heilbarkeit durch das Messer," "Dtsch. Ztschr. f. Chir.," xiv, 1880-81, pp. 548, 550.

# Primary sarcoma and melano-sarcoma of the penis are also very rare. After considerable search I have found the following cases: W. H. Battle describes ("Primary Sarcoma of Penis," "Trans. of the Path. Society of London," xxxvi, 1885, p. 271) a case of a man aged sixty. T. Holmes, in the same society's "Transactions," vol. xxiii, 1872, under the title "Melanosis of Penis," narrates the case of a man aged fifty-two. In Gross's "System of Surgery," sixth edition, p. 834, the case of a negro, aged forty-four, is given. In Guy's Hospital Museum a morbid specimen, removed by Golding Bird, is preserved.

My colleague, Dr. A. W. Stein ("Medical Record," May 21, 1887), has reported the case, with autopsy, of a man, aged thirty-three, with generalized melano-sarcoma, and with marked infiltration into the bladder, urethra, corpora spongiosa and cavernosa, testicles, and cord. No history of the primary development of the disease could be obtained.

The case of Démange ("Etude sur la lymphadénie," "Thèse de Paris," 1874) and Vidal has been quoted as an instance of primary melano-sarcoma of the glans penis, but its history shows that the disease began upon the extremities, and that in about three years the genital organ was attacked.

\* Read before the American Association of Genito-urinary Surgeons at its third annual meeting, May 21, 1889.

† "Pigmentsarkom der äusseren Genitalien," "Centralblatt für Gynäkologie," October 1, 1881.

‡ "Mélanose généralisée ayant débuté par une petite lèvre de la vulve," "Annales de gynécologie," July, 1886.

# "Zur Casuistik der Neubildungen an die äusseren weiblichen Genitalien," "Berliner klin. Woehenschrift," No. 31, 1881.

ly seen in the form of secondary deposits (using the word "frequently" with a due appreciation of the rarity of these growths). As a primary disease it is of great rarity, and as a type it should be classed with its kindred growths, outlined in subdivisions 1 and 2 (*vide supra*).

In a general way it may be stated that the conditions inherent in the tissues to the development of melano-sarcoma vary in progressive degrees, according to the amount of pigment which normally exists in them. For example, the uveal tract (the choroid and its folds) is the seat of by far the largest number of these new growths; the skin is much less frequently affected, and the mucous membranes much more rarely than the skin, in all of which tissues there is a decreasing ratio of pigment.

CASE I—*Personal.*—Mrs. X., aged sixty-two, the wife of a well-to-do merchant, mother of five healthy daughters, came under my care June 1, 1887. She had always enjoyed good health, had never suffered any injury to her genitals, nor, to her knowledge, had there been any abnormal condition of them, even slight. Her family history was excellent, and cancer was unknown in her family. The history obtained was as follows: About two years previously (she being then sixty years old), she experienced a slight smarting sensation in the vulva, and several times saw a little bloody stain on her under-linen. She then noticed a bluish streak in the sulus between the large and small labium of the left side. This was followed in a few months by a small, round tumor, which was seated on the same side near the meatus urinarius, and, in a short time after, by a small pea-sized tumor to the right of the meatus. At this time there was a painful lump in the right groin. The vulvar lesions were pronounced to be cancer by Dr. Trenholme, of Montreal, who removed them with the knife in the latter part of June, 1886. The wound healed promptly, showing no trace of the neoplasm. About two months later she noticed a little blue spot to the right of the urethra, which grew rapidly until October of the same year, when it was excised by Dr. Trenholme. About this time it was observed that a marked swelling existed in the left groin, and it was thought that the lump in the right groin had become smaller. About November of this same year another small blue, wart-like tumor was observed a little to the right of the meatus and extending to and along the upper right-hand margin of the introitus vaginae. From that date until June 1, 1887, a period of about eight months, this new growth increased in size, and about April a smaller growth began to the right and just above it, on that portion of the labium minus which draped off from the clitoris. The appearance of the lesions as I first saw them are well shown in the colored plate. The large tumor was of a bluish-black color, perfectly smooth, homogeneous, and slightly shining on its surface. It looked like a ripe plum, except that it was conical on its upper end, near the clitoris. It was about an inch and a half long by an inch and a quarter wide. Its structure was firm, but compressible with moderate force. It was firmly adherent to the mucous membrane on the right of the vaginal orifice, and its base, which was about an inch in diameter, encroached up to but did not involve the meatus urinarius. Traction upon the tumor caused elevation of the subjacent tissues with it. The tumor, thus growing on the right side of the vagina, inclined inward and stopped up the vaginal orifice like a plug. The smaller tumor was evidently seated well under the mucous membrane, which, being mildly stretched, allowed it by its translucency to shine through as an oval mass which was quite firmly fixed to the subjacent tissues. The two tumors were continuous with each other. There were no inflammatory com-

plications, nor was there a particle of abnormal discharge. In the right groin were a number of hyperplastic ganglia matted together in a tumor of the size of a walnut. The left groin showed marked salience in its middle portion. Here was seated a hard, slightly lobulated, conical tumor, the base of which seemed fully three inches in diameter, and its obtuse apex protruded fully an inch above the normal plane, being covered with healthy skin. Examination showed that the hyperplastic ganglia were quite firmly adherent to the deep fibrous tissues, and that the mass could be moved slightly by sliding it, but could not be pinched up.

The vulvar lesions caused the patient much mental anxiety. The presence of the large tumor caused local uneasiness, especially on lying down, and it was a slight impediment to urination. The recurrence and persistent growth of the tumors, the thought that they were incurable, and the fears of possible untoward complications, preyed on the patient's mind and kept her in a state of constant terror. This was shown, in a measure at least, in her great emaciation, her want of strength and of appetite, and her troubled look. Both she and her husband insisted that the vulvar tumors should be excised. To the latter I explained that such an operation could only be palliative, and that the leaven of the disease would still remain in the infiltrated ganglia, which could not be operated upon with any certainty of thorough extirpation, and which would necessitate an operation-wound of some size. The fact of the former relapses was also emphasized, and the possibility of a similar recurrence dwelt upon. On the other hand, the amenability and accessibility of the tumors to ablation and the possibility of perfect healing (as we so frequently observe after the removal of sarcoma and pigment sarcoma) were also brought forward, and it was decided that the operation should be performed. This was done June 16th in the presence of Dr. Morrow and Dr. Trenholme. Having made traction upon the tumor, I snared it with a galvano-cautery wire, heated to a dull-red color, as near its base as I could get. When the wire was well imbedded in the tumor, the battery (which had just come from the maker's hands in supposed perfect condition) gave out. I then cut off the tumor just above the normal level of the labium minus, and proceeded to get the base away piecemeal. This was a long, tedious task, and was best done with my thumb-nail by persistent but cautious gouging, scraping, and pinching manipulations. In this way I removed all of the morbid tissue and exposed the fascia, which looked as smooth as one's palm. Care was taken that no minute specks or filaments of the neoplasm were left in the contiguous territory. The hemorrhage was very slight. The after-treatment consisted of scrupulous cleanliness and light dustings with iodoform, covered with simple gauze. Complete healing, which was accelerated toward the end by slight stimulation with nitrate of silver, took place in twenty-four days. Thereafter the site of the neoplasms showed a small, pinkish atrophic cicatrix.

The health of the patient improved in a marked manner. She regained her strength and spirits and became five pounds heavier than before the operation, one pound less than her maximum weight at any time. On her return from the country in October, I began the use of hypodermic injections of Fowler's solution, which it had been my wish to commence in July. For a period of two months she received these injections in doses commencing at seven and ending at ten drops. She had one abscess during this time. The injections, made with great antiseptic care, were administered on the thigh and on parts as near as admissible to the large mass of ganglia in the left groin. By the patient's preference the arsenic was then given by the mouth for a month, and as it by this method also produced annoying symptoms, it was discontinued. The result of

the three months' course of arsenic was the perceptible subsidence of the tumor, which became distinctly more movable and decidedly more lobulated on its superior surface. In December, 1887, the patient complained of coldness in the left heel; in June, 1888, her appetite began to fail. Then she had numbness in the leg and the corresponding arm, which was followed by slight loss of muscular power. This sensory and motor disturbance kept on apace. In April the right pupil became persistently enlarged, and there was right hemianesthesia of the face. The left-sided paralysis and the right-sided disturbances continued, marasms supervened, and the patient died July 26, 1888, about thirteen months after the last operation, and three years from the date of invasion of the initial new growth. She was under the care of another physician in a distant city during the last six months of her life.

**CASE II—Göth.**—The woman, age not stated, first seen in February, 1882, had been healthy all her life, and never had borne children. For two years previous to date she had noticed the development of a tumor on the vulva which caused neither inconvenience nor pain. Göth found a rounded tumor of the size of the fist, of a bluish-black color, not sensitive to pressure, but with a tendency to bleed, and upon it several small ulcers dependent on the loss of epithelium. Close examination showed that the tumor was composed of a large upper and a smaller under flap, which fell together and appeared like a single tumor when the patient was in the horizontal position. The upper portion developed from the superior portion of the left labium minus, extended over the præputium clitoridis and down the right labium minus for a short space. Its length was 7 cm., width 5 cm., and thickness 2·5 cm. The small lower flap seemed to spring from the lower portion of the left labium minus. The growth reached backward to the posterior border of the vulva and ended in a number of digitate processes. The tumors were traversed by numerous superficial fissures, giving the under surface an uneven and the outer a lobular appearance. The presence of the tumor compressed and pushed the urethra out of its axis, and obstructed the vaginal orifice. The lymphatic ganglia were not enlarged, and the patient seemed in fair condition. Under chloroform narcosis, the upper flap was drawn firmly upward and forward, transfixated with a sharp-pointed scalpel, and removed. The haemorrhage, though profuse, was, with some effort, controlled. The lower flap was removed by a deep incision, extending well into the posterior vaginal wall. Care was taken to clip away all suspicious filaments. Under careful antiseptic measures, perfect healing resulted in four weeks. Göth emphasizes the facts of (*a*) the relatively benign course of the new growth; (*b*) the absence of infiltration of lymphatic ganglia; (*c*) the non-recurrence of the disease five months after ablation.

I may add that it is a great pity that the report of the case was not delayed until five years after the operation.

**CASE III—Terrillon.**—An hysterical woman, aged sixty-two years, was admitted to the hospital April 28, 1885, suffering from mental derangement and hemi-anesthesia of the left side, and gave a confused history of moderate pain in the vulva, and of slight bloody discharge, both of recent date. Examination showed, on the right labium minus, a small tumor of the size of a large nut, firm, smooth on its surface, and absolutely black. It spread out by prolongations beyond its insertion, and was movable with the labium minus. Around the tumor the mucous membrane was of a uniform black color, studded with little patches of healthy tissue. This discoloration existed on the opposite labium, and was traced into the vagina as far as the os uteri. There was no tumor, however, except the one mentioned. There was no swelling in either groin, nor could any tumor be found on deep palpation in the iliac fossa.

The tumor gave rise to no pain, and it could be examined without discomfort to the patient. It was removed on June 28, 1885, by means of the galvano-cautery. The wound healed kindly by the 15th of July. Early in the following November the patient, who had become much emaciated, presented in the right groin (corresponding to the side of the ablated tumor) a distinct, uneven swelling of the ganglia. From this time on multiple tumors developed rapidly in various portions of the body. The woman's general condition became much worse. She walked with difficulty, lost her appetite, and presented every indication of a profoundly morbid state of the system. On the 17th of February, eight months after the operation, still more marked changes were observed. The discoloration had increased; the labia majora were swollen and oedematous; there were several small, prominent black nodules on the left labium minus, while the cicatrix of the operation was unaffected. The orifice of the urethra was invaded, and there was a blackish mass of the size of the little finger upon the posterior surface of the vagina. At this time the tumor in the right groin was of the size of the fist, uneven on its surface, and adherent to the deep tissues. The overlying skin was healthy, though somewhat thinned, and through it the ganglionic tumor presented a blackish color. In the left groin there were several small, hard, and isolated infiltrated ganglia. There was also a large indurated ganglion in the right subclavicular fossa, and a nut-sized black tumor upon the integument of the back. The patient's general condition continued to be very bad; emaciation was great; the face was swollen, and the abdomen and legs swollen and oedematous. She grew worse and died March 6th, suffering from violent dyspœa and severe abdominal pains. At the autopsy the inguinal, iliac, abdominal, and thoracic ganglia were found to be filled with a black substance, and some of them were of a pulpy consistency. The liver and spleen contained blackish nodules. Examination of the post-mortem specimens by Cornil showed generalized melanotic sarcoma.

**CASE IV—Müller.**—This case, which is entirely wanting in the details of age and clinical history, was taken from the private journal of Martin, of Berlin, after his death, by his assistant, Müller.

A tumor of the size of a goose-egg involving the clitoris was removed by operation. The woman was too weak to undergo a second operation on the enlarged inguinal ganglia. She died twelve days after the operation. At the autopsy, melanotic sarcomata were found in the brain, lungs, pericardium, liver, spleen, kidneys, retro-uterine fossa, bladder, round ligaments, stomach, jejunum, and thyroid, tracheal, bronchial, suprarenal, mesenteric, and inguinal ganglia.

It is not certain that the disease began upon the clitoris. The principle of "better late than never" seems to have guided the operator in this case.

**CASE V—Haecel.**—A woman, aged sixty-nine, well nourished and strong for her age, was first seen April 9, 1887. She had had six children and two miscarriages. Eleven months previous to examination she had noticed a small tumor on the external genitals which gradually grew larger. Five months later the left inguinal ganglia became swollen, and five months after that those of the right side became affected. Her only complaint was of a sense of fullness in the vagina. Haecel found a tumor of the size of a child's fist, of a dark-blue color streaked with white, which was seated on the whole of the left labium minus, on the clitoris, and on the upper part of the right nympha, and resembled a horseshoe with unequal shanks. The bluish-black new formation, which contrasted strongly with the color of the surrounding tissue, jutted into the left labium majus and in a less degree into the right one. There was a small nodule at the orifice of the urethra and two others between the left la-

bium majus and minus. In the depth of the mons Veneris two hard cords were felt which were supposed to be the infiltrated crura of the clitoris. In the left groin there was a plum-sized mass of infiltrated ganglia and a smaller one on the right side. The left epitrochlear ganglion was enlarged. There were no abnormal pigmentations upon the body, and no pigmented nevi. An operation was performed by which all the vulvar mass and the fatty tissue of the mons Veneris and the infected ganglia were removed. The healing of the wound was rather slow. Ascites, icterus, oedema of the lower extremities, together with severe cachexia, developed, and the patient died five months after the operation.

CASE VI—*Bailly*.—A woman, aged seventy-two, of nervous temperament, had suffered from rheumatism prior to her sixtieth year, after which she was well. Ten months before examination she felt an indolent tumor of the size of a lentil in the thickness of the right labium minus near the clitoris. After remaining quiescent for rather less than a year, this tumor grew with great rapidity and became superficially ulcerated. Later on a tumor identical in structure and course appeared on the left labium minus externally and toward the fourchette, which obstructed the vaginal orifice. Patches of black pigmentation also were present on the vulva and in the vagina, which, owing to tenderness, was not accessible to examination. The tumor was ablated.

The history of this case was written a month after the operation, at which time the wound had not healed and there was no apparent ganglionic involvement; but the ominous statement is made that the patient presented a pinched and care-worn look, that she was growing thinner day by day, and that she kept her bed.

CASE VII—*Fischer*.—A woman, aged fifty-six, was first seen April 22, 1870. Five months before, a small swelling appeared upon the left labium majus, which grew to the size of a walnut, ulcerated, and bled. The corresponding inguinal ganglia became enlarged simultaneously with the appearance of the new growth. The tumor was ablated and the patient discharged, healed, in four weeks. A few weeks later a recurrent growth appeared upon the labium. Six months after the operation the inguinal ganglia became ulcerated, and the patient became weak and died. It was thought that the irritation of a chronic leucorrhœa was a possible factor in causation.

*Clinical History.*—The mode of development of these melano-sarcomatous tumors of the vulva is essentially the same as that of their congeners of dermal origin. In their course, however, the former present certain peculiarities and modifications which are ingrafted upon them by the highly vascular nature of the mucous membrane, and by the anatomical conformation of the parts. A knowledge of the clinical history of cutaneous sarcomata is of much aid in this study.\*

\* In this connection it may be interesting to present the brief notes of cases of juxtapudendal melano-sarcomatous tumors which are scattered throughout medical literature, and have passed current as vulvar tumors.

A tumor, in all probability of melano-sarcomatous nature, was reported by J. Fergusson ("Recurrence of a Melanotic Tumor; Removal," "Lancet," 1851, vol. i, p. 622). A woman, aged forty-five, had a solid, movable tumor, of the size of an orange, in the right groin, extending from the iliac spine half way down Poupart's ligament. Two years previously she had a small pedunculated, bluish-black tumor on the right side of the mons Veneris. The skin over it ulcerated, and a fungous growth remained, which bled profusely. This was ablated and healing followed. The inguinal tumor (undoubtedly lymphatic in origin) was

Melano-sarcoma of the vulva begins as a minute red or purplish spot seated in the deeper portions of the mucous membrane. This spot soon becomes a papule and then a nodule, a good example of which is shown in the chromolithograph in the smaller oval lesion just within the margin of the right labium majus and above the tumor proper. This nodule on a flat surface is of round or oval shape, but in a cleft like that of the labial sulcus it may be of linear shape (as it was at the inception of the disease in my case). On an anfractuous surface (near urethra, vaginal orifice, and fourchette) the shape of the lesion would be indefinite. The nodule being, as we may say, the well-developed lesion of the morbid process, its subsequent progress is readily traced. If it enlarges in area it produces at first sessile tumors, but if, as in my case, the morbid growth is very exuberant in an outward direction, a true pedunculated tumor may be the result, as shown in the colored plate.

When a larger extent of surface is involved we find sessile tumors of various sizes, which may be as large as the fist or a goose-egg, as in Göth's and Müller's cases; or, not reaching this magnitude, they may merely jut up more or less from their bed, as they did in Terrillon's case. To the touch these tumors are firmer than sponge and less resistant than unvulcanized rubber; their density may be compared to that of a plum. Their surface may be smooth, or finely or coarsely lobulated. They appear to be composed of a homogeneous substance, and, in different shades of light, present black or blue tints, or a combination thereof. Though firmly adherent, motion or traction is readily produced. When very large, these tumors may become warty, or even fungous, upon their surface, and then from them exudes a bloody ichor (perhaps of offensive odor), and they may become more or less incrusted. Superficial ulceration from erosion may occur, and in this, as well as in the warty or fungating stage, haemorrhage, mild or severe, may occur. Central softening of the tumors may also take place, and foul and destructive ulcers may result. We are unable to say whether in this form of melano-sarcoma spontaneous absorption takes place, as it sometimes does in kindred skin lesions. From the fact that the connective tissue is sparse on the vulvar sites of these tumors, it is not probable that we shall see anything analogous to the subcutaneous

secondary to that of the mons Veneris. No microscopic examination was made, but the tumor was pronounced melanotic.

*Fischer (op. cit.)* reports the following case: A woman had had since her thirty-fourth year a blackish growth on the perineum. Prior to her fifty-fourth year, a tumor of the size of two fists, involving the left inguinal ganglia, appeared, which was extirpated. Eleven years after there was no recurrence.

Wagstaffe ("Pigmented Myxoma, Alveolated, removed from near the Labium Majus," "Trans. of the Path. Society of London," vol. xxiv, 1873, p. 167) reports the case of a woman, aged forty-two, having a conical tumor, of the size of a pigeon's egg, on the left labium majus, near the point of origin of the gracilis muscle, which began deeply in the connective tissue. It was pronounced to be of the type of myxomata and sarcomata.

It may be mentioned that melanotic growths of the uterus are very rare, and are usually of the form of melano-sarcoma. Neither melanocarcinoma nor melano-sarcoma has been found to originate primarily in the ovaries or vagina.

nodules of cutaneous melano-sarcoma. Ablation of these tumors may or may not be followed by perfect healing.

From our present knowledge it may be stated that the progress of these malignant growths is sometimes slow and again quite rapid, while it is decidedly exuberant. This being the case in old subjects, it will be interesting to watch the course of the disease in younger ones should they present themselves.

In Terrillon's ease a diffuse black pigmentation of the whole vaginal membrane, without any other form of hyperplasia, is mentioned. This would seem to be analogous to the general bronzing of the skin which is sometimes seen in melano-sarcoma of the skin. It was also seen in Bailly's case.

The symptoms of melano-sarcoma of the vulva are decidedly mild. Early in their course they cause slight pruritus or smarting, and they may give rise to more or less hemorrhage. Later on they cause inconvenience by reason of their size. If developed near the urethra, they may act as impediments to urination, and if near the vulva, they may be very objectionable mechanical obstacles. In the stage of degeneration of the tumors they may cause much suffering and worry.

Such are the uncertain mode and course of the generalization of melano-sarcoma, like those of all malignant growths, that it is impossible to give a description of it, since in no two cases is it similar. The dissemination of the disease in this form is through the lymphatics, which lead directly to the viscera; therefore it is in these organs that we should expect to see the gravamen of the secondary infections. In skin sarcomata the malignant dissemination is through the vessels and lymphatics, and by contiguous infection; therefore we so constantly see new erops of the disease upon the cutaneous envelope. It is probable that in melano-sarcoma of the female and male genitals the skin will not be involved so early and so frequently as the lymphatic system and the viscera. It is to be noted, however, that in Terrillon's case, in addition to great visceral infiltration, a melano-sarcoma nodule was found upon the back.

In my case it is probable that the metastatic malignant new growth was seated in the lower part of the pons. From the absence of symptoms it is probable that there was not metastasis to any other organ.

The date of the generalization or metastasis of melano-sarcoma of the vulva, like that of the whole family of sarcomata, is uncertain. In Terrillon's case it began in the groin, in about eleven months, and in my case the appearance of the morbid nervous phenomena, about thirty months after the onset of the disease, gives weight to the view that secondary changes began in the brain about that time. But it must be remembered that the ganglionic enlargement began between a year and eighteen months after the onset of the disease. Since death occurred in Haeckel's ease five months after the operation, in Fischer's case in six months, and in Bailly's case in all probability in a few months, it is fair to assume either that marasmus set in or that metastatic growths were developed. The cases of Göth and Müller give us no information on this subject.

In my case and that of Terrillon the age at which the malignant growth began was sixty years, and, though Göth fails to state it, it is evident, from his description, that his patient was beyond the middle period of life. Haeckel's patient was sixty years old, Bailly's was seventy-two, and Fischer's was the youngest on record, being fifty-six. The statistics of other forms of sarcomata prove that they are more prone to appear late than early in life, but the foregoing figures would seem to indicate a more uniform evolution of melano-sarcoma of the vulva in late periods of life. Thus Kaposi, speaking of skin sarcomata, places the date of invasion between forty and sixty-eight; Tanturri, according to Perrin,\* between forty-three and sixty; and De Amicis, between the thirty-ninth and seventy-fourth years of life. Exceptions to these averages are not common. Köbner's ease was that of a girl nine years old; Billroth's patient was ten years, and Perrin's twenty-two years of age—all the growths were skin sarcomata. It is probable that further statistics will place the period of invasion of sarcomata of mucous membranes in middle and old age.

*Microscopical Examination.*—The anatomical diagnosis in my case is small-spindle-celled melanotic sarcoma. The mottled black and gray pigments of the tumor consist of clusters of closely aggregated, small, spindle-shaped cells, lying in a scanty stroma. The epithelial investment of the vulvar region was not present in any of the sections. Both the stroma and the tumor cells contained granules and larger and smaller masses of brownish pigment (see Fig. 2). In some places the sections are comparatively free of pigment. In other places hardly anything else but masses of pigment can be seen. The examination and microscopic drawing were made by Dr. Ira Van Gieson.

In Göth's ease the anatomical diagnosis was melanotic alveolar sareoma.

In the tumor in Terrillon's case the round cells of melano-sarcoma were found. Examination of the blood and urine showed the presence of minute blackish granules.

Microscopic examination of the tumor in Müller's, Haeckel's, and Bailly's cases showed melanotic sarcoma.

*Aetiology.*—There is nothing in the history of these cases which gives even a clew to the origin of this malignant new growth. From analogy with kindred skin lesions it may be inferred that any congenital lesion, particularly if pigmented, any structural defect of the parts, hereditary or acquired, or that irritation or traumatic causes, or simple hyperplasia, might serve as the starting point of it, but we have no positive knowledge.

Hildebrandt† speaks of the case of an old woman in which sarcoma of the vulva supervened upon the repeated cauterizations of some caruncles of the urethra with the actual cautery and acids. The lesson conveyed by it is that in old subjects these lesions should be excised rather than cauterized. Indeed, any irritated hyperplastic growth of the genitals of old women, or of those of middle age even, may take on a malignant nature; therefore they should be

\* "De la sarcomatose cutanée," Paris, 1886.

† "Die Krankheiten der äusseren weiblichen Genitalien," Billroth's "Handbuch der Frauenkrankheiten," Stuttgart, 1877.

handled cautiously.\* Leucorrhœa was looked upon as a possible causative factor in Fischer's case.

Taking an average of all the cases of sarcomata reported, it is found that they occur more frequently in males than in females.

*Diagnosis.*—So well marked are the features of melanosarcoma of the vulva that their recognition is usually easy. A distinction may be necessary between it and melanotic carcinoma, which is prone to appear on cutaneous surfaces (the labia majora), or at their junction with mucous membranes; also on the skin of the extremities.

Melanotic carcinoma has the general appearance of epithelioma; is often accompanied by small or large pigment deposits, and the initial nodule is soon followed by new ones in its vicinity. In its course it is more rapid than pigmented sarcoma of these parts. In general, the carcinomatous growths tend to burrow rather deeply, while the sarcomatous luxuriate upward. Kaposi says that a moderate amount of swelling and diffuse infiltration of the surrounding tissues may occur early in the disease. It is important to remember that melano-sarcomatous tumors may later on become warty or fungous on their surface, and that this feature appears early in the course of melano-carcinoma. It is of vital importance that the diagnosis should be made at an early date in this, as in all forms of cancer, since upon it depends the future of the patient.

*Prognosis.*—It has been tritely remarked that the invasion of mucous membranes by sarcomatous growths is a sign of evil omen. This statement made regarding secondary deposits in cases of cutaneous and visceral sarcomata is particularly true concerning those of the primary invasion of mucous membranes. In these very vascular structures the morbid growth is exuberant and the disease seems to

\* Cases of melano-carcinoma of the vulva are also rare, and are sometimes classed as sarcomas. The following have been reported:

Prescott Hewitt's case ("Melanosis of the Labium and Glands of the Groin," "Lancet," vol. i, 1861, p. 264) was that of a woman, aged fifty-nine, who observed a tumor on the anterior surface of the labium eight months before the operation. It was thought that it began upon a brown spot which had been there for years. The tumor grew rapidly, ulcerated, and bled freely. Though only palliative, the operation was radical, and included the removal of two or three black spots seated deeply in the wound. Two months later the disease reappeared *in situ*, and cerebral symptoms supervened, which led to the woman's death six months after the operation.

Klob ("Pathologische Anatomie der weiblichen Sexualorgane," 1864, p. 467, quoted by Haeckel) briefly mentions the case of an old woman who had a melano-carcinomatous nodule on the labium, and who died of a disseminated metastasis of the disease.

Müller (*op. cit.*, p. 447) reports the case of a nulliparous woman, aged thirty-three, who had a dark-blue, elastic, painless tumor, of walnut size, on the inner surface of the right labium majus, near the clitoris, which had grown rapidly within a few months. This tumor was quite well circumscribed, and became lost in the depth of the tissues, as far down as the pubic bone. It had not been preceded by a nævus-like growth. It was removed by deep incisions, the wound healing satisfactorily. Just after the operation the right inguinal ganglia became enlarged, but they afterward became normal. Three years after the operation the patient was well. Microscopic examination showed the tumor to be of a melano-carcinomatous nature.

In Kaposi's "Atlas der Syphilis" (Heft i, Taf. xii) will be found an excellent colored drawing of a melano-carcinoma of the external portion of the left labium majus.

take an especially firm hold upon them. Then, again, those portions\* of mucous membranes upon which sarcomata, simple and pigmented, show a tendency to develop (the face and genitals), are in closely contiguous relation with large groups of lymphatic ganglia, which seem to be more readily infected than when the new growths are seated in the skin. In my case, and in that of Terrillon, death was induced in about two and three years, and in both the new growth reappeared within a few months after the removal of the initial tumor. Göth's case of freedom from the disease five months after the removal of the pigment sarcoma stands for nothing. It should have been reported five years after operation, rather than five months. The significant fact appears in Terrillon's report at the date of his operation, that the inguinal ganglia corresponding to the seat of the vulvar tumor were not perceptibly enlarged, and that, although the new growth did not reappear on that side, eight months later a ganglionic tumor, of the size of the fist, was found there.

And it may be added that in the literature of malignant new growths in general, the fact is not infrequently noted that a patient discharged cured after extirpation of the tumor returns later on, in months and even years, with infiltrated ganglia which, upon dismissal, had been thought to be unaffected. In no case, therefore, where the tumor is removed and no enlargement of the ganglia is found, are we warranted in assuming that the patient will not have a recurrence in them or elsewhere.

In cases where the tumor is young, small, readily removable, and without ganglionic implication, a guarded and moderately hopeful prognosis may be given. When the new growth is old, large, and firmly fixed, and particularly when accompanied with lymphatic complication, the outlook is gloomy. Early enlargement of the ganglia is a serious symptom, and the late development of this condition inevitably brings death in its train. The death of my patient and of Terrillon's, at the end of about two years, together with that of Haeckel's and Fischer's within a few months, emphasizes its lesson.

Upon the fact that the sarcomata are more prone to form metastases through the medium of the vascular system than the carcinomata, which, as a rule, form metastases through the lymph channels, the greater malignity of the former depends.

*Treatment.*—It may, I think, be stated as an axiom that all sarcomatous growths of the vulva, simple or melanotic,

\* Mr. Jonathan Hutchinson—"Clinical Lectures and Reports of London Hospital" ("Cancer of Female Genitals"), London, 1865—speaking of epithelioma of the vulva, says: "The average length of life is scarcely longer than it is in the cases of medullary cancer of bones and testis, and it is very much shorter than what occurs in cancer of the breast. The explanation of the rapidity of progress is to be sought in the vascular condition of these parts, their rich endowment with lymphatics, and the early age of the patients attacked. We very often meet with cancer of the female genitals in patients under thirty, and I have observed it as early as twenty-four. In the young the processes of growth and absorption are much more rapid than in the old. Hence all varieties of cancerous action tend to be acute if occurring in comparatively young persons." Since melano-sarcoma of other parts has been observed in the young, it is possible that it may appear at earlier dates than it did in the six cases detailed in this essay.

being of such extreme malignancy, should be removed as quickly as possible. The sight and presence of these growths tend to demoralize the patient in mind and body; consequently, if there is a reasonable chance of subsequent healing, ablation should be performed. Though there is in all cases a probability of relapse *in situ*, and almost inevitably subsequent deposit in some part of the economy, the patient's comfort is greatly conserved by operation. My experience with these and other malignant forms of new growths of the vulva has convinced me that the best proceeding in general is to first remove the greater portion of the mass down near the skin level, and then to finish the operation by patient clipping and picking, by gentle gouging with the nails or with the handle of the scalpel, until all suspicious portions are removed. Such a course is far preferable to the destructive cauterization, chemical and thermic, which is recommended by some. When in these cases the lumen of the urethra or vagina is invaded, the task of the surgeon is much more difficult and tiresome than when the tumors are seated on the labia alone. For some cases the galvano-cautery is applicable, for others the knife is required. The haemorrhage may be profuse, but it is readily controlled. Such is usually the woe-begone condition of these patients at the time of operation that the simultaneous removal of infiltrated ganglia is hardly warranted. The propriety of their subsequent removal must be left to the good sense and experience of the surgeon. If the ganglia are movable, and the mass is not too old, they may be removed. In my case, where the mass was as large as a goose-egg and firmly adherent to the fascia, an operation would have been simply foolhardy.

In these cases, where the outlook is uniformly so gloomy, all measures which offer a chance of future immunity should be tried. With the experience of Shattuck,\* in his probable cure of a case of melano-sarcoma, and of Köbner,† in his case of seemingly positive cure of a child similarly affected, in my mind, I began, at the first available opportunity, the use of hypodermatic injections of arsenic. This agent certainly did soften the mass and caused its partial absorption. Earlier in the history of the case it might possibly have been curative. The logical conclusion, therefore, to be derived from our present knowledge of the effect of arsenic on the sarcomata is that it should be administered hypodermatically, in full and increasing doses, as early and for as long a period as possible.

Though the outlook is inevitably fatal, there is a modicum of satisfaction in the assurance we can give the patient that, when perfect removal of the vulvar mass is practicable, she may thereafter be free from this hideous reminder of her doom.

**The University of Vienna.**—According to the "Lancet," Dr. Anton has qualified as Docent in nervous and mental diseases, and Dr. v. Metnitz as Docent in odontology; Dr. v. Wagner and Dr. Lihotzky will during the summer session deliver the professorial lectures on mental diseases and midwifery respectively; Dr. Czermak is acting for Professor Fuchs, one of the ophthalmological professors, who is absent on sick leave.

### THREE REMARKABLE CASES OF COMPOUND DEPRESSED FRACTURE OF THE SKULL, WITH HERNIA CEREBRI. *OPERATION, RECOVERY.*

BY LOUIS A. RODENSTEIN, M. D.,  
CHIEF OF MEDICAL BOARD, AND ATTENDING SURGEON, TO THE MANHATTAN  
GENERAL HOSPITAL, NEW YORK, ETC.

The subject of compound depressed fractures of the skull has recently been so thoroughly discussed in the various medical journals, and the proper methods of treatment have been so ably described, that but little remains for me to say on the subject. I will therefore briefly narrate the histories of three cases, each of which was followed by hernia cerebri, and all ending in recovery, which were recently under my care at the Manhattan General Hospital, in the hope that they will be of interest to the medical profession as still further showing the value of a thoroughly antiseptic treatment for wounds which were formerly almost uniformly fatal:

**CASE I.**—Charles E., aged six; residence, Edgewater, N. J.

On the morning of August 27, 1887, he was playing near one of his father's horses, when suddenly the animal gave the lad a vicious kick, striking him just above the left temple and back of the left eye. This happened at ten o'clock in the morning. The boy was carried into the house, bleeding profusely from what seemed a simple scalp wound.

He soon began to grow drowsy, and ultimately to lose consciousness, and finally he was put into a wagon and brought across the river and conducted to the Manhattan Hospital, where he was received, by the surgeon in charge, in a terribly exhausted condition, having continued to bleed from 10 A. M. to the time at which he was received, 5.30 P. M., an interval of seven hours and a half. The patient at that time was almost bloodless, with a pulse slow and very feeble; pupils equal and nearly normal, with a tendency toward dilatation; extremities cold; and complete unconsciousness.

A hasty examination revealed an extensive compound comminuted depressed fracture of the left side of the skull. There was complete paralysis of the left side of the face. The patient was immediately carried to the operating-room of the hospital and quickly got ready for an operation. Owing to his unconscious condition, I operated upon him without employing any anaesthetic.

There was a scalp wound, somewhat ragged in character, extending from the temporal ridge on the left parietal bone at about a quarter of an inch behind the point of meeting of the temporal ridge and the coronal suture, downward and slightly forward, a distance of two inches, to a point about midway between the upper and lower point of articulation between the anterior border of the squamous portion of the temporal bone and the greater wing of the sphenoid bone. Externally the wound passed from the side of the head at about the middle of, and about an inch and a half above, a line of the outer canthus of the eye to the external auditory meatus, downward and forward to a point half an inch beyond the outer angle of the left orbital cavity.

The scalp around the wound and to a distance of about two inches therefrom was shaven; the wound and scalp were then washed with soap and warm water, then irrigated with a 1-to-2,000 solution of mercuric bichloride, and other preliminary antiseptic precautions were taken. Then the wound in the scalp was enlarged by an incision about an inch and a half long, made at right angles with the original wound. The flaps thus

\* "Journal of the American Medical Association," July 4, 1885.

† "Berliner klin. Wochenschr.," No. 2, 1882.

made being laid back, the depressed portion of bone came into view.

The fracture was comminuted, but the general shape was that of a crescent, as though the hoof of the horse had struck the head in such a manner as to cause a fracture following the lines of the iron shoe, and a continuation of the lines of fracture would have formed a complete horseshoe-shaped figure. The

inches and a half long by an inch and a quarter wide in its widest part, this being about the center of the crescent. The middle meningeal artery, though exposed in the upper part of the space left by the removal of the parietal fragment, was intact.

After the removal of the bones, the dura mater was seen to be uninjured except at the lower part of the opening, somewhat below the point of junction of the parietal and temporal fragments of bone. At this situation both the dura mater and pia mater were ruptured, and there was a hernia cerebri of about the size of a nickel which projected through the rupture, and from whose somewhat lacerated surface blood and a small amount of brain substance were oozing. There was also a small clot of coagulated blood beneath the dura mater just adjacent to the point where the hernia protruded, but it was small and was not interfered with. The opening was then cleansed with mercuric-bichloride solution (1 to 2,000) and packed with iodoform gauze, the edges of the scalp wound were confined at their outer extremities by single catgut sutures, and a dressing of bichloride gauze and absorbent cotton was applied with a tight bandage.

During the operation there was considerable haemorrhage, which caused some delay, but was finally checked by compression. At two different periods during the operation work had to be suspended and the patient resuscitated, as evidences of heart failure and respiratory paralysis were present. Subcutaneous injections of whisky and digitalis (20 minims to 1 drachm of whisky) were twice given, and artificial respiration was also resorted to. The duration of the operation proper was twenty minutes.

After the operation the patient was put to bed; hot-water bottles were placed around the feet and lower extremities. The pulse was very weak. The patient recovered partial consciousness about 7.30 p.m. Complete hemiplegia of the right side was then noticed. At 9 p.m. the pulse was much better. There were some pain and restlessness. He was given by the mouth, bromide of potassium, gr. x; chloral hydrate, gr. v. An ice-bag was applied to the head. He passed a fair night.

The next day, August 28th, the outside dressings were removed and, as there was nothing but very slight discoloration of the gauze, the iodoform packing was not removed from the wound, but only a clean outer dressing applied. The patient at this time was semi-conscious, seemingly comfortable; temperature normal; pulse, 74; respiration, 28. In the afternoon, temperature, 99.2°; pulse, 102; respiration, 28. At night, the patient was given the bromide and chloral mixture as on the previous evening. He passed a quiet night.

*August 29th.*—Head not touched. Morning temperature, 9.98°; conscious.

*30th.*—Outer dressings only changed. No haemorrhage or discharge of any account. Paralysis persistent; temperature, 98.4°; pulse, 78; respiration, 18. Afternoon, temperature, 100°; pulse, 82; respiration, 20. The usual sedative at night; passed a fair night.

*31st.*—Morning, temperature, 99°; pulse, 74; respiration, 20. Afternoon, temperature, 100°; pulse, 80; respiration, 18.

*September 1st.*—Packing removed from wound; no pus in wound; the hernia had enlarged somewhat, but had not degenerated. Paralysis persistent and of the same extent. Morning, temperature, 99°; pulse, 72; respiration, 18. Afternoon, temperature, 100°; pulse, 84; respiration, 24.

The head was redressed every other day until September 10th without any untoward symptoms. The scalp wound was beginning to granulate well; the hernia was commencing to granulate and to diminish in size, the dura mater encroaching and closing in on it from all sides. There was felt at this time some fluctuation just above the left ear. An aspirating needle

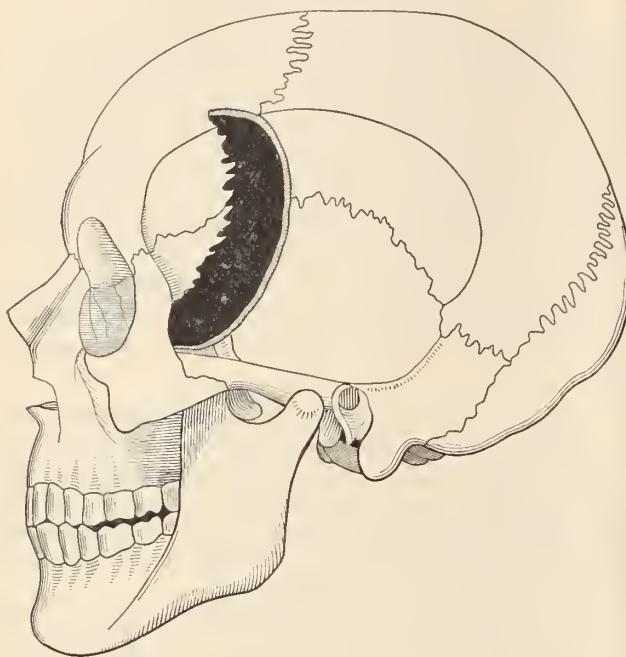

FIG. 1.

fracture extended from the point where the temporal ridge crossed the coronal suture, downward and forward, the convexity of the crescent being backward, to a point situated at the lower and anterior portion of the zygomatic fossa, behind the anterior part of the zygomatic process.

As it was unnecessary to trephine, the elevator was the only instrument needed. The depressed bone was imbedded at its anterior portion in the brain substance, and was partly concealed by it. The amount of depression varied from half to three quarters of an inch, the greatest amount of depression being near the lower part of the fracture. There were noticed three large pieces of bone and five or six small pieces. The large pieces were respectively parts of the temporal, parietal, and frontal bones, the force of the blow having not only caused the fracture, but also separated the bones at the temporo-parietal and coronal sutures. Attached to the inferior segment or temporal portion of fractured bone was found a small piece of the greater wing of the sphenoid bone about three quarters of an inch by one quarter wide.

The bones were raised by means of an elevator (the periosteum being lacerated and ground away by the blow) and extracted by means of a suitable forceps. When laid in their proper position with relation to each other, the bones formed the crescent-shaped figure before mentioned, the posterior or convex border of which was clean-cut and angular, the anterior border more irregular, and the apices rough and jagged. The bone itself was about three sixteenths of an inch thick at its thickest part, the inner table being very thin and of about one third the thickness of the outer table. This state of things was normal to the age of the patient. There were several cracks and fissures of the inner table which were absent in the outer. The whole amount of bone, when removed and placed in its normal anatomical relation, covered an area which was four

was introduced but no pus met with. This fluctuating point gradually disappeared under pressure. About this time, also, there appeared a slight amount of movement in the right leg. Patient comfortable.

The temperature between September 1st and 9th varied between normal and 99.6°, averaging 99.1°. On September 9th, however, the temperature fell to just 97°, the pulse went down to 60, and the respirations to 16. The patient soon rallied, however, and the temperature came up to about 98°; pulse, 78; respiration, 22.

On September 10th the temperature was normal; the pulse averaged 82; the respiration, 19. The wound was dressed every other day up to September 19th with iodoform; once or twice, as occasion required, fused nitrate of silver was applied. The hernia was growing smaller; there was no suppuration of the brain substance. Peruvian balsam used to-day. The movement in the right leg was getting much freer; slight movement in right arm and forearm was noticed to-day for the first time; facial paralysis much improved; less dribbling of saliva; speaks very distinctly; tongue getting nearer the median line. The mental faculties, however, seem to be impaired, evidenced by his laughing immoderately and exaggerating his play, unlike other children in the ward.

The head was redressed every other day between September 19th and November 8th, the dressings being varied as occasion required. By this time no dressing was required; the hernia was covered over and the parts were looking well.

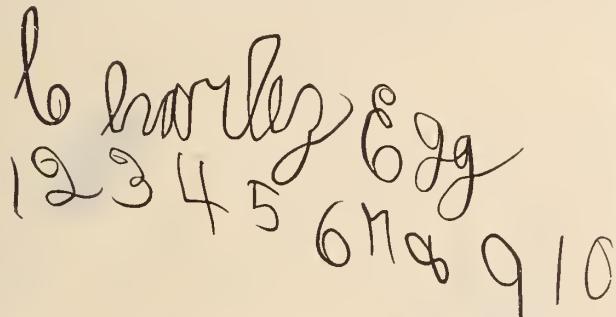

FIG. 2.—Fac-simile of the patient's handwriting before the injury.

The mental condition was about the same. The right leg could be moved with ease in all directions; the right arm moved quite easily; there was also movement in the hand, but it was slight.

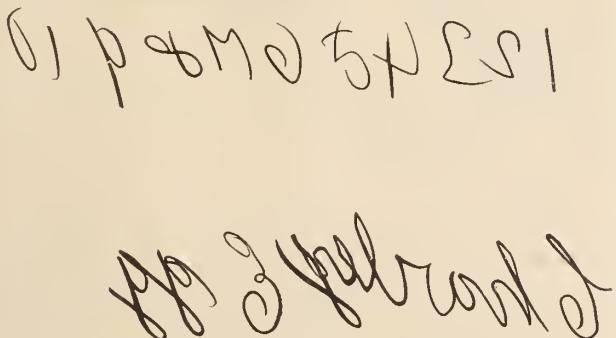

FIG. 3.—Fac-simile of the patient's handwriting after the injury.

*November 8th.*—The patient was dressed and sat in a chair. From this date on, the paralysis, both of leg and arm, rapidly improved, until by November 12th the patient was able to walk, assisted by a nurse, or by supporting part of his weight on the frames of the bed.

*20th.*—Patient could walk without aid, and even run a very

little, but could not move the right side with so much ease as the left side of the body.

The mental condition began to improve, and there were indications that the impairment would ultimately disappear. During the preceding eighteen days the temperature had averaged 98.6°; pulse, 85; respiration, 24.

*28th.*—The patient was taken home in a carriage. His parents were asked to report with him in a short while, but he did not appear until one day in December, 1888, over a year after his discharge. At that time there was still a little mental impairment, and, while able to move his limbs perfectly in walking, he exhibited a very slight halt of right foot, causing a very minute amount of lameness.

The scar is firm, and the patient feels well in every respect.

**CASE II.**—Antonio V., aged twenty-four, a native of Italy. This patient was brought to the Manhattan Hospital in an ambulance, on the afternoon of October 11th, from Shaft 27 of the new Croton aqueduct. While he was working at the bottom of the shaft a long piece of iron pipe, falling from the top of the shaft, struck his skull about half an inch to the right of the sagittal suture and a little behind the coronal suture, the pipe falling a hundred and forty feet, striking end first, and producing a compound comminuted fracture of the skull. The dura mater was lacerated and the brain substance protruded through the scalp wound to a height of three fourths of an inch. The fracture was of the right parietal bone. The patient was conscious when brought in, but drowsy and stupid. The wound was cleansed with mercuric-bichloride (1 to 2,000) solution and bichloride gauze applied. There was no operation performed on him that night.

On the next day, contrary to expectation, the patient was alive, but the stupor had increased. On removing the dressings, the protruding part of brain was found to have receded greatly. A finger was then passed into the wound, which was a clean-cut punched-out one, and a piece of bone was found to have been driven directly inward for a distance of half an inch. This depressed portion of bone was raised up from the brain, and, on

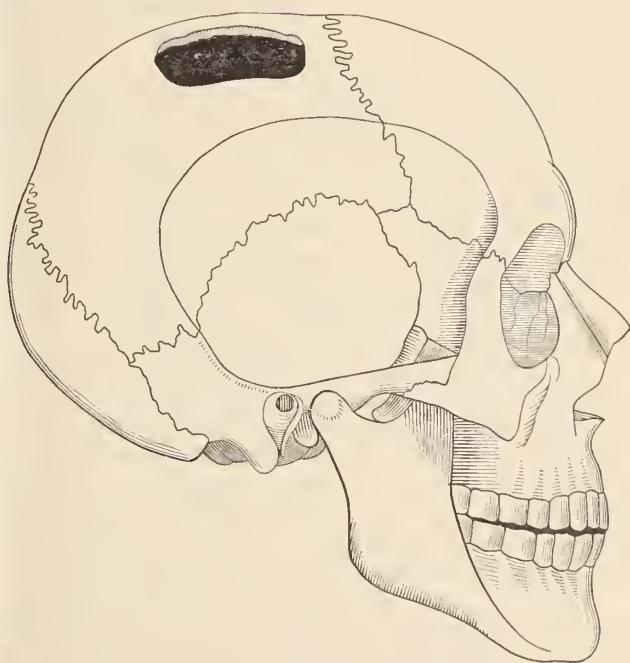

FIG. 4.

examination, was found to consist of two large fragments, making altogether a piece about an inch wide by two inches long. In addition, several small fragments of bone were removed.

There was some loss of brain substance caused by the sharp cutting edges of the fragments as they were driven in. The fracture of the skull seemed to be over an area having the ascending frontal and ascending parietal convolutions of the brain immediately beneath it. The symptoms manifested seemed to denote a lesion of the ascending frontal convolution of the brain. There was little hemorrhage, however. The sharp edges of the skull around the hole were rounded off; the wound was cleansed with solution of mercuric bichloride and packed with iodoform gauze.

On the 13th of October the condition of the patient was unchanged, and, as the dressings were dry and no increase of temperature had appeared, they were allowed to remain until it was necessary to change them.

There was complete hemiplegia of the left side.

*October 14th.*—Patient lies in a stupid condition all the time, but when spoken to seems to be conscious.

*15th.*—To-day the dressings were removed and some clots and broken-down brain tissue washed away with an irrigator containing a 1-to-2,000 solution of mercuric bichloride. There was no foul odor from the wound. It was packed with iodoform gauze and a bandage applied as usual. The left eye is inflamed, and there is a yellow discharge from it. The general condition of the patient is unchanged.

*18th.*—Head redressed. Wound looked well, but the general condition of the patient seemed somewhat worse than previously.

*20th.*—Head redressed. Patient seemed much brighter to-day.

*21st.*—Patient looking in good condition to-day—perfectly conscious and pretty bright.

*22d.*—Dressing removed. Brain protrudes through the wound an inch or more. Wound irrigated and redressed.

*24th.*—Brain protrudes about an inch and a half and is slightly sloughy. Wound cleansed and dressed.

*28th.*—Condition about the same.

*November 3d.*—Patient has been improving slightly since last date; the protruding part of brain is granulating well. Temperature, 101°.

*5th.*—The temperature has remained at 101°. Over the anterior quarter of the hernia there is a slough, which is apparently superficial. At the lower part of the slough there is a small sinus, through which a probe can be passed a distance of at least half an inch, and probably farther, and from this opening there issues a serous or sero-purulent discharge.

*10th.*—The head has been dressed every day since the 5th inst. Serous fluid still escapes from the opening mentioned. The wound is granulating well around the edges.

*12th.*—To-day three skin grafts were applied to the surface of the hernia, and a vaseline dressing was applied.

*14th.*—Head redressed. The skin grafts look healthy and seem to have attached themselves to the brain tissue.

*15th.*—To-day two more skin grafts were applied.

*20th.*—Head redressed to-day. Only one out of the five skin grafts has taken root. The hernia has grown slightly larger since the last date, and presents a smooth, somewhat shiny appearance. It is almost perfectly elliptical in shape, and protrudes about an inch and a half above the level of the skull.

*25th.*—Last night the dressings were found to be soaked with a watery fluid, and on removing them the tumor was found to be considerably reduced in size. There is an opening in the upper and anterior part of the tumor into which a director can be passed downward and forward a distance of two or more inches without meeting with the least resistance. Through this opening an aqueous fluid escapes which is slightly turbid and of the specific gravity of 1.030. It contains an abundance

of chlorides and traces of albumin and sugar. From the same opening a probe was passed into a superficial sinus situated in the posterior portion of the tumor, and this cavity contained a brownish fluid. A bichloride-of-mercury compress was applied.

*December 8th.*—To-day an incision was made in the protruding part of the brain. A probe was passed in about two inches and cut down on. A drainage-tube was inserted and a dressing of bichloride gauze applied.

*15th.*—There has been no movement in either arm or leg so far until to-day, when a very slight amount of movement appeared in the leg and the faintest suspicion of movement in the arm.

*21st.*—To-day he can lift his knee from the bed and can move the arm slightly.

*February 10th.*—Patient has been improving steadily since the last record; the hernia has been gradually disappearing and the skin closing over, till at present the hernia has gone, and there is a slight depression covered by normal skin. The patient now has power enough in his leg to permit him to walk about the ward daily. The power in his arm has partially returned.

**CASE III.**—John W., aged nineteen, a salesman. This patient was brought from the thirty-fifth precinct, in the hospital ambulance, on Washington's birthday, February 22, 1889. He was struck by a locomotive near Woodlawn station, and, on his arrival at the hospital, was immediately carried to the operating-table. He was comatose. Examination disclosed a compound depressed fracture of the skull a little posterior to the parietal foramen on the left side, the fracture being a comminuted fract-

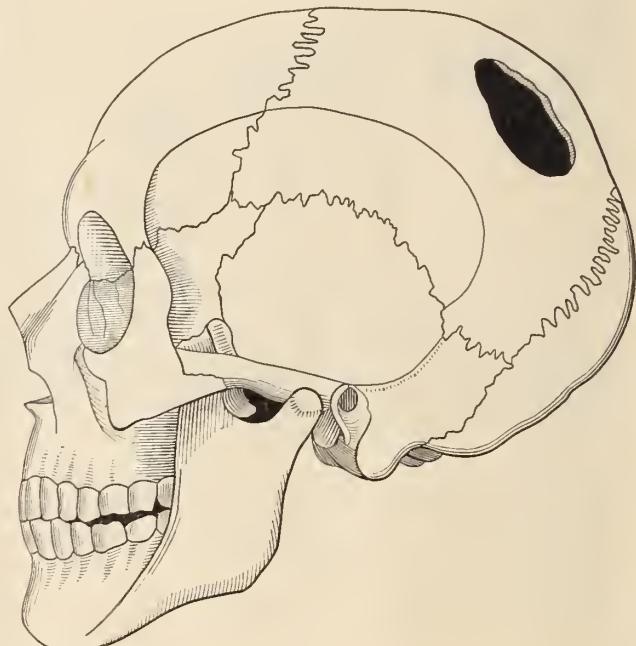

FIG. 5.

ure of the parietal bone. The dura mater was torn and fragments of the bone were driven into the brain substance for at least an inch. On account of the comatose condition of the patient, no anaesthetic was necessary. The several depressed fragments of bone were removed in the usual way, the use of the trephine being unnecessary. The wounded brain was cleansed, the dura mater laid over it as well as possible, the scalp wound sewed up except at the lower extremity, and the patient put to bed.

*February 27th.*—Since the accident the patient has remained comatose, with occasional intervals of delirium. He has retained a fair amount of nourishment. His urine has to be drawn with a catheter. The bowels are constipated and not

affected by enemata. This evening he had a slight rise of temperature, and the pulse was more frequent than before.

His neck is drawn backward and his muscles are very rigid.

*March 2d.*—The rigidity of his neck has slowly passed away. Two days ago he was given fifteen grains of calomel, with the result of free evacuation of the bowels. Yesterday he spoke rationally for the first time and recognized his friends. To-day his condition is the same as yesterday.

*6th.*—The patient is perfectly comfortable and conscious, also rational. The wound, which has been regularly attended to, looks well. There is a slight hernia cerebri. He suffers somewhat from vesical irritability, which has to be relieved. The urine is somewhat above normal in amount. Throughout the entire case there has been marked absence of paralysis of any kind.

*8th.*—Patient better to-day. The protruding part of the brain is suppurating freely and beginning to granulate. Wound dressed daily with wet creolin gauze.

*14th.*—A small abscess was to day noticed beneath the granulating surface of the brain. It was opened and a few drops of laudable pus were found. The cavity was packed with wet creolin gauze, and a large wet dressing applied over it.

*17th.*—The abscess cavity opened on the 14th has grown steadily larger. It is now three quarters of an inch in diameter and an inch and a half deep. It secretes a moderate amount of laudable pus. The floor and walls are formed of a soft white substance resembling the softened white matter of the brain. The cavity is packed daily with wet creolin gauze.

*19th.*—The walls and floor of the abscess cavity are granulating and discharging much less pus.

To-day the patient was seen and examined by Dr. Seguin. The lesion was said by him to correspond to one of the angular gyrus of the brain. The examination showed that the muscular sense on the right side was somewhat impaired. The patient is now sitting up. The abscess cavity is all closed in.

*26th.*—The patient goes out in the air. He is practically cured. The wound in the scalp is barely noticeable.

## THE PREVENTION OF SUMMER DIARRHŒA.

By WILLIAM A. NORTHRIDGE, M. D.,

BROOKLYN,

PHYSICIAN FOR DISEASES OF CHILDREN TO THE OUT-PATIENT DEPARTMENT OF THE LONG ISLAND COLLEGE HOSPITAL; SURGEON TO THE CENTRAL DISPENSARY.

THREE factors enter prominently into the aetiology of this disease—viz., heat, moisture, and improper food. Heat and moisture acting upon the food supply cause fermentation and rapid increase in bacterial development. The ingestion of this altered food is in many instances followed by dyspepsia and diarrhoea. A hot summer is always accompanied by a high mortality among infants living in large cities. This destruction of lives so valuable to the commonwealth may be mitigated by the instruction of parents:

1. As to the danger of heat and how to avoid it.
2. How they may prepare the food of the infant so that it will not do harm.
3. How to carry out the simpler rules of hygiene.

The heat it is very important to combat. Babies should be taken to the hill country or sea-shore as soon as the "heated term" commences. But, alas! few can leave their treadmill. It behoves us to do the very best we can for

them in town. Parents should be instructed to avoid and combat heat. During the hot part of the day the baby should be kept in the coolest part of the house; the clothing should be lessened in amount and water given regularly. In the early morning and late evening the streets are cooler than the house. The child should then be kept out in the air. Children may be taken to public squares, parks, along the water front, in open cars, and on ferry-boats. Strict regard must be paid to the food supply. Breast-fed children are by no means so likely to get the disease, and when they do, are much more readily cured. But many are artificially fed. A perfect substitute for mother's milk has not yet been found. It is now very generally conceded that cows' milk modified by the addition of certain substances is the *best* substitute, approaching *most* nearly to the natural supply. The wise physician is he who avoids prescribing the manufactured foods, save in rare instances. With a little care, children do very well upon a milk diet until the hot weather. A day or two of this and the trouble begins. The milk undergoes certain changes. It rapidly absorbs atmospheric impurities. If kept in an open vessel in an ice-box along with tainted meat or decaying vegetables, it will quickly acquire a peculiar taste and odor. Milk is very apt to become sour and undergo fermentation during the night. Many children are given milk which has become altered since the mother went to bed. The child is hungry and crying. The mother has no fresh supply, so the infant gets a dangerous food. Many diarrhoeas start in this way which would never occur if pure, unchanged milk was given. If we hinder fermentation and prevent impurities getting into milk, we shall prevent much disease. To avoid contamination by surrounding air impurities, milk at the dairy should be placed in tightly sealed vessels, instead of being kept in cans as it commonly is. The bottled-milk idea is a step in the right direction. The purchase of milk in bottles from a reputable dairy-man should be advised. If we can hinder the fermentation of milk so that the infant will just as surely get a sweet, clean supply by night as by day, we can prevent many cases of diarrhoea. If the nursing could be put directly to the udder of the cow, an aseptic, unchanged supply would be insured. This is impracticable, both from the inaccessibility of the cow and also because of the advisability of modifying cows' milk by the addition of certain substances, that it may more nearly approach the human. Milk should be sent to its destination as quickly as possible. When received it should be sterilized in a water bath, after the method advised by Dr. Soxhlet and Dr. Caillé, or some modification thereof. Fermentation being thus prevented, the milk should be kept in bottles, tightly corked, in a cool place until wanted.

On the morning of June 26, 1888, I obtained a quart of milk from a reliable source. I performed the following experiments:

Six new two-ounce bottles were very thoroughly washed in hot water. Three bottles were filled with milk and placed in a water bath. In twenty minutes they were removed, quickly corked, and when cool placed in an ice-box. Twenty-four hours afterward one bottle was opened. The milk was found to be perfectly sweet. On the evening of the

same day, thirty-three hours having elapsed, another bottle was opened. Taste and smell could discover nothing amiss. On June 30th the third bottle was opened. The milk was tested by several persons and declared to be perfectly sweet and good. This after four days. The experiment represents what we wish to do: render innocuous any harmful element contained in milk, and keep it pure and unchanged. It demonstrates that milk may be kept wholesome for even a longer time than is necessary. The baby may have a proper food supply in hot weather and the food cause of diarrhoea be obviated.

The remaining three bottles were used as follows: One was filled with milk, placed in a water bath for twenty minutes, removed, and put on ice, *uncorked*. After twenty-four hours, the milk was slightly sour to the taste. This represents the common method of boiling milk to prevent souring. It is good as far as it goes, but is inefficient, because milk exposed to air absorbs new impurities and changes start up again. Another bottle was filled, corked, and put on ice without being exposed to the heat of the water bath. Twenty-four hours after, the milk was found sour to the taste. In this experiment the changes due to contained fermentative elements went on, although the milk was protected from the atmosphere. The sixth bottle was filled with milk and placed on ice, uncorked. Twenty-four hours afterward the milk was decidedly sour. In this the milk was neither sterilized nor protected. The result, the common one, was the worst possible. This plan for preventing milk changes I carried out among a considerable number of sick babies last summer. The sick with diarrhoea received great benefit by this method combined with anti-septic medication.

But it has seemed to me that often we might *prevent the disease* by a few minutes' instruction to the mother. The mother is directed to obtain two small soda-water bottles. They are strong and can be tightly corked. The rest of the apparatus will be found in every household. A saucepan is to be filled with water sufficient to reach to the neck of the bottle. The bottles are to be thoroughly washed, filled with milk, and placed in the saucepan, which is laid on the range. A cover excludes the air. In about twenty minutes, or as soon as the milk froths up, the bottles are to be tightly corked and laid in a cool place. Mothers readily understand this procedure and carry it out successfully. A few cents paid for bottles covers the cost of the apparatus. When the child is to be fed, one of the bottles is opened, and the amount required poured out. The bottle is to be corked and returned to a cool place. The second bottle is not to be opened until the contents of the first are exhausted. The infant's sanitary surroundings should be carefully inquired into. Mothers should be instructed to keep the child perfectly clean. Soiled linen should be immediately removed. The child should be frequently bathed and an abundance of fresh air and light afforded.

**The Vermont State Medical Society.**—The June meeting of this society was adjourned to July 9th and 10th, so as not to conflict with the Newport meeting of the American Medical Association. The place of meeting is Brattleboro.

THE  
NEW YORK MEDICAL JOURNAL,  
*A Weekly Review of Medicine.*

Published by  
D. APPLETON & CO.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JULY 6, 1889.

THE INFLUENCE OF THE TESTICLES ON THE ORGANISM.

In a recent communication to the Paris *Société de biologie*, an abstract of which is given in the "Progrès médical" for June 8th, M. Brown-Séquard gave an account of certain odd experiments that he had undertaken in an endeavor to ascertain the effects produced upon the economy by the supposed action of the testicles on the blood circulating through them. It seems that he gave some attention to this question so long ago as in 1869. At that time he had concluded theoretically that the influence of the testicle was enormous. In 1875 he began experimenting by means of grafts containing testicular tissue; and, although all but one of these experiments failed, in that one an old and broken-down dog was endowed anew with the friskiness of comparative youth. More recently M. Brown-Séquard has pursued his inquiry by means of experiments on himself, employing subcutaneous injections of blood from the spermatic veins of a young animal, mixed with the juice obtained by crushing its testicles and with a little water. The distinguished author is by no means a young man—unless we are mistaken, he is verging on fourscore—but these injections seem to have rejuvenated him. He reports that his muscular strength has returned in great measure; that that torment of the aged, intestinal atony, has disappeared, so that defecation has become normal again; that the bladder has regained its contractility, as shown by an increase of force in the stream of urine; that he finds mental exertion very easy once more; and that there are other manifestations of his return to youthful vigor. The injections are said to be painful, and it is added that they are sometimes followed by redness of the skin, but that this is without serious consequences. It is not the seminal fluid to which M. Brown-Séquard attributes these wonderful results, but rather the venous blood that has passed through the testicles, for with semen, crude or filtered, he has been able to produce nothing but abscesses.

It is true that at the meeting some cold water was thrown on M. Brown-Séquard's new elixir of life; M. Dumontpallier remarked that the imagination probably played a certain part in such cases, and M. Fétré suggested that a local inflammation of the lymphatic vessels, such as any subcutaneous injection might produce, was capable of giving rise to a subfebrile state that would have the effect noted. To this M. Brown-Séquard replied that it was precisely the punctures which had produced no local reaction that had been followed by the most decided dynamic effects, and that ordinary subcutaneous injections, such as those of morphine, gave rise to no gain of muscular power, notwithstanding the inflammatory nodules that they so commonly set up. Certainly, M. Brown-Séquard's inferences

need confirmation. If there should prove to be any truth in them, our views of the physiological importance of the testicle must be enlarged, and we may even be led to suppose that like properties reside in the ovary, and to question whether the "unsexing" of women is the only evil incurred by removal of the sexual glands.

#### THE OFFICE OF CORONER.

THE coroners of Hudson County, New Jersey, are said to have almost unanimously expressed their regret that they accepted their offices. They complain that they are overworked, that they are poorly paid, and that they have not even the satisfaction of getting promptly the insufficient payments that come to them.

Perhaps this dissatisfaction may be the entering-wedge leading to the abolition of that relic of barbarism, the coroner's position in that State. With regard to New York State, no serious indications have been noticed which give promise of any such happy result. We are all well enough aware of the faulty workings of the system, and yet indifference in the profession, in our societies, and in medico-legal circles, permits these faults to continue year after year. A case has been reported from a city in New York State which, briefly told, amounts to this: An irregular and uneducated practitioner was expecting to be brought into court on a charge of criminal abortion when he took his own life. The coroner was summoned and held an inquest. Under his manipulation the testimony was so guided or suppressed that the public records will forever show that this doubly guilty man died by "heart-disease," or some other similar convenient covering of facts that should not have been suppressed. When coroners of the class to which the individual in question happens to belong put upon the records a truthful statement of the cause of death in their inquest cases, it must be largely accidental and because there is no occult reason why their reports should be falsified. The time must come, we are persuaded, when this sham judicial officer will be laid upon the shelf, as has been done in Massachusetts. That commonwealth was the first to establish a State board of health, and many other States have followed her example. The same will occur, without doubt, in regard to the example set by her in establishing a system of medical examiners. This did away with the antiquated coroner and substituted in his place a medical man having skill and training. Under this system thirteen thousand cases of violent and suspicious deaths have been investigated in a satisfactory manner since 1877. At a meeting lately held in New York, Theodore H. Tyndale, Esq., of the Boston bar, gave his views of the salutary effects of the new system. He said: "With the abolition of the composite functionary and of the jury, we gained a highly trained class of medical examiners—an office gladly accepted by the best physicians of the State—and we have opened the door to fields of detailed investigation in pathology previously unknown. We have laid the foundation of a valuable collection of observed facts as shown by the publication of our medico-legal transactions contributed entirely by the medical

examiners. We have attained accuracy, and we have never, since the passage of the Act, failed in a single prosecution for want of or insufficient clearness of medical testimony."

#### MINOR PARAGRAPHS.

##### AN IRISH WOMAN, AN AUSTRALIAN GIRL, AND A CHIMPANZEE.

A PAPER written by D. J. Cunningham, M. D., professor of anatomy in the University of Dublin, recently communicated to the Royal Society, is entitled "The Spinal Curvature in an Aboriginal Australian." The object of the effort, which is mathematically severe and profoundly abstruse, is to demonstrate certain subtle points of similarity and difference assumed to exist in the antero-posterior curvature, in various regions of the spine, of the typical European, the aboriginal Australian, and the average chimpanzee. After apparently years of patient research in this important direction, and deplored the "absence of fresh spines of the lower races," the author finally succeeded in importing from Australia the intact spinal column, "packed with great skill and care," of an Australian girl aged sixteen. The other spines obtained for comparative analysis were those of an Irish woman aged thirty-five, and a young female chimpanzee. Careful examination of the sectional drawings illustrating the article leads the thoughtful and unbiased mind to conclude that this particular Irish woman and this particular Australian girl were as similar, so far as their spines were concerned, as could be expected, considering their respective ages and habits. The former had, it must be admitted, a by no means defective curve in the upper dorsal region, while the chimpanzee's spine bears just about such resemblance to the two others as the average man bears to the average monkey, which is saying a good deal: but, then, *cela va sans dire*. Speaking seriously, the progress of comparative anatomy may be impeded by lack of such data, but the author has been unfortunate in the selection of bases for his argument and deductions, and has neutralized the power of his equation by repeatedly admitting the use of imperfect factors. Surely *cacoethes scribendi* and chronic Darwinism are deplorable ailments.

#### A TROUBLESOME MEDICAL WOMAN.

ON many occasions we have spoken in commendation of medical women, but we trust that their well-wishers will not often be hampered by such incidents as one that recently happened in Paris. According to the "Progrès médical," one Mlle. D., a Russian étudiante, was appointed a hospital externe and attached to the *hôpital Saint-Antoine*, where the interne soon found it necessary to remonstrate with her upon the irregular quality of the services that she rendered. This he is said to have done with all proper moderation, but the young woman became insolent and procured the assistance of a fellow-student, a male Russian, who sought to fasten a quarrel upon the interne, at whom, indeed, one Russian student aimed a blow with a cane, which luckily was parried. The outcome of the affair was that Mademoiselle's appointment was revoked, and her champion had to answer to a charge of assault before a police magistrate.

#### THE EXCITING CAUSES OF HYSTERIA.

IN a recent work by Georges Guinon, "Les agents provoateurs de l'hystérie," which, the "Progrès médical" says, reflects equal honor upon its author and the Salpêtrière school, the following are given as the exciting causes of hysteria: Moral emotion; attempted hypnotism; nervous shock, as from

earthquakes, injuries, and peals of thunder; general infectious diseases, such as typhoid fever, pneumonia, scarlet fever, acute articular rheumatism, diabetes, malarial infection, and syphilis; morbid states characterized by considerable general exhaustion, such as haemorrhages, mental or physical overwork, sexual excesses, anaemia, and chlorosis; poisoning, either in the chronic form, as with lead, alcohol, mercury, etc., or in the acute, particularly that produced by chloroform for surgical anaesthesia; and diseases of the nervous system, such as multiple sclerosis, locomotor ataxia, primary progressive myopathy, and gradual compression of the spinal cord in Pott's disease. The author does not ignore the fact that all these causes may produce other nervous troubles, notably neurasthenia, and recognizes as well the existence of a form of hysteria due to general malnutrition that includes a malnutrition of the nervous system.

#### THE PHYSICIANS OF JOHNSTOWN.

THE "Maryland Medical Journal" has received and distributed funds for the physicians of Johnstown who lost their all, Dr. J. W. Hamer being its almoner. Other journals may have done the same thing, but the Baltimore weekly is the first one that has fallen under our notice. There are physicians in the afflicted valley who before the floods were accounted well off, who now have not a penny except what comes to them as a gift or as payment for services. And some of them now complain that the visiting volunteers of the Red and Yellow Cross are taking professional business away from them, so that the earnings and the occupation—both of which would be helpful to them—go to those who need neither. They have made representations of these conditions to the State authorities, but their complaints were not entertained. If any funds collected by medical men or societies remain unforwarded, we suggest that the journal above named, or Dr. J. W. Hamer, be the channel for their distribution.

#### THE STAPHYLOCOCCUS PYOSEPTICUS.

THIS is the name that Héricourt and Richet have given to a micro-organism which they accidentally discovered in an epithelial, non-ulcerated swelling on a freshly killed dog. This coccus very closely resembles the *Staphylococcus pyogenes albus*, except in the following characteristics: In peptozized bouillon it forms whitish masses on the surface, which have a tendency to divide into delicate threads, while the *Staphylococcus albus* becomes distributed more evenly and does not form masses on the surface. It is also more virulent, one or two drops of the cultivation fluid having killed rabbits in from twelve to twenty-four hours. An equal quantity injected under the skin caused a large, gelatinous, transparent oedema, while the *Staphylococcus albus* injected in the same manner produces suppuration almost without oedema. They have also successfully undertaken to produce a protective inoculation in rabbits, not only by Pasteur's method, but also by injecting the blood of dogs into the peritoneal cavity. If the blood was taken from the carotids of dogs which had previously been inoculated with the *Staphylococcus pyo-septicus* and had recovered, and injected into the peritoneal cavities of rabbits, these rabbits were proof against infection with this micro-organism. If the blood of uninfected dogs was employed, the rabbits presented an increased power of resistance to infection with the *Staphylococcus pyo-septicus*, as was shown by the mildness of the local symptoms after inoculation. From this they think it possible that by the transfusion of the blood of animals which are proof against certain micro-organisms one may be able to confer immunity, or at least increased resisting power, upon other classes of animals.

#### FEVER IN FILTERS.

THE sixth annual report of Dr. C. V. Chapin, of Providence, deals with the outbreak of typhoid fever in the winter of 1888-'89. It contains an example of very painstaking work on the part of the health officials to discover the causation of the attack. Grave suspicions as to the pollution of the water-supply having arisen, the study was at first limited to the bacteriology of the Pawtuxet River water, but with negative results. The thought thereupon occurred to investigate the filters in use in houses where fever had existed. They were given to Dr. Prudden, of New York, and others skilled in bacteriological work. In three of these filters the typhoid organisms were found. Besides the typhoid bacilli, several organisms peculiar to faeces were associated with them. Dr. Prudden described the contents of one of the filters as a mixture of water, carbon, and human excrement. These three filters were not alike in their name and make. A diagnosis of the outbreak by exclusion gives a very strong presumption of river-water infection by typhoid excreta, and the laboratory investigations appear to give this view a significant confirmation. These inquiries also make it certain that the filters that are in ordinary use are sources of danger to the families using them, since they collect filth and micro-organisms from the water and serve as hatcheries to the latter.

#### CARE IN PRESCRIPTION-WRITING.

A DEATH by poisoning, arising in part from a want of care (so it is alleged) in the writing of a prescription, has occurred in France. A physician gave to his own brother, who was suffering from migraine, an order for a dose of antipyrine. So he intended, at least, but the prescription fell into the hands of the apothecary's female assistant, and she interpreted it as calling for atropine instead of antipyrine, and dispensed the fatal dose. Care should be exercised not only in the ordering of potent drugs, but also of those not so powerful, lest the writing be misinterpreted and a poison be dispensed where none was intended. Let the writing always be distinctly legible.

#### "THE SWIFT, THE SWALLOW, AND THE MARTIN."

DR. GEORGE BUCHANAN, a medical officer of the English Local Government Board, is often very happy in his way of putting things. Of this an instance has come to hand in his introduction to Dr. Klein's study of milk-searlatina, wherein that writer contends that the disease in the cow is the same disease as the scarlet fever of man, and not cow-pox as is asserted by some; and that the *Streptococcus searlatinae* of man can by inoculation beget a bovine searlatina. Dr. Buchanan's point is that similarity is not identity in regard to the streptococci any more than it is as to the birds above the housetops. He says: "To the less educated judgment there is as little difference between one and another of the chain-forming micrococci as, to the eye of the ordinary dweller in towns, exists between the swift, the swallow, and the martin."

#### ITEMS, ETC.

**The Association of Acting Assistant Surgeons of the United States Army** held its first annual meeting at Newport, R. I., on Monday, June 24th. The following officers were elected for the ensuing year: President, Dr. A. Reeves Jackson; vice-presidents, Dr. J. L. Ord, Dr. A. J. Comfort, and Dr. D. S. Lamb; treasurer, Dr. R. J. Dunglison; registrar, Dr. Benjamin L. Holt; recorder, Dr. W. Thornton Parker; council, Dr. William Deeble, Dr. S. S. Turner, Dr. H. E. Sabin, Dr.

H. R. Porter, Dr. J. P. Pratt, Dr. H. E. Turner, Dr. S. B. Stone, Dr. John S. Warren, Dr. S. O. L. Potter, Dr. E. W. Thompson, and Dr. John T. Nagle. The association now numbers seventy-seven members. Applications for membership should be addressed to Dr. W. Thornton Parker, Narragansett Pier, R. I.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 2, 1889:

DISEASES.	Week ending June 25.		Week ending July 2.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	7	0	11	3
Scarlet fever.....	81	8	71	7
Cerebro-spinal meningitis.....	1	0	3	3
Measles.....	89	7	88	4
Diphtheria.....	115	35	99	27

**Recent Deaths.**—Dr. William N. Curtis, of East Albany, N. Y., died on June 6th, aged forty-five years. He was a native of London, England. He was graduated from the Albany Medical College in 1870.

Dr. Charles William Wolfertz, who died at West Orange, N. J., on June 19th, was one of the vaccinating corps of the Department of Health. He was an alumnus of the College of Physicians and Surgeons of the class of 1886. He was only twenty-five years old when his death, by pulmonary phthisis, took place.

Dr. Daniel W. Hand, of St. Paul, Minn., died on June 1st, of uræmia, in his fifty-fifth year. He was born at Cape May Court-House, N. J., August 18, 1834. He was educated in arts at Lewisburg, and in medicine at the University of Pennsylvania. From 1857 to the breaking out of the war Dr. Hand resided at St. Paul. His services as regimental surgeon, brigade surgeon, and medical director were meritorious and efficient. He was wounded at Fair Oaks. He was a prisoner at Libby prison for a short time. In August, 1864, he was at Newbern, being medical director of the State of North Carolina when yellow fever visited that city, carrying off over twelve hundred of the citizens and eleven of his assistant surgeons. He was attacked by the fever, but recovered quite promptly, although with a renal disease established which eventually ended his life. In 1865 he returned to St. Paul, and before many years stood in the front rank of the profession of his State. He was for many years the president of the State Board of Health.

Dr. William Elmer, an ex-president of the New Jersey State Medical Society, died at his home in Bridgeton on June 27th in his seventy-fifth year. He was a graduate of Princeton in 1832 and of the University of Pennsylvania in 1836, which latter institution has given not fewer than nine of the Elmer family to medicine. Dr. William Elmer had been a leader in Cumberland County not only in medicine, but in religious and charitable administration for half a century. He was the president of the State society in 1860, and was interested in the early movements by which the State board of health became a permanent institution. He occupied official positions in the State Lunatic Asylum, in the State Home for Feeble-minded Children, and in a number of organizations efficient for good in southern New Jersey.

Dr. Samuel Brandeis, of Louisville, died on May 24th, aged seventy years, of disease of the heart, from which he long had been a sufferer. He was a native of Prague, graduated at Vienna in 1846, and left his country for America a few years later. In 1852 he settled down for life at Louisville, where his eminent ability was soon marked by a large following. He was an industrious and scholarly practitioner, who found time to de-

velop a culture and refinement in extra-professional fields that are attained by few; educational progress interested him in a special manner. He held many places of honor and trust, both with his associates and with the general public.

**The Superintendents of the Insane.**—The following officers of the Association of Medical Superintendents of American Institutions for the Insane were elected at the recent meeting at Newport: President, Dr. W. W. Godding, of Washington, D. C.; vice-president, Dr. Henry P. Stearns, of Hartford, Conn.; secretary and treasurer, Dr. John Curwen, of Warren, Pa.

**The Nova Scotia Medical Society.**—The twenty-first meeting convened on July 3d at Halifax. Dr. Donald Campbell, of Halifax, is the president, and Dr. W. S. Muir secretary. The programme of scientific business presents over twenty titles of papers and reports as having been promised for the first two days. One of the members gives notice that he will raise the question of whether it is right that duty should be levied upon surgical instruments and medical works. A second question to be raised is the manner of the appointment of the Provincial Medical Board, whether by the Government or by the medical profession.

**An International Congress of Otology and Laryngology.**—The twenty-first meeting convened at Paris, for a six days' session, beginning on September 16th, the hall of the Trocadéro to be the place of meeting. The committee of organization is made up of very eminent specialists from all parts of France, with Dr. Duplay as president. The secretary, Dr. Loewenberg, may be addressed at rue Auber, 15, Paris.

**The New York Cancer Hospital.**—Dr. G. A. Kletsch has been appointed an assistant surgeon.

**The Woman's Hospital.**—Dr. G. A. Kletsch has been appointed an assistant surgeon.

**The New York Polyclinic.**—Dr. Henry C. Coe has been appointed a professor of gynaecology, in place of the late Dr. Hunter.

**The Transactions of the Medical Society of the State of New York.**—The volume for 1889 of this annual publication gives an account of the eighty-third session at Albany, last February. Not only is this an unusually prompt appearance, but the book has a cleaner, brighter look than its predecessors. It was printed for the society by a Philadelphia printer. These improvements must have been undertaken with no little courage in view of the fact that the report of the treasurer shows an increasing deficit, amounting this year to over \$500.

**The Tennessee Medical-Practice Act.**—The new medical-practice act of Tennessee is thus summarized in the "Atlanta Medical and Surgical Journal" for June: There is a board of examiners, six in number, not more than four of whom are to be of the same school of practice. They are appointed by the Governor. No one may practice medicine without a certificate from this board, under penalty of \$100 for the first offense, and of \$200 afterward. All persons in practice at the time of the passage of the act are entitled to such certificate. Those thereafter desiring to begin practice must present a valid diploma or pass an examination. The examination fee is ten dollars, and the certificate fee is one dollar. Itinerants are to pay \$100 a month. The act does not apply to midwives. It has gone into effect, the "sixty days" limit having expired.

**College Notes.**—Fifty-seven degrees of M. D. were granted at the recent Harvard University commencement. The Uni-

versity of Michigan had eighty medical graduates. The Medical School of Maine had twenty.

Dr. Paul B. Barringer, formerly of Davidson College, N. C., has been elected to the chair of physiology and surgery at the University of Virginia, to take the place of Dr. James L. Cabell, who has resigned from active service. Dr. Barringer is the author of a brief history of the medical department.

Dr. John Whitridge Williams has been appointed chief of the obstetric clinic at the Johns Hopkins University. He will also assist Dr. Howard A. Kelly, the newly elected professor of obstetrics.

Dr. Christopher Johnston, Jr., of Baltimore, has resigned his lectureship on ophthalmology at the University of Maryland. He has been appointed to a fellowship in the Johns Hopkins University. He leaves medicine for philology, and his life-work will probably be given to that department which is designated as Assyriology.

Dr. George Ross has been appointed to the chair of the practice of medicine in McGill University, to be followed in the chair of clinical medicine by Dr. Richard L. MacDonnell.

**The Transplantation of a Medical Fraud.**—The attention of the New Jersey Board of Health and of the Medical Society of that State is called to the fact that there appears to be in Jersey City an alleged medical college which strongly suggests that miserable affair "The United States Medical College," formerly situated in New York. The "Tribune" of June 29th reports an alleged commencement of that college with twelve graduates and certain other forms of mimicry of a genuine institution of learning.

**Journalistic Changes.**—The "Weekly Medical Review," published in St. Louis, announces that it will be enlarged to the size of this journal. Another medical weekly is said to be on the ways at St. Louis. The two medical monthlies of Buffalo have coalesced under the title of the older one, the "Buffalo Medical and Surgical Journal." The junior journal, named the "Medical Press of Western New York," existed four years under the able editorial conduct of Dr. Roswell Park.

**A Malpractice Suit.**—Dr. Mansfield and Dr. Sheldon, of Wakefield, Mass., have been in the fiery furnace of a malpractice suit conducted against them by General B. F. Butler. They escaped with their lives, the jury deciding in their favor, but, as the "Boston Medical and Surgical Journal" intimates, the next worst thing to losing a suit of this nature is to win one; the annoyances and the losses of time, money, and peace of mind are not compensated for by the fact that the jury has happened to side with the defense.

**The Honorary Degree of LL. D.** has been conferred by Yale University on Dr. Horatio C. Wood, of Philadelphia.

#### Society Meetings for the Coming Week:

**TUESDAY, July 9th:** Vermont State Medical Society (first day—Brattleboro); Medical Societies of the Counties of Chautauqua (annual), Clinton (semi-annual—Plattsburgh), Greene (quarterly), Jefferson (semi-annual—Watertown), Madison (annual), Oneida (annual—Utica), Ontario (annual—Canandaigua), Schuyler (semi-annual), Tioga (semi-annual—Owego), and Wayne (annual), N. Y.; Norfolk, Mass., District Medical Society (Hyde Park).

**WEDNESDAY, July 10th:** Vermont State Medical Society (second day); Tri-States Medical Association (Port Jervis, N. Y.), Franklin (quarterly—Greenfield), Hampshire (quarterly—Northampton), and Worcester (Worcester), Mass., District Medical Societies.

**THURSDAY, July 11th:** Medical Society of the County of Fulton (semi-annual), N. Y.

**SATURDAY, July 13th:** Worcester, Mass., North District Medical Society.

#### Letters to the Editor.

##### SUBLUXATION OF THE HEAD OF THE RADIUS.

30 WEST FIFTY-NINTH STREET.

*To the Editor of the New York Medical Journal:*

SIR: In the interesting paper by Dr. Morris, published in your issue of the 22d instant, Dr. Van Arsdale is quoted as saying, as lately as last March, that the anatomical nature of the injury had not as yet been satisfactorily described; and this statement stimulated Dr. Morris's experiments on the cadaver. Both these gentlemen seem to have overlooked an essay on this subject by Dr. E. M. Moore, of Rochester, read before the New York State Medical Association at its annual meeting in 1886, and published in the third volume of its "Transactions," in which he described the lesion experimentally produced on the cadaver by him in terms almost identical with those used by Dr. Morris. Two specimens illustrating the condition in question were exhibited at the meeting above referred to. It is, of course, doubly satisfactory that the same results should be obtained from separate investigations independently conducted, but it is only fair that priority should be awarded to Dr. Moore for the solution of a much-vexed surgical problem.

In corroboration of Dr. Morris's suspicion that there are cases in which reduction is not effected either by art or by nature, I have had under my care a gentleman whose radius was subluxated two years previously by sudden extension in sliding a heavy weight from a cart on his Western "ranch." The medieval man who saw him at the time failed to detect the character of the injury, and the pain caused by attempts at movement induced him to keep the elbow flexed at an angle of about 130°, until adhesions stiffened the joint and required considerable force to restore motion. The thickening about the radial articulation was so great that freedom of pronation and supination will never be practicable. In view of the rarity of this accident in an adult, the case is of interest, and it is noteworthy that its cause was similar to the force commonly applied by nurses to children—namely, sudden extension at the elbow with the wrist in a partly flexed position.

ALFRED L. CARROLL, M. D.

207 WEST FIFTY-SIXTH STREET, June 25, 1889.

*To the Editor of the New York Medical Journal:*

SIR: In an article by Dr. R. T. Morris, in last week's issue of your paper, the author, after referring to a paper read by me on so-called subluxation of the head of the radius, describes some experiments done and observations made with a view to determining the real anatomical lesion in these cases. As my paper may not come before all your readers, and as the author's article appears apt to give rise to misconceptions in regard to my views on the subject (especially as my conclusions are not given verbatim), I would state that, so far from being unacquainted with the chief conclusion of the author's (that the injury was due to interposition of the orbicular ligament between the head of the radius and the capitellum), my whole paper goes to prove that this is one of the three most probable theories admitted (the two others being injury to the radial head and partial anterior displacement, respectively).

The identical experiments illustrated by the author's cut

were done by Streubel in 1850, and others in Germany, and in this country by Van Santvoord and by E. M. Moore ("Trans. of the N. Y. State Med. Assoc.", 1886).

I myself, as late as March 11th of this year, demonstrated a specimen similar to that figured by the author to the Surgical Section of the Academy of Medicine (to which, however, the author has not done me the credit to refer) as illustrating an old and favorite theory, but one not above criticism.

The objections raised by me to this theory are: 1. That, although the interposition of the capsule of the joint is very easily observed on traction, when the skin and muscles have been dissected away, yet in the living subject the muscles and tissues surrounding the joint are so intimately connected with the ligaments that such interposition is improbable; and, if it did occur, muscular action would readily dislodge the interposed parts; and, again, if interposition of so much tissue took place, the fact could be easily made out by clinical observation. Nor does the snap heard clinically on reduction correspond to that produced in partially dissected cadavers.

2. The fact that such an acute observer as Streubel, eleven years after advancing the theory of interposition, was induced by clinical experience to discard it again argues against it.

3. The fact that in many clinical cases the head of the radius can be felt anteriorly displaced, speaks against the theory of interposition.

In a case of subluxation of the radius head shown by me at the May meeting of the Surgical Section of the Academy, the chairman asserted that he could feel this displacement of the head.

I believe that the theory of the author's, that relaxation of the biceps muscle is necessary to the successful production of the injury, is entirely original. But, in my opinion, when a child stumbles or falls while its hand is firmly held by the nurse, the biceps, so far from being taken unawares, is much more apt to produce a displacement of the radial head anteriorly, as was held by Goyrand and Lindemann. When a child stumbles in this way it does not relax its biceps, it is more apt to rupture it.

It is very easy to obtain conditions similar to those described by the author after the most diverse manipulations when partial dissections have been made; but whether they are so readily obtained in healthy children is a question upon which I am somewhat skeptical.

W. W. VAN ARSDALE, M. D.

## Proceedings of Societies.

### AMERICAN MEDICAL ASSOCIATION.

*Fortieth Annual Meeting, held in Newport, R. I., Tuesday, Wednesday, Thursday, and Friday, June 25, 26, 27, and 28, 1889.*

The President, Dr. W. W. DAWSON, of Cincinnati, in the Chair.

**The Address of Welcome.**—The proceedings of the first day were opened by an address of welcome by the Hon. Herbert W. Ladd, of Providence, Governor of Rhode Island. He spoke of the occasion as an exceptional one, for, as a rule, the visits of doctors were not associated with pleasure, and it was rarely that they could be greeted with a smile. Now, however, he hoped they would not only feel they were welcome, but would soon experience that cordiality for which Rhode Island was proverbial.

**The President's Address.**—After a few other interchanges

of complimentary formalities the president delivered the annual address. It was arranged to cover, by sectional headings, the entire position of American medicine. Prefacing this segregation of his subject, he referred to the future position of the learned professions. Such future, he said, was certainly most conspicuous and its obligations imperious. Medical men must be loyal to this grand destiny. Criticism abounded concerning the defects of medical education, but such criticisms came too frequently from gentlemen unacquainted with teaching, with no practical knowledge of the constitution of medical colleges or of the toil, devotion, and sacrifice made necessary by those engaged in didactic and clinical instruction. Education, it must be remembered, could not make all great or equal, but it tended at least to make all safe. In the crucible of private, practical life evolution asserted itself and the fittest survived. The position of the profession in the matter of medical teaching in this country was peculiar. For many years, and even now, with few exceptions, medical colleges were the creation of the members of the profession, most often of the faculties composing the schools, without endowment, without governmental aid, and depending for support upon the sacrifice of time and money on the part of the gentlemen occupying the chairs; and not only were the schools without patronage from the government, but society, from some unknown cause, had ever been against legitimate medicine, depending upon the scientific physician in time of trouble, but in the interim openly supporting all sorts of shams, frauds, and impostors. Elsewhere college work was provided for by the state, especially laboratory investigations. Hence it was not to be wondered at that in such departments this country might be somewhat behind the countries of Europe. While, however, they had been engaged there in elaborating experimental studies, the profession in America had developed the practical. Everywhere could be seen an earnest, burning desire for higher culture, for more exact and thorough knowledge. Especially was this true of the younger members of the profession. A movement was now on foot to concentrate those who possessed preliminary advantages and who could enter the profession with college educations. This was a move in the right direction, if it was not made too exclusive. Every effort which tended to refine the profession without emasculating it should meet with judicious approval. The answer to the question, "Whence are medical students to come and what facilities are now afforded or promised in the future for the education of the 'coming doctor?'" would, he trusted, give some comfort to the pessimist and soothe the restless and at times unreasonable critic. In the first place, the normal schools might be looked to for the supply of better material, year by year, from which medical students would be drafted. Then the most generous provisions were being made all over the land for institutions which would be worthy to be called universities. From these, graduates would emerge fit to rank by the side of those bearing the prized degrees from Oxford, Cambridge, Paris, Heidelberg, or Leipsic. The future was aglow with promise. Liberal donations and bequests were now being made by generous citizens to be used in developing higher culture. The poor in medicine, however much one might deplore him or train him, would, like the poor, be "always with us." As to the physical qualities of the "coming doctor," it was to the country schools, not the city bred, that medicine must look for many of her strong recruits. Cities would often emasculate, and young men were vitiated by indulgence and vice before they became possessed of serious thoughts. In many of the States of the Union already colleges were established in which the degrees of A. B. and A. M. might be obtained. Too strong insistence could not be made as to the necessity of a classical education. Without a knowledge of Latin and Greek

sure and distinguished success was uncertain. It was well not to be impatient. The influences were already projected which should give to the country students equal to the highest standard of preliminary preparation. Much had been done in a most primitive stage, and, he would ask, could more have been accomplished in a century?

Touching upon the subject of medical schools, the speaker referred again to the fact that in this country everything was endowed except medical colleges. All financial responsibilities had been assumed by the members of faculties, who gave every hour not devoted to "earning the guinea" to college work, and in most instances this was done without pecuniary reward. It was only recently that the wise, the generous, the favorites of fortune, and a few of the States had conceived the idea of endowing medical schools—institutions where medicine and surgery could be cultivated without the embarrassments of financial responsibility. In the metropolitan colleges every physician might feel just pride; their graduates, for the most part, would compare favorably with those educated anywhere on this earth. The accomplished Dr. Senn had said, after considerable experience with foreign schools, that the average American student learned more in one month than the average German student in three. Not because he had better teachers or better facilities, but because he made better use of his time. The provincial schools were also doing thorough work in training, and many supplemented their practical clinical studies by hospital attendance in the great cities and by post-graduate courses, and it was most gratifying to know the advantages offered by these organizations. Touching upon the subject of medical journalism, the president said: "Medical journals, metropolitan and provincial, are the heralds, the vanguards of medical progress, the exponents of professional culture. They are closely associated with the colleges in education and in post-graduate instruction. In them appear the best thoughts of the best men; they constitute the great forum of intellectual combat; upon their pages pretension is analyzed and estimated, and worth recognized; that which is new or original is endorsed, or rather encouraged." After passing in critical review the subjects of laboratory work, the history of medical teaching, the medical and surgical library and museum at Washington, the "Medical and Surgical History of the War of the Rebellion," and so on, the speaker went on to say that there were yet clouds. "What," he said, "has been accomplished by the profession in this country, self-reliant and, as heretofore stated, without governmental or social support, is certainly worthy of congratulation, and gives ground for hope of a rosy-hued future; but, alas! there are some dark clouds to be seen, some spots on the sun of promise. Have we inherent defects in our organic law—our *esprit de corps*? Upon the face of our promising future some omens of evil appear—indications which look not up but down, not forward but backward, not to the elevation but rather toward the degradation of our profession. Heretofore we have been an organization into which no species of fraud could enter; pretension, ignorant pretension, stopped at the door. No *ism* or *pathy* was admitted. Something more than a diploma, 'a legal diploma,' was required—a clean bill of conduct, free from false assumption, assumption of universal knowledge of specific remedies, of imaginary potencies; in fact, of all shams and false pretensions; a guild in which there was the greatest freedom for the truth, the largest liberty for the right. No vendor of secret remedies was admitted, because of the ignorant presumption in which they were conceived and propagated. But, alas! that we should have fallen upon the evil times when 'patented processes' are attempted, when 'processes' applied to valuable remedies are kept secret. These remedies made with 'patent processes' are in daily use. This

is one of the dark spots in the picture. It came in with the 'legally qualified practitioner.' What are antipyrene, antifebrine, salol, sulphonial? The reliant patient may well propound such questions. Who can answer them?" He then went on to say that it might be asked if the standard of professional excellence had been raised by the laws enacted in many States for the regulation of the practice of medicine. These laws, while they banished those without diplomas, made quasi-respectable those who had so-called diplomas from whatever source. Had not such diplomas tended to make vice and presumptuous ignorance respectable?

The profession must be kept pure—pitch could not be touched without defilement—or it would degenerate and sink to the level of a trade. In the State boards of health, by the side of physicians were to be found these "legally qualified" practitioners. Where lay the responsibility? Self-examination on this subject should be searching. If there had been failure on the part of physicians as a whole in their duties to humanity, let them be swift to acknowledge and eager to correct the error. In conclusion, the speaker made an earnest and stirring appeal to the members of the profession, urging the necessity for a national organization to which all questions could be referred for just and final decision. But let them not lose their loyalty to this parent association. Of the American Medical Association let them unite in saying *Esto perpetua*.

This ended the business of the day, and during the afternoon and evening the members and ladies accompanying them availed themselves of various courtesies by the people of Newport and the vicinity.

**The Proposed Rush Monument.**—The reports of various committees having received attention early on Wednesday, Dr. WILLIAM PEPPER, of Philadelphia, delivered the address of the day, which was virtually an appeal to the sympathies of the association on behalf of the fund for the desired monument to the late Benjamin Rush. Rush, he said, had been a true social reformer, a denouncer of slavery, an opponent of the use of ardent spirits, though not insisting upon total abstinence. While Rush had been active in philanthropy, education, and religion, still he had been, above all else, a physician. Students had gone to Philadelphia from every State to avail themselves of his teachings. He had been among the earliest to advocate an advanced medical education.

The chairman of the Rush Monument Committee, Dr. ALBERT L. GHON, of the Navy, then stated that but little progress had been made in the matter of the monument. The medical profession in this country was a hundred thousand strong, and if only forty thousand of these would contribute a dollar each a noble monument could be erected. Dr. Gihon's enthusiasm was so warm and his appeal so earnest that quite a furore was created. Business was suspended for the time being, and in a short while \$264 were subscribed toward the Rush Monument Fund.

**The Report of the Committee on State Medicine.**—Several important reports from section committees were handed in for the consideration of the third day's General Session. Among these was the following definite recommendation by the Committee on State Medicine:

"Your committee on uniform medical legislation have the honor to submit the following report, to wit:

"That, in our judgment, the best interests of the public will be subserved by the enactment of efficient medical legislation in every State of the Union.

"That, for the convenience of the profession of this country, it is advisable to secure uniformity of legislation in the essential features of all medical practice acts.

"This committee therefore begs to recommend as follows:

That in future medical legislation the essential features of the enactment be as follows: That all persons commencing the practice of medicine in any of its branches shall possess a license from the State Board of Medical Examiners, and that every candidate for a license shall submit satisfactory documentary evidence that he or she is a graduate in medicine of a medical institution in good standing with the said board and having a curriculum possessing at least the following requirements: First, an examination to test the student's fitness to become a practitioner. This examination shall include at least English grammar, composition, geography, history, arithmetic, algebra, physics, and the natural sciences, together with at least one of the following languages: Latin, French, or German; provided, however, that the graduates of regular colleges be exempted from said examination. Second, before receiving a degree of M. D. or M. B., candidates for the same shall have attended at least three full and regular courses of medicine of not less than six months each. All candidates for a license shall undergo examination by said board of medical examiners upon the branches usually taught in medical colleges. Said examination shall be both scientific and practical, and of sufficient severity to test the graduate's fitness to practice medicine and surgery. Said board of medical examiners shall issue a license to only such persons undergoing the examinations as may be deemed suitable to practice medicine. Said board may refuse to issue license for the following-named causes—to wit: Chronic and persistent ineptitude, criminal abortion, or gross unprofessional conduct. All licenses shall be recorded and made a matter of public record with the county clerk or the clerk of the district court in the county wherein resides the interested person. Said board of medical examiners shall be appointed by the Governor for a period not to exceed five years, the members thereof to be chosen from among the reputable practitioners of the State of not less than five years' residence."

The report was accepted, as was also the following:

"Whereas, It is of the utmost importance that the people of this country should enjoy the same advantages from the advances in *materia medica*, chemistry, and pharmacy that are possessed by the people of Europe and other favored nations; and

"Whereas, The patent laws of the United States appear to be so construed as to protect the foreign manufacturers and purveyors of chemical products and to discriminate against domestic manufacturers by creating monopolies in the supply of certain new and valuable products; therefore be it

"Resolved, That the American Medical Association hereby most respectfully petitions the courts of the United States to instruct the proper committees to investigate the subject, to take testimony of any such discrimination, to compare the legislation on this subject of the leading governments of Europe and the practical working of our own laws upon copyright, trademark, and any other protection afforded to foreign manufacturers of drugs in frequent use or to be used in the treatment of the sick, and to report such action as it may deem desirable to correct any abuses or injustice to American citizens if they find such abuse or injustice to really exist."

**The Statistics of Blindness.**—The Section in Ophthalmology offered the following resolution, which also passed the General Session :

"Resolved, That the Ophthalmological Section respectfully desires the General Assembly to authorize this Ophthalmological Section to use what influence it can command to induce the census committee of the United States for 1890 to extend the tables relative to the blind and to tabulate to the greatest extent possible the causes of blindness."

**The Address in Surgery.**—The paper of the day was an ad-

dress on general surgery by Dr. P. S. Connor, of Cincinnati. Going over the beaten path in dealing with surgery as it was, the speaker brought his subject up to date. There had been as yet but a beginning in intrathoracic surgery, and so far but few subpleural tumors had been attacked, but there was reason to believe that ere long a decided advance would be made in handling forms of thoracic disease now considered as beyond the reach of surgical art. Passing, then, from a *résumé* of what had been accomplished in the surgery of the brain and the spinal cord, he went on to speak at some length on the subject of tuberculosis and cancer of the former. We had learned that it might attack any part of the blood circulation disturbed by general enfeeblement or by even slight injury. The bacilli might be destroyed or become encapsulated, and the softened tissues be taken up or shut in. Then, if the diseased foci were completely removed, as might often be done, the part might be as if it had never been so affected. As to whether diseased joints were best treated by arthroectomy or by typical incisions or by amputations, that matter was at present *sub judice*, but there was little doubt that further knowledge on the subject of tuberculous disease would also determine such surgical measures as would tend to the amelioration and cure of one of the most important and destructive of external diseases. As to cancer, the deductions from a series of carefully prepared statistics demonstrated the fact that one in fifty of the deaths in an aggregate city population of over five millions were due to some form of this disease. The affection was becoming more common throughout the civilized world—certainly so in this country and Great Britain. No more inviting field was open to the bacteriologists and experimenters than this one of cancer. So far as practical treatment was concerned, of nothing were we more certain than of the immense advantage of speedy removal, and, on the other hand, of the utter uselessness, so far at least as ultimate result was concerned, of any interference after wide extension had taken place. In nothing could the association do more than in determining, by collective investigation, all the available facts with reference to the disease, for it was only by combined scientific and practical work that conclusions could be reached as to the causes which excited the disease and the measures best adapted for its relief or cure.

The Auditing Committee reported that there had been paid into the treasury of the association during the year ending June 26th current the sum of \$33,798, and that there had been expended the sum of \$32,825, leaving an unexpended balance of \$973.

The meeting for the ensuing year, it was voted, was to be held at Nashville, Tenn., beginning on the third Tuesday in May.

**The Association and the Railways.**—A discussion then ensued, or rather a unanimous outburst of indignation against the railroads was expressed, about the persistent manner in which the reasonable title of the association to reduced passenger rates had been hitherto ignored. While base-ball clubs, theatrical troupes, and small picnics could always secure this accommodation, the association had ignominiously failed. Measures were adopted by which it was hoped the difficulty might be overcome and the railroads properly approached on the subject. From a disinterested standpoint it appeared that the difficulty arose from uncertain engineering, and that the broth had been spoiled by a superfluity of cooks.

**Officers for the Ensuing Year.**—The Committee on Nominations reported the following officers for the ensuing year:

President, Dr. E. M. Moore, of New York; first vice-president, Dr. J. W. Jackson, of Missouri; second vice-president, Dr. W. W. Kimball, of Minnesota; third vice-president, Dr. J. H. Warren, of Massachusetts; fourth vice-president, Dr. T. B.

Evans, of Maryland; treasurer, Dr. R. J. Dunglison, of Pennsylvania; permanent secretary, Dr. W. B. Atkinson, of Pennsylvania; librarian, Dr. C. H. A. Kleinschmidt, of the District of Columbia. Dr. N. S. Davis, of Illinois, will deliver the address in general medicine; Dr. H. McGuire, of Virginia, the paper in surgery; and Dr. A. L. Carroll, of New York, the address in State medicine.

**The Progress of Medicine in the Past Half-Century** was the title of an address by Sir JAMES GRANT, M. D., of Ottawa, Canada, who was then introduced and invited to address the meeting. He said: Mr. President, Ladies and Gentlemen, I must offer you sincere thanks for the cordial invitation extended to me, not only to be present at your meeting, but to take a seat on this platform with the intelligent magi of the profession who are presiding over this great body. I am reminded of the fact that when the Marquis of Lorne was Governor of Canada the Royal Society was invited to luncheon at the Government House. When the health of the President of the United States was proposed—and I must tell you that there is no sentiment proposed in our country, next to that of Her Majesty, which is received with more warmth and genuine cordiality than that of your President—Mr. Mark Twain, who was present, was asked to respond. He thanked His Excellency for the compliment, but regretted that, being unprepared, he felt unequal to the demand. Now, gentlemen, I feel much in the same position upon being unexpectedly called to speak to this large assembly. For fully twenty-five years I have had the pleasure of attending at various times and places the meetings of your association, and it is to me a source of pride and gratification to note the evidences of progress everywhere observable in that profession to which I have the honor to belong.

As I was coming into this meeting I was told that certain gentlemen, pointed out to me, were the insane doctors. Further explanation, I am glad to say, dispelled this unpleasant suggestion, and I learned that they were merely members of the Section in Insanity who were in convention near by. While upon this subject, I may take the opportunity of drawing your attention to the fact that in no part of the domain of medicine has there been more valuable progress than in the treatment of the poor insane. Once these people were subjected to the most atrocious and barbarous usage, being treated, in fact, no better than quadrupeds. It is now, however, over forty years since the whole practice of restraint was thoroughly done away with, chiefly through the intervention of Gardner Hill, of the Lincoln Lunatic Asylum, whose name is intimately associated with this remarkable change for the better in dealing with the problem of the treatment of insanity. Now we find in the great institutions of this country for the care of this class of patients every indication that progressive development in the principles of the treatment of mental aberration is being carried into operation most successfully. The investigations by the late Dr. Gray, of Utica, whose name I mention with reverence and respect, are doubtless well known to you all. The subject of cerebral pathology attracted his closest attention, and his demonstrations by means of microscopical research did much to convey an accurate idea of cerebral structure under very diverse conditions. Strange to say, some of the most pronounced forms of insanity show no evidence of brain lesion or structural changes. Such also was the impression conveyed to me by Tuke, of Edinburgh. Under these circumstances is not the trite and laconic observation of "Punch" most apropos?—"What is matter? Never mind. What is mind? That's the matter."

Pursuing this subject further, the investigations of our physiologists within the past quarter of a century have certainly accomplished much as regards our knowledge of the nervous system. By processes of careful analytical induction such men as

Ferrier, of London, Hamilton and Seguin, of New York, and Hammond, of Washington, have been able to define the changes in, and locate the region of, disturbed centers. Disturbance of function caused by organic changes in localized centers of brain tissue become doubtless telegraphed to the periphery, and the resulting facial expression gave a clew to physiologists which, being followed up, has enabled surgeons such as Horsley, of London, Macewen, of Glasgow, and Weir, of New York, to explore the cranial cavity for the existence of cerebral tumors. You know well how these have been operated upon with marvelous success. I am gratified to see near me on this platform an ex-president of this association, Dr. Bowditch, of Boston, one of the original pioneers in the subject of tapping the chest in pleuritic effusion, and one who has worked so vigorously to convey his accurate impressions as regards the treatment of this important disease. Not alone have his observations been confined to the chest, but in the domain of preventive medicine he has also been a pioneer. It has been well said that "an ounce of prevention is better than a pound of cure," but the efforts of the medical profession in this direction prove its members to be a most disinterested class of philanthropists, who, by strenuously endeavoring to prevent the inroads of epidemic influences, thereby curtail their own means of food supply. The great public institutions—such as your churches, public halls, schools, asylums, and general buildings, your jails and hospitals—are now constructed with due appreciation of the most advanced principles of sanitation. Drainage and water supply are carefully scrutinized, and inspectors are appointed by the local authorities to see that structures in these particulars are according to legal requirement. Then, again, in the matter of food supply, investigations are equally extensive and interesting. That menstruum fluid which is so essentially the pabulum of the rising generation—milk—is known to be often the carrier of scarlet fever and diphtheria. So much is being accomplished by these investigations that I can see no tangible reason why the rising generation should not enjoy greater immunity from disease than their predecessors, who had to eke out existence without the grand principles of sanitation now enjoyed. Let me speak for a moment on the subject of what has been termed the great gymnasium of the system, the abdominal cavity, in which such remarkable surgical progress has been made. The name of Ephraim McDowell, of Kentucky, stands forth prominently associated with this progress, for he possessed the skill, the forethought, and the knowledge which enabled him to undertake the first ovariotomy. Following in his path came rapidly to the front Kimball, of Lowell, and Dunlop, of Ohio. In these three men America possesses an intellectual tripod of wonderful activity.

Their achievements are creditable to this country, and their operations are alike appreciated throughout the civilized world. Before me I see a gentleman whose name I can not refrain from mentioning—Dr. Senn, of Milwaukee, who has done so much with reference to lesions of the intestinal canal. While speaking thus eulogistically of my brethren on this side of the line, I feel confident that you reciprocate as to the influence in the same direction of thought which has been exercised by such men as Sir Spencer Wells, Thornton, Lawson Tait, and Keith, of Edinburgh. Almost every organ of the abdominal cavity has been operated on successfully, and such achievements mark, beyond a doubt, the progress of surgery during the past half-century. The exhibition in the adjoining hall gives evidence of the great advance which, within a few years, has been made in the *materia medica* in this country. This has been chiefly brought about through the instrumentality of the various pharmaceutical associations. The elixirs, the triturates, and the various materials, such as peptonoids, for assisting disturbed

digestive functions are certainly steps in the right direction. Medicinal substances are introduced into the system to combat the abnormal decay of tissue. Pain and suffering are relieved by the inhalation of toxic agents such as chloroform and ether, and we all know what has been done in this respect by our American brethren. Then again the heart's overaction is controlled by digitalis, and febrile exacerbations are reduced by reliable antipyretics. What a change, too, has come over the old *materia medica* of half a century ago! Not only are medicines administered to-day with greater accuracy and less empiricism, but nothing is now accepted or taken for granted in this field of inquiry. The why and the wherefore are scrutinized. The laboratories in pharmacology are institutions in Canada, one of which is presided over by Dr. Stewart, of McGill University, who, with Shoemaker, of Philadelphia, is actively engaged upon analytical research into the action of therapeutic agents and the processes by which practical remedial results are brought about. While traveling from Boston here yesterday I was reading an address delivered to the Law Society by the Hon. Chauncey M. Depew. From it I learned the remarkable fact that of the twenty-three presidents of the United States, eighteen had been members of the legal profession, and that during eighty-two years of the past century the presidential chair had been occupied by members of the legal fraternity. It seems to me, gentlemen, that the profession of medicine in the United States does not take a very deep or abiding interest in the affairs of state; otherwise more of its members would be represented and thus enabled to guard over our best interests. In the Commons of Canada there are at least fifteen or twenty medical men, irrespective of those in the Senate. In our British High Commission there is also an able medical man whose knowledge in this particular enabled him to direct the authorities with reference to the condition of cattle sent from Canada to England, saving to the Dominion a trade worth several millions annually. Through the members of the medical profession we have acquired a bill in the local legislature of Ontario for the establishment of medical education and registration. That council, with which I have been identified since its inception, over twenty years ago, appoints annually its own examiners irrespective of the teaching bodies. It exacts a high standard of preliminary education, and also a curriculum of medical study equal to those of the best British or American institutions. Through this portal our students must pass before they can be admitted to registration. Thus we guard the best interests of the profession in our country. I was pleased with the resolution from your association presented this morning embracing the idea of advance not only in the principles of preliminary education, but also as concerns the various branches of medical education. With the hundreds now teeming from the numerous universities, and the field of practice being overstocked, it is necessary that as high a standard of excellence as possible should be brought about. Around me to-day I find many of the junior members of our profession. For the benefit of these I would refer to an anecdote told of a young doctor hailing from away West. He was visiting the Parisian hospitals, and, meeting one of the leading professors, was interrogated as to where he came from. "Don't you know my preceptor, sir?" answered the Westerner, naming his State. "No, I do not," said the professor; "what has he written?" "Well, he has not written anything, sir, but he has a *very large practice* down there." Now, to our young men I would say, Keep your notebooks, report your facts, record your observations day by day. In this way you will in time not only be able to assist the medical journalism of the country, but to add to that literature of the profession which has so much enhanced the reputation of

this republic. Just reflect on the intellectual activity of such men as Gross, Dunglison, and Biggs; of Van Buren, Gurdon Buck, and Markoe; of Mott, Hamilton, Brainard, and Jewell; of White, of Buffalo, and Bigelow, of Boston, and then on the men who are leading the literature in diseases of women, such as Thomas and Emmet, Goodell and Storer, and other lights too numerous to mention, but whose names are household words with us in Canada. Are not these electric lights in their way radiating an influence for good of a most remarkable character? We on our side of the line, though separated by imaginary chains, feel that in our profession we are united. We are with you in all this achievement of progress and in appreciating the same influences which have prompted you to the accomplishment of so much good. I feel, gentlemen, that I can not better express what I mean than by referring to the message sent over the first completed cable between here and the old country by Queen Victoria: "What God hath joined together let no man put asunder." We are one people; we enjoy the same liberties, civil and religious; we speak the same language; we take our inspirations from the same fountains of science in all that pertains to the best interests of our profession. Therefore I think I can do better than quote, in conclusion, the expressive lines by your gifted poet who now slumbers with the illustrious dead of this great republic:

Let us, then, be up and doing,  
With a heart for any fate;  
Still achieving, still pursuing,  
Learn to labor and to wait.

The address was frequently interrupted by expressions of gratification by the meeting, and at its close the speaker was awarded round after round of applause.

In the evening a concert and a reception were given by the Newport profession at the Ocean House.

**The Address in State Medicine.**—The General Session met on Friday at 10 A. M. to listen to an address by Dr. WILLIAM H. WELCH, of Baltimore, on State medicine. Dr. Welch delivered what was really an exhaustive survey of the bacteriological deductions up to the present time. He concluded by warning his hearers to avoid the acceptance of exclusive dogmas or hypotheses as to the exact processes by which pernicious bacteriological agencies might make themselves actively infectious. It was not by sanitary prophylactic measures in one particular direction or another that we could hope to control the prevalence of disease, but by securing sanitary arrangements as far as possible perfect in every particular.

By resolution, the sympathy of the association was expressed for such members of the profession as had been sufferers by the Johnstown calamity, and their dues were ordered to be remitted for the year. Votes of thanks were then passed to all those who had in any way contributed to the well-being or enjoyment of the association in Newport. A special vote of thanks was proposed by Dr. Pancoast, of Pennsylvania, to Sir James Grant.

A deputation was instructed to introduce the new president, Dr. E. M. Moore, but urgent business had called him home.

The proceedings then formally closed.

In the afternoon there was an excursion upon Narragansett Bay.

#### NEW YORK ACADEMY OF MEDICINE.

*Meeting of May 2, 1889.*

The President, Dr. ALFRED L. LOOMIS, in the Chair.

**Discussion on Phthisis Pulmonalis.**—Dr. W. B. JAMES read a paper on "The Relation of the Tubercle Bacillus to its Etiology." He concluded that Koch's results had been com-

pletely confirmed by investigations made in the seven years since they had been published. The tubercle bacillus must be present in phthisis pulmonalis and as a focus in all the other tubercular inflammations, although the greatest variety of inflammations of other sorts (still further modified by differences in the various tissues composing the body) might arise secondarily. In the lung the essential factor was always the presence of the tubercle bacillus.

He would next consider the question whether the bacilli acted alone, or whether other factors were needed in conjunction, in order that, once inoculated, they might grow. It had been noticed that some individuals were affected by such an infection very differently from others, and also that the same person would not be affected in the same way at different times. A change of climate made at the beginning of a phthisical process often caused its suspension. If rabbits were inoculated with tubercular virus, and some of them were then confined in cellars and others ran free, the latter would more or less escape the disease, while the former died of it. Autopsies made on the bodies of those dying from various other causes in the New York Hospital had shown that in half of these bodies there were areas which had once been the seat of tubercular inflammation. Such observations furnished the best reply which could now be made to the question under consideration.

There was no doubt that bronchial catarrh and pleurisy favored the implantation of the virus in the lung. On the other hand, it was certain that in many cases pleurisy and bronchial catarrh were secondary to a tubercular focus so small or so hidden away (as in the bronchial glands) that it was unrecognizable during life, if no further development of the infection occurred. It had been shown that tubercular infection occurred more readily in parts whose vitality had been impaired by local injuries of any sort, but there was no doubt that the virus could be introduced and grow in perfectly sound tissue. The number of the germs introduced, and their malignancy or virility, also had much to do with the result in the body. The number and distribution of the lymphatics and their relation to the site of first infection might also determine in large measure whether the bacilli were conveyed to the bronchial glands or the lymph nodes, or were left to grow in the walls of the air vesicles. But, in conclusion, he would repeat that the only always-essential factor was the tubercle bacillus.

Dr. J. W. ROOSEVELT read a paper on "The Relation of the Tubercle Bacillus to the Early Diagnosis and Prognosis of Phthisis." The question resolved itself into this rather: What value was to be attached to the discovery of tubercle bacilli in the sputum of patients as a means of making an early diagnosis of phthisis? We were often confronted with a problem such as that in the following case: A young man is engaged in a business of such a nature that, in order to either advance or even hold his own, he must give it all his time and an unremitting attention. He works hard; after a time he runs down, and begins to lose sleep; he has little appetite, and coughs most of the time. He consults a physician as to whether or not he has the beginning stage of phthisis. If the answer is in the affirmative and a change of climate is advised, the young man's business is ruined, but his life is saved—in case the diagnosis is a correct one. A mistake in diagnosis might unnecessarily sacrifice either his business or his life. Now, the question arose at that point whether the presence or absence of bacilli in the sputum would be positive evidence in favor of or against the existence of phthisis. This question could be answered decidedly in the negative as regarded the latter half of the question. If no bacilli were found we could not say that the young man might not have phthisis. To establish that, not only must the sputum be found free of bacilli in many successive tests, but the exami-

nation of the chest, the family history, etc., must also give negative evidence. Often, in a phthisical patient, no deposit of tubercle was situated so as to have any direct or open connection with the air passages. These deposits might be extensive and yet no bacilli appear in the sputa. Again, the bronchial discharges might be so profuse that, like the needle in the haystack, the bacilli could not be found. In advising patients we must not wait to find the tubercle bacillus, or the opportunity of saving life might be neglected till it had passed by.

Phthisis was a complex disease in which several varying factors of causation were present, and in which the pathological results were numerous and much diversified. A common form in New York was one in which the only pathological elements were a deposit of tubercles which gave rise to some pleurisy and some bronchitis. In this form of the disease there was little tendency to the breaking down of pulmonary tissue, and no consolidation could be detected. Thus the physical signs were of no value, even when the disease was far advanced. In these same cases the detection of the tubercle bacillus was commonly impossible early in the disease, when such a discovery would be of most value. In such cases all the physical signs, the history of the patient's family, and careful observations on the course of his symptoms must be taken into account in arriving at a probable diagnosis.

As to the prognostic value of the presence or numbers of bacilli in the sputa, as related to the upward or downward course of the disease, it could be said with emphasis that there was no such value to be considered. On the contrary, it was a great and common mistake to regard the discharge of bacilli increasing, diminishing, ceasing, or absent as a test which would determine whether or not the patient was likely to recover. Manifestly the progress of the disease in the lung and other areas of tissue in the body, near or remote, could not be materially affected by the discharge or the retention of purulent matter containing a few of the many millions of bacteria. And yet the whole antiseptic treatment of the disease was based, apparently, on this idea, and had led to the dosing of these patients with active poisons. We often heard that, under such and such a form of treatment, by inhalations of germ-destroying vapors the "cough diminished, the temperature moderated, the night sweats became less frequent, and the number of bacilli in the sputa became diminished." In a completed history it usually needed to be added to this shortly that the patient presently died. As long as the complex body cell was easier to kill than the simply organized tubercle bacillus, it was idle to put antiseptic drugs into the body in the hope of killing the latter only. A much better and more reasonable plan was to feed the phagocytes. As yet, certainly, there was no specific bacillary poison known. His conclusion, then, was that the discovery of the bacilli was a matter having great positive but no negative value in arriving at a diagnosis, and little value in prognosis.

Dr. JAMES TYSON, of Philadelphia, present by invitation, spoke of the proofs afforded of the bacillary origin of phthisis. The conditions to be fulfilled were as follows: A vegetable organism must be found in the blood and tissues; it must be capable of being removed in a state of absolute purity from the blood and tissues, and, if reintroduced in a state of purity into the blood of an animal susceptible to the disease, must be afterward obtainable from its blood. All these conditions had been met, and the proofs substantiated by the modern culture method. Some interesting corollaries were deduced from this demonstration; thus we must consider it an inevitable conclusion that phthisis was contagious. At the same time every one would admit that it was but slightly so, and that the records furnished comparatively few cases of this sort. For the reason

of this we must look to the mode of action of the tubercle bacillus; it acted as an infecting agent when inhaled with minute particles of dried sputum, and carried in sufficient amount into tissues not capable of resisting it. Like typhoid, it was not easily contagious, because the germs must enter the mouth and pulmonary passages, just as it was necessary that the typhoidal virus should reach the intestines. The experiments of Cournet, who produced tuberculosis in susceptible animals by culture fluids derived from the sponge scrapings of the walls of rooms in which tuberculous patients had been confined and failed to produce it in other rooms where the walls had been scraped, had furnished positive evidence in this direction. A well-known factor determining the malignancy of the disease was the crowding of people in confined quarters; we had a fourfold mortality in prisons and a double mortality in manufactories, as compared with ordinary habitations. Flick, of Philadelphia, having had all the houses in a ward under observation for twenty-five years, had found that those in which tuberculosis occurred were usually (in 90 per cent.) not isolated from other houses, but adjoined houses in which tuberculosis had occurred; and that in 33 per cent. of the houses in which it did occur there was more than one case. A second corollary, founded on the same evidence, was that tuberculosis must be communicable by the taking of food containing its bacilli; and facts had long been accumulating to show that such was the case. Gurley had found that young animals fed on the milk of tuberculous cows developed tubercular affections often enough to show that here was a possible avenue of infection. Bang and others had demonstrated bacilli in the milk of cows having tubercular mammitis. In Cornil's report to the Paris congress he had shown that cultivations of the bacillus put into the lumen of the intestinal canal soon reached the glands of the mesentery. Still, it was a curious fact that there were few well-proved cases of harm sustained by human beings in this way. It was, however, well established that the swallowing of sputum by phthisical patients had often been followed shortly by the diarrhoea and emaciation of intestinal tuberculosis, which was perhaps always brought about in this way. Fowls that had eaten the expectoration of phthisical patients had been found to have tuberculosis of the intestines and liver.

As to the congenital or post-genital inheritance of phthisis, where the former occurred, it must be through the placenta that the actual germs reached a foetus whose tissues already furnished a soil favorable to their growth. The view that the ovum might take up bacilli at the time of its impregnation was purely speculative.

Dr. H. M. Biggs remarked that there was little to be said in regard to the relation of the tubercle bacillus to phthisis, as there was so little doubt that this relation was a causative one. It seemed to him that we had absolute proof of the nature of this relation. Indeed, there was no fact in medicine, except, possibly, the relation of the anthrax bacillus to splenic fever, which was better proved. The profession could not too soon surrender the even now quite generally accepted views as to the causation of phthisis. The tubercle bacillus was the cause, and the only cause, of tuberculosis. This was the fact of prime importance and should be brought out in sharp relief.

Undoubtedly there were other factors that had some influence in the causation of the disease, but the only essential one was the introduction of the tubercle bacilli. A reduction in the tissue resistance, so that the dose of bacilli needed to start the process was diminished, he considered as the factor second in importance. A large enough dose of bacilli, however, would always and in any person produce the disease without the action of any other agencies.

Heredity in phthisis meant to him not the transfer from par-

ent to child of the actual bacilli, or even of a predisposition or special susceptibility to the disease, but the transmission of organs and tissues that had little resisting power, and easily succumbed when exposed to active noxious influences of any kind, one of which was the tubercle bacillus. A study of the principles of evolution had shown that in heredity there was really a remarkable tendency toward the transmission from parent to offspring, not of disease, but of the best in everything which could be given by the parent body. Only a negative condition—that is, the relative absence of strength—might necessarily be transmitted by feeble parents, even if the best possible was given.

The speaker concluded that the disease was distinctly a contagious and preventable one, and that it was a matter of the greatest moment for the coming generation that intelligent and decided action should be taken for the systematic destruction of the sputa of all phthisical patients, since by this means could be secured the restriction if not the eradication of the disease. We had as good reason for taking such measures as for stopping the spread of scarlet fever and small-pox by quarantine arrangements. It was impossible to speak too strongly on the subject. The sputa of tuberculous patients must be destroyed or safely disposed of, and tuberculous animals must be killed.

Both the profession and the laity needed to be educated into a knowledge and practical recognition of the fact that the germs in tubercular sputum could not multiply outside of the human or animal body, and that when the disease occurred it was due to direct transmission from some other human or animal body affected with it. The speaker closed with a strong plea in favor of a more general, full, and sharp recognition of the fact that the tubercle bacillus was the only cause of phthisis, from a strictly pathological point of view, and that the disease was chiefly produced by inhaling dried and pulverized tubercular sputum suspended in the air as dust.

Dr. H. P. Loomis asked whether there might not be a second primary factor in the causation of the disease—what might be called a pre-bacillary state of the constitution. How much this state consisted in lowered vitality, and how much in other unknown vices in the constitutional or vital make-up, we were not yet in a position to decide. We knew that a condition in which, clinically, the liability to phthisis was notable was sometimes hereditary, or, again, due to vices or habits of living, to alcohol, or to senile parentage. But we did not know why, of all those having such ancestry or vices, or who lived in adjacent dwellings under conditions equally bad, some contracted phthisis and died of it, and some did not contract it. The problem resembled that respecting the reason why mental strain produced insanity in a certain limited class, while in those not included in that class no tendency to the development of insanity appeared after mental strain, though the greatest variety of other mischiefs might be given rise to.

In regard to the number of those in whom phthisis came to an end without getting more than a foothold, as shown by autopsies after deaths from other causes, he would say that sixty per cent. of all bodies showed in some tissue the changes pointing to the presence there in the past of a tubercular inflammation.

Dr. E. L. Trudeau, of Saranac Lake, present by invitation, showed specimens illustrating the growth of tubercle bacilli in great numbers on sections of a potato, and the effects of the inoculation of the lungs of rabbits with tubercular virus after thirty-six days. Inoculations of the virus in animals had been found to produce the most different sorts of tubercular inflammation, according to the site of the injection of the virus, its amount, and the conditions of living to which the animal was afterward subjected. A large dose being put into the vein of

the ear of a rabbit, general tuberculosis of the liver, spleen, and joints, as well as the lungs, had at once followed. A very small dose being put into the apex of one lung and the creature being kept outdoors, a phthisis of a chronic sort followed, in which the fibrous elements greatly predominated, the other viscera escaping entirely.

Dr. W. H. THOMSON read a paper on the influence of the microbe theory on treatment, opening with a review of the different antiseptic methods of treating phthisis which had been tried and abandoned within recent years, and always because they failed to make any difference in the final outcome of the disease. Among the remedies spoken of in this connection were sodium benzoate, salicin, iodoform, tannin, and bichloride of mercury given internally; iodoform and allied drugs used as an injection for cold abscesses; sulphureted hydrogen enemata, inhalations of hydrochloric acid, and the use of creasote, tannin, and menthol. Experiments on animals, made in Germany, in which maximum doses of each of the eight best-recommended antiseptics had been given to animals already inoculated with tubercular virus, and without altering in any way the progress of the disease, warranted our dismissing all expectation of destroying the bacilli in living patients in this way. Even half a pint daily of a one-to-one-thousand solution of corrosive sublimate injected into the tissues of a tuberculous guinea-pig had failed to check the course of the disease. Experiments made to ascertain the effects of extreme altitudes on tuberculous animals had also yielded negative results. The speaker had never seen a case of small-pox, scarlet fever, or measles shortened in its course a single day by the use of an antiseptic or any other drug. An entirely similar question to him would be that of whether a field of potatoes could be so treated with a chemical agent that the weeds should be killed, but not the potatoes. He did not see how we could so change the common pabulum that the vegetable but not the weed, the body-cell but not the parasite, should thrive in it. Indeed, he had never hoped that we could kill the bacilli of disease safely.

It might be asked whether he had hopes of any practical result whatever arising from Koch's discoveries. He would answer that one such was already known. He referred to our knowledge of the apparent independence of successive bacterial growths of different sorts on each other. It was not often suggested by writers on these diseases that other bacteria than those called the specific ones took a part in the process. And yet it was, as a fact, a rare thing to find a single variety of bacteria acting alone. In the putrefaction of meat a series of thirteen different sorts of bacteria were required, one set appearing and carrying the process to a certain point, and there giving place to a new species, which carried it through the next successive stage. It had been found that the *Streptococcus pyogenes aureus* was the most widely active infecting agent known; in fact, it was somewhere present in most infectious diseases when suppuration occurred; thus in erysipelas, puerperal fever, diphtheria, suppurative synovitis occurring with endocarditis in scarlet fever or pneumonia, and also in typhoid fever when suppurative collections of matter formed. Might it not be thought probable that work done by this bacillus prepared the way, in many cases, for the growth of the tubercle bacillus? It was well known that the rapidity of the advance of phthisis bore a close relation to the amount of suppuration going on. Accordingly, it became an object of importance to prevent the initiation of a suppurative process, and to either remove or prevent the decomposition of pus formations. The caustic or corrosive action of pus on the living tissues was well known. In such cases creasote might be of real value by checking the suppurative process. In many cases in which he had employed it he had either greatly prolonged life or effected a cure. Most

of the success he had met with in the treatment of phthisis had been achieved by the use of creasote.

It was perhaps possible to bring about a limitation of the process by bringing up the resistance of the tissues to the point which obtained in the great majority of people, and an effort was always to be made most faithfully in this direction by every possible improvement in the patient's mode of life.

In conclusion, the speaker described two strongly contrasted types in the physiognomy of people who were born with a liability to phthisis on the one hand and chronic bronchitis on the other, and which appeared before the disease had begun in either case.

The inference to be drawn from this was that such constitutions should be recognized and their powers of resistance increased before the invasion of the bacilli had begun.

Dr. L. WALDSTEIN related two clinical histories which enforced Dr. Roosevelt's conclusions as to the aid in diagnosis and prognosis to be looked for from an examination of the sputa for bacilli.

Dr. B. F. WESTBROOK, of Brooklyn, thought that several of those preceding him who had emphasized the importance of the bacilli in the aetiology of the disease had overstated the case. He could not agree with Dr. Biggs in making the tubercle bacillus so conspicuous among the factors of the causation of phthisis. He believed that there were others more important. Causation in the organic world was a very complex matter, as had been pointed out by Aristotle two thousand years ago. While, according to present knowledge, the bacillus might be the only directly exciting cause by which phthisis was originated, it was far from being the only factor in that result. Moreover, it was one which could not well be excluded, while some of the others might be, if once thoroughly investigated. In regard to the matter of positive diagnosis by the discovery of bacilli in the sputa, he thought the facts had been somewhat overstated. He had never met with a case of ordinary phthisis in which bacilli were expectorated where a physical examination and the history of the case would not give the diagnosis independently. Still there were cases of pleurisy where suspicious râles were heard at the apex of the affected lung, and the question arose whether primary pulmonary phthisis or pleuritic tuberculosis was present. Here an examination of the sputa might exclude the latter disease if bacilli were found. Emphysema also sometimes gave a crackling at the apex of the lung not distinguishable from that of tuberculosis. Here, too, an examination of the sputa might be of value in diagnosis, both positively and negatively.

With regard to the value of the bacilli in prognosis, if he had a case of pulmonary disease presenting signs of consolidation and excavation, fetid breath and copious expectoration, and if he found no bacilli in the sputa, he would conclude that the case was one of interstitial pneumonia and that the prognosis was good; if at any time bacilli and fever appeared, he would consider it a bad sign. He thought treatment based on the fact that a bacillus had been discovered had been pernicious on the whole. Antiseptics had their only value in the relief of fetid bronchitis, in cleansing cavities, and in clearing out the air passages. To fortify the constitution of the patient that he might withstand the disease was the essential thing.

Dr. F. P. KINNICKUT agreed with the views expressed by Dr. Roosevelt and Dr. Thomson as to the real utility of the germicides. Their use, and it was a very distinct one, was to render the diseased surfaces aseptic, to aid in the removal of the secretions, and to prevent fermentation and catarrhal disorders in the alimentary canal. Some of them also had a stimulating effect on the nutritive process, and he thought that the value of creosin lay in this direction mainly. Controlling little details in the

daily life of the patient was the really efficient plan of treatment, as shown by the comparative number of the recoveries so obtained.

#### MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Meeting of April 22, 1889.*

The President, Dr. ALEXANDER S. HUNTER, in the Chair.

**The Treatment of Acne without Arsenic, Sulphur, Ointments, or Lotions.**—Dr. G. H. Fox read a short paper with this title. He did not object to the employment of these remedies, but he wished to make clear that their value was a very limited one, and did not entitle them to forming a routine treatment. A few cases of acne could be relieved by local measures alone, but, in the majority of cases, general treatment of the patient himself, and not of his skin alone, must be combined with these. In this general treatment, medicines might play an important part in certain cases, but it was still far from being generally recognized that diet, exercise, and other hygienic observances were of more account in getting lasting improvement in acne than all drugs put together.

In deciding on treatment it was convenient to recognize two forms or stages of the disease, the irritable and the indolent, as long recognized in the treatment of ulcers. The irritable form was largely reflex in origin, and due to disturbances of menstruation and of digestion. Here usually the skin of the face flushed easily, was fine and soft, and readily became inflamed under stimulating agencies. A watch-key used to press out comedones was apt to raise a red spot. Here all local treatment, except of the most soothing character, was contra-indicated, and constitutional treatment was mainly to be relied on. In the indolent form, vascular excitability was not present, and glandular obstruction was the prominent feature in the condition. The skin was apt to be coarse and doughy. Minute white nodules of sebaceous matter were constantly forming and being retained in the skin, with a termination in inflammation, papules, pustules, or abscesses where the constitution was strumous. Now, the indolent form of the disease demanded vigorous local treatment, and especially a thorough cleansing of the skin. This could not be accomplished by washing with soap, by lotions, or by ointments, but by mechanical evacuation of the engorged glands.

In the first of these two clinical forms of the disease, physicians had for years relied mainly upon arsenic for treatment, and often to the exclusion of other measures entirely. Of this practice he would remark that he believed that if arsenic should be banished from the globe the general practitioner would meet with better success than now in the treatment of acne and allied affections. Another drug which had been extensively used, and with better results than arsenic, was sulphide of calcium. It was often certainly of some value, in cases where there existed a pyogenic tendency, and small doses gave the best results always. But in most cases it was without effect; its virtues had been much overestimated, and its employment was apt to divert the attention of both physician and patient from more important measures.

The value of ergot had not been duly recognized. This drug was of some service in the indolent form of acne. By acting on the muscular fibers about the sebaceous glands and causing an evaenuation of their contents, or else by lessening the caliber of the blood-vessels supplying the glands, it seemed to be of benefit in these cases. However, he knew that it was without effect in the hyperæmic form of acne. Here lotions were of some but only of slight value, in his experience. Too often they were the sole remedy used. After years of experimentation with the best prescriptions in this line which he had read of or could devise, he now seldom used a lotion at all. The line of treatment that

had, in his hands, been followed by the best results was neither new nor original, and consisted of two things, diet and local massage. Of these, diet was the more important, and he wished to lay stress on this, for, while all physicians would freely admit the value of regulating the diet, few enforced such regulation. In other words, but few recognized that to control the diet was to strike at the root of the matter. The irritable form of acne might be associated with disordered menstruation or other genito-urinary troubles in either sex, but most of the cases would be found due to bad digestion. Local massage could be applied by the fingers or by instruments adapted to the purpose. Its objects were to empty the glands and to cause the disappearance of inflamed lesions. It should leave the skin smoother, softer, and paler. It consisted in pinchings and firm rotary pressures with the finger tips. Its employment must be persisted in faithfully. A gentler and more agreeable way of emptying the glands was by a large circular curette such as the gynaecologists used. Its use had been approved by authorities both abroad and in America, yet was not general. It gave the best results with the least pain. The redness left soon disappeared. While the measures thus far mentioned were usually the only ones required, it remained for him to say, in conclusion, that no fixed plan of treatneut would be found to suit all cases.

**Psoriasis and its Treatment.**—Dr. L. DUNCAN BULKLEY, in a paper devoted to this subject, embodied his clinical studies and analyses of two hundred and sixty-four cases of psoriasis which had been under his care in the past twenty years. Being so common and persistent a disease, it merited careful study. Its cause was almost unknown. It should not be confounded with eczema or scaly papular syphiloderma. It appeared mostly on the body, rarely on the palms or soles. He had never met with it on the tongue. It was less common among the poorer classes. It seemed to exist more in climates where the moisture was great and severe changes of temperature were common, but not in malarious regions. It was common in New York, Boston, Chicago, and Toronto; less so in Baltimore and St. Louis. It varied in different years. His statistics with respect to the ages at which it appeared agreed with those of standard writers. In 81 per cent. of his cases the disease had manifested itself before the thirty-first year, and in only 7 per cent. after the fortieth. Between the ages of ten and fifteen it appeared twice as often in females, but with double the frequency in males between the ages of fifteen and twenty-five. Few of his cases had come under his care at the beginning of the affection; on the contrary, it had usually existed for from five or ten up to forty and fifty years, and this was important, since the longer the duration the harder to effect a cure. Still, even where no cure was possible, the eruption could often be held in check for long periods of time. The disease had no tendency to self-limitation, but its severity could be greatly modified, often by medicines used persistently, by correct diet, baths and general hygiene, and by certain climatic influences of the nature of which little was known. Still there were some cases which remained intractable even under the best treatment. On the whole, psoriasis was one of the most rebellious of all the diseases appearing on the skin. Success in treatment depended on the age of the patient, the date of beginning treatment, and persistency in continuing it. The disease was most curable in children, very rebellious between the ages of twenty and twenty-five, but often curable in later years, especially if associated with gout or rheumatism, with which it had several points in common. Excessive meat-eating and the use of stimulants often precipitated an attack. Oils and fats in the diet, if digested, clothing adapted to prevent chilling of the surface (pure woolen next to the skin), and a warm and equable climate were important factors in treatment. As to internal medication, arsenic was one of the most

efficacious remedies. Alkalies were often of benefit, and were best given in the form of the acetate of potassium, lithium, or calcinm. Iron and cod-liver oil were useful. Local applications used early might prevent in large measure the development of the eruption. The use of chrysophanic acid and chrysarobin he had abandoned. The white-precipitate ointment he had found more useful than any other application of this sort. Visits to mineral springs reputed to cure psoriasis led only to disappointment. He had had his patients try a large number of them. He did not know of a single cure effected by sulphur waters, though the reputation of such waters was the highest of any. The curable cases could be found only by trial, and that of the most patient and faithful sort.

Dr. R. W. TAYLOR opened the discussion of the two papers. The iconoclastic spirit of the first he thought justifiable, and, as it led at the same time to a building up with better material than it destroyed, commendable. For the purposes of discussion, its distinction between an irritable and an indolent form of acne was clever and convenient. The author's want of faith in the efficacy of arsenic was well founded in the main, though it must be said that arsenic did good in some cases. The disease showed itself under so many different forms, in so many different skins, and from such varying causes, that it was hard to generalize in a short paper as to proper treatment. Not enough attention had been given to a possible microbic origin for some forms of acne. Where that could be proved, it would be irrational to treat follicles containing pus resulting from an infection from without by an internal remedy, such as sulphide of calcium, which was supposed to act as an absorbent or disorganizer of pus. Ergot sometimes did good and again did not, or else disordered the health of the patient. The curette and massage (any one of a number of different sorts would answer) were the reliable remedial agents. Pressure in itself acted beneficially. Tubs due to cell exudation and without much epithelial growth could be made to disappear by pressure, and just so acne pimples. The curette was good in itself, and also prepared the way for other agents. Lotions, ointments, and powders should not meet with wholesale condemnation.

In regard to Dr. Bulkley's paper, it was difficult to criticise it; it followed the traditional lines of the text-books and dealt with statistics largely, any inferences drawn from which he regarded as highly untrustworthy. The most important point related to the curability of the disease, and that this was greater the earlier it was attempted he had himself taught for years. He had never been able to decide that there was a diathesis behind psoriasis. There were no proofs of its having a connection with rheumatism, or of its being due to dram-drinking, etc. The most we could say was that the disease represented a bad habit in the skin, and that, the latter being very closely connected with the functions of the body and exposed to weather, clothing, etc., great variety in the course and severity of the disease resulted. Its heredity was admitted by leading dermatologists; it commonly appeared in the children with a certainty proportionate to its intensity in the parents.

Dr. H. G. PIFFARD said he could agree with Dr. Fox in his generalizations, but not in regard to particulars. Thus, Dr. Fox made acne due to gastric rather than genital troubles, and he (the speaker) believed just the reverse was true. He believed it a disease which might be either of internal or of parasitic or bacterial origin. He did not think we knew anything as to the mode of action of ergot, but he had observed that the severer the case the more likely was ergot to act favorably. By regulating conditions in the uterus it might stop a reflex irritation beginning there. He had used sulphide of calcium, but in as large doses as the stomach would bear—a fourth or a half of a grain. He used it in the indolent form of the disease, and gave

it till the skin was enlivened and the lesion took on an active state, aiding in this result by gymnastics, scrubbing, etc. Evacuation of the pustules it was always well to accomplish, but he had found that the wound made by a slender lancet healed more quickly than that following the use of a curette.

The genital origin of the disease he had seen illustrated in many of his cases. As Denslow had pointed out, urethral irritation from a stricture near the meatus or phimosis frequently gave rise to acne in young males; he always made an examination of the genitals in males, and especially looked for evidences of gonorrhœa or masturbation.

With regard to Dr. Bulkley's treatment in psoriasis, he was surprised to hear that he had abandoned the use of chrysarobin. In his experience it had caused the eruption to disappear more quickly than any other topical agent. Its use involved some pain and staining of the clothes, but was justified by the result gained. Arsenic he used in full doses for long periods.

Dr. C. W. ALLEN had often seen decided benefit from the use of sulphide of calcium in acne, given in doses as small as the twentieth of a grain every two hours or oftener. He had noticed that ergot more commonly relieved acne in women than in men. He believed it useless to treat an acne due to uterine disorder otherwise than by attention to the latter trouble. In men he had applied ergot externally, the fluid extract or a combination with collodion, and with apparent good effect. As one papule helped to induce others, it was important to keep them empty from the first, if possible. He thought highly of the external mechanical treatment of acne. He preferred the comedo extractor of Auspitz as modified by Dr. Piffard to any form of puncturing. The entrance of micro-organisms into the acne pustule was probably the cause of the diffused induration so often appearing, in time, and this infection spread, if left alone, to other papules. This would indicate the necessity of an early evacuation of the obstructed glands, and the value of antiparasitics used externally.

As to psoriasis, he believed it hereditary. He had found no reason for abandoning either anthrrobin, pyrogallol, or chrysarobin, but used more of the latter. If mixed with collodion or liquid gutta-percha, its disagreeable effects could be avoided, and in combination with salicylic acid it was especially beneficial, as the skin was softened at the same time that the infiltrated parts were acted on.

Dr. E. B. BRONSON, speaking of the causes and treatment of acne, laid great stress on the important relations of sexual disturbances in the aetiology of the disease. He had found sexual hygiene, a thing commonly best secured by wedlock, of the utmost value in improving the complexions of these patients. He considered acne as a developmental disease. As the beard began to grow, an erythema in the sebaceous glands was developed not unlike the increased activity in the hair bulbs, both glands and hair follicles seeming to have an intimate connection with the sexual system. With digestive disturbances he had found rosacea more commonly developed. As to removing comedones, there were many cases in which it was better to leave them untouched, if they were at all hard to extract, until their removal became easy, lest an increased inflammation be set up. Sulphur he considered an important remedy in the right cases; the amount of suppuration determined the good to be obtained from its use (as a germicide). In acne indurata, operative treatment was that most needed. It was not always recognized that any acne tubercle which blanched on pressure contained gummy or cheesy matter, a surprising amount of which could often be scooped out.

In psoriasis he had found chrysarobin to be of much more value than the mercurial ointments or tar of the old-time treatment. Anthrrobin came next, and was sometimes of equal

value. It did not inflame the skin, and so was indicated in cases complicated by eczema, or in which for any reason chrysarobin could not be borne.

Dr. SHERWELL, of Brooklyn, agreed with Dr. Bronson that acne was a developmental disease, and almost entirely of internal causation. Especially close was the aetiological connection of troubles situated somewhere in the pelvis, constipation, and uterine or any other genito-urinary disorders. Where urethral engorgement or stricture had been found, he and others had repeatedly cured acne by the passage of cold sounds. With regard to psoriasis, he regarded it as arising commonly, in some way, from non-oxidation in the tissue changes—what might be called sootiness in the flues; also from rheumatism and uncleanliness of living, the disturbance due to which acted on a limited pathological area. He agreed with Dr. Bronson as to the value and employment of chrysarobin and anthrarobin.

Dr. WILLIAM H. THOMSON, speaking from the standpoint of a general practitioner, said that for many years he had been accustomed, when consulted for the relief of acne, to examine the genitals in both sexes. He also looked into the state of the digestive apparatus. It was very essential to remember that troubles in this region were commonly associated with and often due to genital disorders. But for the more immediate causation of acne, he now looked to a self-infection by alkaloidal substances arising from intestinal fermentation. There was no one cause for acne. Fermentation of food was in his opinion as active a one as genito-urinary trouble. Acne often occurred in chlorosis and in affections of the liver or pancreas. He had cured acne in several instances recently by giving benzoate of sodium, naphthol, and salol in combination. In psoriasis he got the best results from liquor potassæ in large doses, together with cinchona. He believed the disease hereditary, having repeatedly seen it appearing in three successive generations. He had been surprised at hearing different speakers call attention to an infection by microbes as one factor in the aetiology of acne pustules, as if on that account their origin was local. Was any fact better known than that the soil presented to a micro-organism was the leading factor, and not the advent of the microbe? Most suppurative skin diseases were microbial, but that which determined the soil for their growth in the skin lesion must chiefly concern the physician. However, our local applications and the use of curette or needle were of service temporarily by disposing of the microbes already growing. The mode in which ergot acted was not yet determined.

Dr. CRANMER thought the facts brought out by the discussion not essentially different from those recognized thirty years ago. Dr. Bronson had given the more important fact, in his opinion. Married life would terminate most cases of acne. Dr. Thomson's line of treatment he thought next in value. He himself used alkalies also, and the old-fashioned but efficacious decoctum aloes. Sometimes two Turkish baths a week were all that were required for a cure.

Dr. BULKLEY thought the lesson taught in the evening's discussion was that there was no one line of routine treatment in skin affections. All the methods spoken of had their value in suitable cases. He was thankful to Dr. Thomson for bringing out the fact that the origin of acne was not altogether in pelvic conditions. He himself had come to regard the digestive much rather than the genito-urinary system as the point of origin for the disturbance. He had cured many cases by attention to the chylopoietic system only. He had met with severe and obstinate acne in a number of married people with large families. Irritation of the surface in acne, as by the curette or a rough shave, had of itself an unquestionable value. For extracting comedones he used a minute cataract knife, and an extractor much like a watch-key. As to heredity in psoriasis, his records

showed two hundred and eighty-six cases where it had occurred in one member of a family, but not in the brothers or sisters, and but forty-one in which the reverse had obtained.

## Miscellany.

**Plants and their Alkaloids.**—In the "Bulletin médical" for May 8th, Dr. S. A. Nitard remarks that, in an important paper recently read at the Paris Academy of Medicine, Professor Germain Séé very correctly stated that in therapeutics alkaloids and the plants from which they were derived should not be confounded. These remarks were made in regard to strophanthus and strophanthine, but the author pointed out that they might be equally well applied to a number of alkaloids and plants used daily in practice. In fact, the essentially different nature of the effects of digitalis and digitaline, of opium and morphine, of cinchona and quinine, and of many plants and the alkaloids derived from them, was well known. Coca, says Dr. Nitard, is indisputably the drug to which, above all others, these remarks may be applied. *Erythroxylon coca* possesses, without doubt, analgesic properties, and is held as a superior local sedative, especially where pain exists in the region of the mouth and the throat (as noted and published by Professor Charles Fauvel long before the discovery of the local effects of cocaine), and in calling attention to the virtues of this plant it may be stated that the beneficial effects of wine of coca have been thoroughly established in tuberculous and other ulcerations on the tongue, in the mouth, on the lips, and on the vocal cords; in all this class of cases such a preparation is of great value, prolonging as it does the anaesthetic and sedative effects of cocaine when applied topically, or when such application becomes for one reason or another impracticable, proving itself of great service to the physician by reason of its local action. As coca differs essentially from cocaine, the action of the plant upon the general economy, and not its local action, should be borne in mind. Coca is a most active stimulant tonic, especially when used in vinous combination. No better preparation can be employed than the *vin Mariani*, which contains all the valuable properties of the plant, combined with a generous and absolutely pure wine. This has been found to give the best results. There are numerous conditions in which this preparation is indicated; in a general way, it is serviceable in all those various diseases which come under the clinical head of anæmia, weak heart, chlorosis, various forms of cachectic conditions, neurasthenia, general debility, and convalescence from fevers. As tuberculosis presents essentially anæmic features, it may readily be understood that in it the happiest results may be obtained by the use of this preparation of coca, as also in the other forms of phthisis. Although coca is not a specific in phthisis, and although the author does not assert that it is a destroyer of the bacillus of Koch, it nevertheless proves its efficacy in that disease, he says, and, as has quite recently been stated in Libermann's important work, "La phthisie pulmonaire et laryngée," the bacillus is not the sole factor to be considered in phthisis. Contained largely as it is in the atmosphere which we inhale, it happily remains inert in the great majority of cases. In other words, its victims are those in whose organism it finds a fertile field for growth and development. All our efforts should therefore be in the direction of rendering this field less susceptible to the inroads of the bacillus of tuberculosis until such time as we may be able to act more directly upon this dangerous germ. Among other means at our command to combat and to guard the organism against these inroads may be mentioned hydropathy, hygiene to the fullest extent, and climatology, which should always be taken into consideration by the physician and the patient. All these data are of absolute importance, and at the same time the physician should have at his command some agent which in all cases will, by its reliable action as a diffusible tonic and stimulant, fill the following indication during treatment, namely: The maintenance of perfect nutrition and the guarding against debility in its various forms. A tonic in every respect answering to these indications, and

one which, it has been found, may be given for an indefinite period without any unpleasant reaction in wasting diseases, is wine of cocaine. The preparation known as *vin Mariani*, which has been employed by the medical profession for the last thirty years, is the only one which has given the author uniformly good results without the unfavorable features which frequently follow in the wake of tonics and stimulants. And he attributes this to the fact that it represents all the volatile principles of the plant, thus differing essentially from preparations made from the dried, comparatively inert leaf (the volatile principles being absent) or, through ignorance of the proper requirements, containing a dangerous added percentage of the alkaloid cocaine. Thus, the author concludes, will be seen the necessity of recognizing the merits of this plant independently of its alkaloid, and the wide field it should occupy in therapeutics.

**The Treatment of Hiccough.**—Dr. John I. Brinkerhoff, of Auburn N. Y., writes that he has found calamus a remedy for hiccough in every case in which he has used it, including some cases of an aggravated character. A very small quantity suffices, only enough to reach the throat when dissolved by the saliva.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the abstract of sanitary reports received by him during the week ending June 28th:

CITIES.	Week ending—	Estimated population.	Total deaths from all causes.	DEATHS FROM—							
				Cholera.	Yellow fever.	Small-pox.	Varioloid.	Vaccinia.	Typhus fever.	Enteric fever.	Scarlet fever.

#### THERAPEUTICAL NOTES.

**Bisulphide of Carbon.**—On the authority of some observations made chiefly in the Purisima Hospital, Santiago, and published in the "Revista médica de Chile," a recent number of the "Lancet" shows that bisulphide of carbon may have more therapeutic power than is usually attributed to it. In England bisulphide of carbon has been employed for diarrhea and externally for ulcers. Sapier used it with apparent advantage in typhoid fever. It has also been recommended in diphtheria and other diseases in which micro-organisms occur. The Chilean cases referred to included one of acute and one of chronic dysentery, one of atonic dyspepsia, one of simple gastric ulcer, and one of typhoid fever. About two ounces of a saturated solution of the bisulphide in water, mixed with half a tumblerful of milk or a little syrup, to be taken half an hour or so before meals, was the dose generally given. In the typhoid case, enemata of a pint of water, containing about half a drachm of bisulphide of carbon, were administered to

the patient, a child of ten years, whose condition was becoming serious. Iodide of potassium and kairin were also given internally. The diarrhea lessened, the stools rapidly lost their offensive character, the gurgling disappeared from the iliae region, and the patient made a good recovery.

**Uralium as a Hypnotic.**—According to one of the March numbers of the "St. Petersburger medicinische Woehenschrift," which quotes from the "Gazzetta degli Ospitali," Poppe employs uralium, a combination of urethane and chloral hydrate, in cases of heart disease, insanity, hysteria, and other nervous affections. He finds that it induces a natural, peaceful sleep, and has a safer and more lasting effect than the hypnotics known heretofore.

#### ANSWERS TO CORRESPONDENTS.

No. 271.—The solution is made with 8 drachms each of sodium bicarbonate and borax, 20 grains each of sodium benzoate and sodium salicylate, 10 grains each of eucalyptol and thymol, 5 grains of menthol, 6 drops of oil of gaultheria, 8½ ounzes of glycerin, 2 ounzes of alcohol, and enough water to make 16 pints.

**To Contributors and Correspondents.**—The attention of all who purpose favoring us with communications is respectfully called to the following:

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Original Communications.

HUMAN CALORIMETRY.

SECOND CONTRIBUTION.

By ISAAC OTT, M.D.,  
EASTON, PA.

THE power to do work is called energy, and the animal body sets energy free in only two ways—mechanical work and heat. The human machine is an apparatus for converting potential into actual energy, the potential energy being supplied by food, which is changed into the actual energy of heat and work by the metabolism of the organism. To heat has been ascribed five sixths and to mechanical work one sixth of the energy set free. In a paper\* recently published there was described an apparatus to determine in a direct manner the amount of heat produced by man. Since that time two improvements have been made in the apparatus; instead of a wooden door an iron one has been used and bound down by eight powerful screw-clamps. The interior edge of the door was lined with rubber as before. In the other apparatus a straight tube permitted the air to enter in a direct way; now it traverses a coiled leaden tube before it reaches the person experimented with. The coiled tube is inside the calorimeter; perhaps it would be better if it was coiled in the water between the cylinders. This arrangement is intended to prevent heat dissipation. With these arrangements and a mattress inside the instrument I have retested the apparatus. As the apparatus necessary for the hydrogen test was not available, I used absolute alcohol. The different physicists who have burned a gramme of alcohol have obtained the following various numbers: Thus Rumford obtained 6,195; Du Long, 6,962; Andrews, 6,850; and Favre and Silbermann, 7,183<sup>6</sup>. These numbers mean so many grammme-calories, and the number 7,183 is supposed to be the most accurate. In their experiments, in order to allow for the loss of heat due to radiation, a preliminary experiment was made with the body whose heat was sought, the only object of which was to ascertain approximately the increase of temperature of the cooling water. If this increase be 10°, for example, the temperature of the water calorimeter was reduced one half this number—that is to say, 5° below the temperature of the atmosphere. By this method the water of the calorimeter receives as much heat from the atmosphere during the first part of the experiment as it loses by radiation during the second part. This procedure is called Rumford's compensation. In the human calorimeter the air-tube must be of considerable size for the air to enter, and necessarily permits of considerable loss of heat by the air constantly traversing the instrument. I have tested my calorimeter before and after the performance of the experiments. I give here a test with alcohol:

Time.	A. T.	C. T.	E. T.	Metres.
1.24.....	83°	74·20°	75·5°	758,274
2.24.....	82·3°	74·61°	75·8°	762,650
	82·6°	74·1°	75·6°	3,376

\* "New York Medical Journal," March 30, 1889.

577·42 = number of heat units required to raise the calorimeter 1° F.

577·42 + .41 rise in calorimeter temperature = 236·74 heat units.

Alcohol burned = 9·235 grains × 7,183 number of grammme-calories by burning a gramme of alcohol = 66·33 kilo-calories. As one kilocalorie is equal to 3·96 heat units, then 66·33 × 3·96 = 262·66.

V = 3,376 litres of air pumped through the calorimeter.

t = 75·6° - 32° = 43·6°, number of degrees the air is heated above 32°.

V + (v × 43·6 × .002035, co-efficient of expansion) = 3,376.

V + .0887260 V = 3,376.

1·0887260 V = 3,376.

V = 3,376 ÷ 1·088 = 310·29.

W = V × .00285, weight of litre of air at 32° F.

W = 310·29 × .00285 = 8·84 lbs.

Q = W × t × specific heat.

Q = 8·843 × 7° × .2374 specific heat of air = 14·69, number of heat units given to the calorimeter by the air.

Then 236·74 - 14·69 = 222·05, number of heat units obtained in burning the alcohol.

But the alcohol burned produced 262·66 heat units, and of these 222·05 have been recovered; then 262·66 - 222·05 = 40·61 = loss of heat units or error of the calorimeter. Then the percentage of error is 40·61 ÷ 262 = 15·5. In other words, all results by the calorimeter must have 15·5 per cent. added to them, that they may be accurate. In this paper I have made the percentage of error 16 per cent., as the mean of several experiments showed this to be the average error of the instrument. The constancy of the error made the apparatus one of precision for scientific work.

In my experiments upon man the calculation was made in the same manner. The specific heat of the body was taken to be 0·83.

In estimating the moisture I used Voit's little respiration apparatus, taking the moisture of the air of the room and deducting it from the moisture of the air coming from the calorimeter. Now, according to Helmholtz, 1,000 grammes of water require 582 calories in evaporation from the lungs and skin; then one gramme of water from the lungs requires  $\frac{582}{1000}$  calories = 2·304 heat units to vaporize it.

The glass bulbs were filled partly with sulphuric acid, and weighed on a delicate balance before and after the absorption of moisture from the air.

The experiments were performed upon a man aged thirty-five years, weighing one hundred and ninety-two pounds, five feet ten inches high, muscular, and in fair health. When he entered the instrument he removed his coat and vest. The observations began about 1 p. m., and terminated at 6 p. m. He dined at 12 m. The food from breakfast and part of the dinner must have been measured in the estimate of heat production, and would give the highest estimate of the twenty-four hours. In my first paper, although the number of heat units obtained was not accurate from want of reliable tests, yet I arrived at the conclusion that the estimates in an indirect manner from the egesta and ingesta were too high. The hourly average was found to be 410 heat units. Now, Leon Frederique, from the computation of several authors, makes 1·15 calories or 5·94 heat units an hour to the kilogramme of weight as the average heat production. This for the man I employed would be 512 heat units. The heat from the aqueous vapor in condensation was estimated, but the major part was condensed on the interior of the instrument as the

hand perceived, or in the twenty-five feet of lead pipe traversed by the air. This point came up in the Clausius-Hirn controversy. As is readily seen, the computations for man in the indirect manner are too high, as I believed in my first contribution. Rosenthal recently has found in animals on full diet that the absolute amount of heat was less than that calculated out from oxidation of food, but with a uniformly constant diet the mean value of heat production corresponded to the heat calculated from the combustion of the food. I also made some experiments upon the amount of heat thrown off by the lungs. A piece was removed from the iron door and the man's head enveloped in blankets inserted within the calorimeter. The person sat upon a chair during the observation. In this manner was obtained an hourly average of 57·98 units, thus being of the whole number of heat units to the hour 14 per cent.

Sebarling used an imperfect air calorimeter, and in a similar manner found the amount from the lungs to be 14 to 20 per cent. of the whole amount. Helmholtz makes the amount 14·7 per cent. as coming from the lungs.

The rapid rise of temperature in pneumonia is probably due to an interference with the heat dissipation of the lungs by the inflammatory state. The thermo-polypneic center may be active as usual, but it can not overcome by maximal stimuli the obstruction to heat dissipation.

By placing a pulley outside the calorimeter and attaching to a leather rope a fourteen-pound weight, the man was able by means of the leather rope to exercise within the instrument. The leather band entered one of the air-holes in the instrument. He was only permitted by a knot in the rope to raise this weight a foot high. By moderately lifting 4,222 foot-pounds, an average increase of 94·21 heat units an hour was obtained.

By lifting an average of 7,623 foot-pounds an hour the amount of heat units was doubled over the normal by about one hundred heat units. Hirn, using an air calorimeter of great inaccuracy, found a man aged forty-two at rest to produce 189 calories, while during movement it amounted to 325 to 356 calories. Pettenkofer and Voit found on hunger-day without work the carbonic acid was on an average 716 grammes; on hunger-day with work (turning a loaded wheel), 1,187 grammes; on food-day without work, an average of 928 grammes; with work on food-day, 1,285 grammes; or in nine hours on food-day without work 400 grammes, and on food-day with work 724 grammes. The researches of Rosenthal show that the hourly dissipation, as estimated by the calorimeter, when compared with the hourly exertion of  $\text{CO}_2$ , shows a very variable relation of the "carbonic-acid factor."

A. T. means air temperature.

C. T., calorimeter temperature.

E. T., exit-tube temperature.

M. T., mouth temperature.

#### FIRST DAY.

Weight, 192·56 pounds.

	81·7	·52	77·5	·3	5,248

H. D. = 285; H. P. = 237·98.

Average, 327·69; add 16 per cent. = 380·12.

#### THIRD DAY.

Weight, 191·82 pounds.

Time.	A. T.	C. T.	E. T.	M. T.	Litres.
1.10 P. M. ....	80·5°	70·83°	72·7°	98·2°	847,825
2.10 .....	80·0	71·40	73·0	98·1	853,415
	80·2	·57	72·8	·1	5,590

H. D. = 301·02; H. P. = 286·11.

Weight, 191·18 pounds.

Time.	A. T.	C. T.	E. T.	M. T.	Litres.
2.52 .....	81·5°	71·37°	73·2°	98·2°	853,415
3.52 .....	79·8	71·97	73·4	98·4	858,821
	80·6	·60	73·3	·2	5,406

H. D. = 319·65; H. P. = 351·38.

Time.	A. T.	C. T.	E. T.	M. T.	Litres.
4.22 .....	77·6°	71·83°	73·5°	98·4°	858,821
5.22 .....	81·0	72·54	74·0	98·4	864,537
	79·3	·71	73·7		5,716

H. D. = 388·22; H. P. = 388·22.

Average, 341·90; add 16 per cent. = 396·60.

Now, the average of the three days' observations is 397·66.

The average amount of moisture coming over from the calorimeter and absorbed by the sulphuric-acid bulbs was 5·49 grammes, and as it requires 2·30 heat units to vaporize a gramme of water, then a gramme of watery vapor in condensing will give off 2·30 heat units, and 5·49 grammes will give off 12·62 heat-units; then  $397\cdot66 + 12\cdot62 = 410\cdot28$  heat units as the daily afternoon average of a man weighing 192 pounds.

#### HEAD ONLY IN THE CALORIMETER.

H. D. = 44·49; H. P. = 44·49.

Daily average, 26·69.

Average H. P. of the two days, 26·83 + 16 per cent. = 31·13.

Now, on an average, 12·5 grammes of moisture come over from the lungs. This would make 28·75 heat units from the condensation of vapor. Then  $31\cdot13 + 28\cdot75 = 57\cdot98$  heat units as the average amount thrown off by the lungs, or about 14 per cent. of the whole amount of heat thrown off by the body. The reason that the moisture coming over from the lungs alone exceeds that normally coming over from the whole body is that the man is breathing immediately under the lead coil through which the air is aspirated; normally he lies with his head at the other end of the calorimeter.

1·12 .....	84·0°	72·34°	74·1°	98·35°	
2·12 .....	83·1	73·28	75·0	98·7	4,868

H. D. = 658·35; H. P. = 716·13.

Lifts 14 pounds 736 times = 10,304 foot-pounds.

Weight, 189·84 pounds.

Time.	A. T.	C. T.	E. T.	M. T.	Litres.
2·51 .....	82·9°	73·23°	75·0°	98·6°	
3·51 .....	81·5	74·31	75·8	98·9	4,911

H. D. = 761·36; H. P. = 808·58.

Average per hour 762·30, add 16 per cent. = 884·26.

Add 21·2 grammes of moisture or 48·76 heat units, and I have 933·02 heat units produced by hard labor in lifting weights; an average of 7,623 foot-pounds producing an increase of 522·74 heat units above his average, over double the normal by about a hundred heat units per hour. Taking the last experiment, elevating about five tons per hour a foot high doubles the heat production per hour.

The following are the chief conclusions of this paper:

1. A man weighing one hundred and ninety-two pounds during the afternoon produces 410 heat units in an hour on

an average, and not 512, as calculated by oxidation changes and the amount of egesta.

2. Of the whole amount of heat dissipated, about 14 per cent. is thrown off by the lungs.

3. The elevation of about five tons an hour a foot high doubles the hourly heat production.

## THE DIAGNOSIS AND TREATMENT OF CERTAIN FORMS OF RHINITIS.\*

BY CHARLES H. KNIGHT, M.D.

SINCE we have learned to recognize the intimate relations between the nose and other organs, the importance of nasal pathology is in danger of being overestimated. Instances of nasal reflex have multiplied to an alarming extent. Asthma, chorea, epilepsy, ocular and aural disturbances, headache, and laryngeal affections are familiar examples. It seems that the list of ills for which the nose is to be held responsible is not limited to neuroses. An attempt has been made to show that intestinal hernia may be caused by intra-abdominal pressure resulting from constant hawking, coughing, and sneezing, provoked by chronic obstruction or disease of the nares.<sup>†</sup> A condition, perhaps not very uncommon, termed by Guye,<sup>‡</sup> of Amsterdam, "aprosenia," is said to depend upon nasal disease. It consists, as the name implies, of inability to fix the attention, is accompanied by marked physical and mental depression, and is supposed to result from obstruction of the lymphatics which pass from the brain to the nasal fossæ. Haek, whose observations in the department of nasal neuroses have been especially numerous, goes so far as to propose treating certain joint affections through the nasal mucous membrane, and it has even been affirmed that such a disease as primary laryngitis does not exist, nasal stenosis or a nasal lesion invariably being found to act as a predisposing cause of simple inflammation of the larynx. Yet, making due allowance for the play of imagination on the part of the observer and of the patient, it must be admitted that nasal lesions aggravate and even excite phenomena in other regions remote from as well as in proximity to the nose. There seems to be no fixed proportion, as regards importance, between the nasal trouble and the associated disorder. Serious nervous phenomena sometimes appear to depend upon comparatively trifling structural change within the nasal fossæ. On the other hand, extensive intranasal disease may fail to produce reflex or other disturbance, and it is not unusual to discover extreme abnormal conditions within the nose the existence of which had not been suspected. In the presence of a decided pathological condition or deformity, such as a collection of polypi or a well-defined ridge or deviation of the septum, it may be quite safe to assume that an asthma, a frontal headache, impaired hearing, or a more serious neurosis, may depend upon the local lesion and will disappear

on its removal. Independently of these grosser lesions, it seems to be an established fact that certain changes limited to the mucous membrane may excite neurotic phenomena. A satisfactory explanation of the relation of cause and effect here displayed can be reached only through a study of the physiology and pathology of the sympathetic nervous system.

Without entering upon a discussion of this question, it has seemed to me that we might profitably give a few moments to a consideration of the changes referred to, which may be included under the terms hyperæmia, hypertrophy, and hyperplasia. Although one or more of these pathological conditions is conspicuous in every case of rhinitis, yet no little confusion exists regarding the meaning and application of these terms, and clinically the conditions are separated by no fixed line, but merge into each other by imperceptible gradations.

Hyperæmia is defined as "preternatural accumulation of blood in the capillary vessels, more especially local plethora"—in other words, "congestion."

Hypertrophy is "the state of a part in which the nutrition is performed with greater activity, and which, on that account, at length acquires unusual bulk." Finally, hyperplasia is "excess of formative action." Dunglison, from whom these definitions are taken, says that "hyperplasia relates to the formation of new elements, hypertrophy being an increase in bulk of pre-existing normal elements." For this reason the former has been called "numerical hypertrophy," the enlargement of the part being due to increase of the number of elements entering into its composition. The word hyperæmia is used to include both capillary congestion and distension of the venous sinuses of the turbinate bodies, the so-called "erectile tissue." The latter process is to a certain degree physiological. In simple hypertrophy there is merely increase of bulk as a result of increased functional activity, but the word is also employed to designate enlargement from prolonged irritation. In the latter sense it may properly include both hyperplasia and hyperæmia, as just defined. But in true hypertrophy, function is more active, while in hyperplasia it is impaired. This distinction is of special interest in connection with a rather sweeping assertion recently made by a distinguished authority to the effect that in all cases of chronic nasal catarrh secretion is actually diminished. The most striking example of genuine hypertrophy is seen in the turbinate enlargement projecting toward the concave side of a deviated septum. At first glance the deflection would seem to be a result of the hypertrophy, whereas the reverse is generally if not always true. As guardian of the inferior meatus, the inferior turbinate body must increase its dimensions as the bending septum expands the nasal cavity. So with increased function we have increased bulk. Strictly speaking, "hypertrophy" should be reserved to describe conditions of this kind, but its application to all forms of thickening of the nasal mucous membrane is to some extent authorized by long usage, and it may now be difficult if not impossible to restrict it within proper limits. Perhaps one excuse for retaining the word hypertrophy as a synonym for hyperplasia is that the former is more euphonious.

\* Read before the Section in Laryngology of the New York Academy of Medicine, May 28, 1889.

† W. Freudenthal, "Monatsschr. für Ohrenheilkd., etc., No. xi, 1887.

‡ "Deutsche med. Wochenschr., No. 43, 1887.

ous. It should be understood, however, that it is not ordinarily applied to simple vascular engorgement of the turbinate body, although it may be in reality more appropriate to that condition. Clinically, therefore, we mean by "hypertrophy" a condition of permanent thickening of the mucous membrane due to the existence of more or less hyperplasia.

From a therapeutic standpoint it is important that we should distinguish between hyperplasia, or hypertrophy, and hyperæmia with turgescence of the turbinate "erectile tissue." Persistence of the last-mentioned condition leads to the former, and here preventive medicine is offered a most inviting field. How may we arrest the tendency of chronic hyperæmia of the nasal mucous membrane to pass on to a condition causing perpetual discomfort to its victim, and requiring for its cure rare patience and endurance on the part of all concerned? To begin with, it is essential that we should be familiar with the objective appearances of these conditions. The subjective symptoms may not much differ, except as regards duration and intensity, but, by combining the information gained by the eye, by touch with the probe, and by the use of cocaine, we may usually discriminate. It may be difficult to assign certain cases which occupy the border line to their proper class, but we may at least determine which type predominates. Hyperæmia finds its typical representation in the condition popularly known as a "cold in the head"—acute catarrhal rhinitis. But, as a matter of fact, persons thus affected seldom consult a physician, so that clinically we most often meet with it in those already suffering from chronic rhinitis. Consequently, the same subject often offers us a field for the study of various pathological conditions, the same nasal cavity exhibiting at one point simple hyperæmia, at another the changes of chronic inflammation. Possibly, too, in neglected cases, or in those affected with a constitutional disease, still another region may have reached that unfortunate condition of atrophy, with its unmistakable symptoms. Admitting, therefore, the possible concurrence of these different conditions in the same individual, we shall more fully realize the importance of identifying them and adapting to each, as far as possible, its appropriate treatment.

It is unnecessary to review all the symptoms of the various forms of rhinitis. I merely wish to remind you of certain distinctive features met with in a rhinoscopic examination. The special points to be noted are the color of the surface, the character of the nasal secretion, the extent and shape of the swelling, its density or resistance, its sensitivity, and its vascularity. Inspection shows the color of the parts in hyperæmia to be intensely red, and the secretion, after the first stage, is copious and fluid. The tumefaction is uniformly globular, easily compressed, usually quite sensitive, and it bleeds readily on rough contact with the probe. In hyperplasia the color of the surface is less intense, it is often livid or purplish, and in advanced cases it is quite apt to be paler than normal. The swelling may have an irregular contour, owing to variation in the amount of new tissue at different points, and is usually neither very sensitive nor very vascular. Occasionally the membrane becomes distinctly lobulated or papillated. This

is most commonly seen at the posterior extremity of the inferior turbinate body, where the shape and color of the tumor have caused it to be compared to a mulberry. Its appearance in the rhinoscopic mirror is pathognomonic. This variety may be exceptionally vascular, and we sometimes observe quite protracted bleeding after the use of the snare in such cases. The nasal secretion is apparently increased, because of the fact that it has become less fluid and more tenacious, and hence is apt to be retained within the nasal cavities. Undoubtedly, with increase of hyperplastic tissue and consequent interference with the function of the glands of the mucous membrane, the secretion is not only perverted in quality, but notably diminished in quantity. Here the cause is largely mechanical. Decrease of secretion may also be observed in certain forms of rhinitis, without marked hyperplasia. In the latter case the interruption of function is perhaps of neurotic origin. The contrast in the behavior of hyperæmia and hyperplasia on pressure with a probe and under cocaine is very striking. The hyperæmic swelling yields readily to pressure, and quickly recovers its shape as the blood-vessels refill. The hyperplastic swelling is much more solid and resistant, lacks the smooth, tense appearance of the former, and is capable of relatively slight compression. The tissues do not give way to the probe, and on the removal of pressure the furrow made by the instrument is slowly effaced. A similar phenomenon is observed with cocaine. The hyperæmic swelling rapidly shrinks to the subjacent bone. In hyperplasia the mucous membrane can not contract more than may be permitted by the new connective tissue. In this way cocaine has become a most valuable addition to our diagnostic resources. It is also of great service in connection with treatment, by mapping out the regions more particularly affected by structural changes. By attention to the foregoing points we may escape at least two errors—first, that of operating with a snare on a simple vascular swelling of the turbinate body, and, second, that of attempting to cure a case of confirmed hyperplastic rhinitis by means of sprays and local medications.

In considering the treatment of these conditions it is impossible to exaggerate the influence of constitution and diathesis. Consequently, general therapeutics, diet, and hygiene must not be neglected. Occupation, habits, and climate are in many cases important factors, and should receive due attention.

Local treatment with sprays, douches, vapors, medicated bougies, ointments, and powders may be used according to the taste or credulity of the practitioner. It may be accepted as a first principle in nasal therapeutics that simple catarrhal rhinitis should receive only the most unirritating applications. In general, everything more than momentarily painful should be avoided. Sedative steam inhalations and preparations of medicated vaseline or oil are usually most grateful and least harmful. Fluid albolene, a petroleum product recently introduced, is an elegant vehicle for many of the more useful medicaments, which may be applied in the form of spray or vapor. Astringents, though largely used, are of doubtful value. Cocaine gives temporary relief by removing stenosis, but there is reason to suspect that its frequent

and habitual use may do serious damage. Antipyrine has recently been recommended by Hinkel,\* and it seems to possess antiseptic, sedative, and haemostatic properties. Its anaesthetic effect is said to resemble that of cocaine, being less marked but more protracted.

The use of sprays has been discarded by some whose opinion is worthy of regard. My own belief is that much of the discredit which has befallen the spray arises from the fact that too much is expected of it. We hear to-day of cases of chronic catarrhal rhinitis cured in a few weeks by sprays of medicated vaseline. There must be something peculiarly antagonistic in the climate of New York, since I am not acquainted with any one here who works these miracles. Again, there is no doubt that damage may be done by excessive air pressure and improper medication, and thus the disrepute of the spray be still further extended. But under proper precautions the spray is a valuable, if not an essential, adjuvant in the treatment and cure of catarrhal conditions. I use the word *cure* with hesitation, since we must all recognize the difficulty of entirely eliminating climatic and seasonal elements, and some of our spring cures are likely to return to us for treatment with the first bleak winds of autumn. In those obstinate cases of chronic turgescence on the border line of hyperplasia linear cauterization, superficial or submucous, may be required. My experience with the latter and with interstitial injections of carbolic acid, ergotine, etc., has been very limited. Reports from certain observers are favorable, yet the precise advantage of these methods is not quite clear.

When, in spite of treatment, or perhaps in consequence of treatment, or as a result of repeated attacks of inflammation, hyperplasia has supervened, these measures are seldom sufficient. The mass of newly formed tissue, which interferes with the functions of the nose, must be removed by surgical methods or destructive agents. The knife, the saw, scissors, drills, the snare, the galvano-cautery, and various chemical caustics may be selected from, according to the indications in each case. At the same time strict cleanliness and asepsis should be maintained by means of frequent irrigations with Dobell's solution or a similar detergent, or weak solutions of bichloride of mercury. It is an excellent rule in these cases to make haste slowly; not attempt to do too much at one sitting. It is much easier to repeat the operation than to restore tissue which has been destroyed. The danger of establishing a condition of atrophy should always be remembered. What we desire to accomplish is not merely the removal of obstruction, but also the restoration, if possible, of normal secreting function. While the morbid process is still confined to the mucous membrane, caustics, of which chromic acid is just now the favorite, and the galvano-cautery will be found most useful. The removal of more extensive hyperplasia may be most readily effected by means of the cold wire snare. In my experience, as a general rule, hypertrophies which can not be engaged in the loop of the snare without the aid of transfixion needles may be more easily reduced by the galvano-cautery. I prefer to use a very

slender electrode at a white heat. Thus the field is not obscured by a clumsy instrument and the tissue is rapidly destroyed. If the space between the walls of the nasal fossa is very narrow the septum should be protected by an ivory shield, or we may use one of the specially devised nasal specula. The heated cautery point buries itself in the tissues, and its detachment is often followed by bleeding, generally insignificant.

In this respect it is superior to the cold wire snare. With the latter, haemorrhage, very slight at first, is apt to be considerable in the course of a few hours. This seems to me to have been especially noticeable since the introduction of cocaine. Moreover, cocaine sometimes shrinks the tissues to such a degree as to greatly increase the difficulty of applying the snare. It may be suggested that cocaine might be used *after* the adjustment of the loop, but in that case, the first steps of the operation often being the most painful, one might as well dispense with the anaesthetic altogether. When the bone has become involved the cold wire snare will frequently answer every purpose, but in some cases the saw, the nasal trephine, and the various forms of surgical drill will do the work more quickly and with but little if any more pain.

In this brief review it has been impossible to mention all the therapeutic resources at our command. My object has been merely to suggest the general principles and a few of the details which guide me in my own practice.

In conclusion, I would speak a word of caution regarding the indiscriminate boring, sawing, and cutting of the nasal passages now in vogue. It is not my purpose to decry intranasal surgery. On the contrary, it is my firm conviction that the most brilliant results may be expected from a judicious resort to surgical expedients in suitable cases, but it has been my misfortune to see irreparable damage done and the most serious risks assumed in the reckless use of certain engines of destruction recently placed at our disposal. What, then, are the indications for surgical intervention in intranasal disease? The answer comes naturally enough when we recall to mind the functions of the nose. Its primary and most important function is respiratory; therefore any obstacle in the nasal passage which compels breathing through the mouth must be removed. Secondly, it is the organ of olfaction, and the sense of smell is not infrequently impaired by conditions which demand surgical treatment. Furthermore, in a limited number of cases, remote disturbances, reflex neuroses, may result from conditions which may not abolish or apparently disturb these special functions. Here also surgery may be our only resource. Finally, a neoplasm, a deformity, or a hypertrophy may encroach upon the nasal passage, but perhaps not enough to seriously or consciously incommodate the patient. The secretions are retained and act as irritants to the mucous membrane. In such case nasal drainage must be restored by surgical measures. In many cases these indications are unmistakably clear. In others we may be able to decide upon the best mode of treatment only after the most careful study. The present tendency in nasal therapeutics is certainly in the direction of "pernicious activity," and it seems to me that the final condition of a large proportion

of cases subjected to modern methods is, if anything, worse after they have escaped our hands. It is surprising with what comfort some people wear their crooked noses until the inquisitive rhinologist makes his ingenious pathological discovery. Every septum that is bent or thickened does not need to be planed down or straightened. Every turbinate body that is enlarged does not need to be snared or cauterized. If the temptation to meddle with them is too strong to be resisted, milder measures may perhaps avail with more comfort to our patients and greater credit to ourselves.

NO. 20 WEST THIRTY-FIRST STREET.

## PARING AND SUTURE CLAMP FORCEPS.

BY EDMOND V. JOYE, M.D.,  
ATLANTA, GA.

WHEN operating for vesico-vaginal fistula I have often been annoyed and delayed by the difficulty of keeping the tissue tense while paring and suturing. To overcome this difficulty I have devised, and caused to be made by George Tiemann & Co., New York, the following instrument, which seems to meet all indications for operation for simple vesico-vaginal fistula and other operations upon the female genitals, and renders the operations comparatively simple and easy, reducing the time of their performance more than two thirds. The instrument consists of two blades, each nine inches and a half long, which are crossed and

equidistant, and has a male screw on one end. The hooks of the extra blocks are exactly like those on the main blade. The blocks are marked with the letters R and L to indicate to which blade they belong. These extra blocks are to be screwed on to the main blades whenever the operator desires to increase the capacity of the instrument, making the instrument to have, at the option of the operator, either two, five, seven, or ten hooks on each blade, respectively, thus giving it a capacity of meeting many and varied indications. When performing any of the operations hereinafter mentioned the operator should notice the amount of tissue necessary to be pared, and should arrange the instrument to meet the needs of each individual case by screwing on to the main blades the blocks that will furnish hooks sufficient for him to hold, pare, and suture the extent of tissue necessary to overcome the existing difficulty. The whole instrument is made as light as is consistent with strength and durability. Fig. 1 represents the instrument with two permanent hooks on the main blades, and the extra blocks, of three and five hooks, respectively, which can be screwed on to the main blades as desired. Fig. 2 represents the application of the instrument. A shows the manner of hooking the blades into the tissue. B shows the manner of rotating the blades after being hooked into the tissue.

The operation for simple vesico-vaginal fistula is thus performed: The patient is placed in the position recommended by Dr. J. Marion Sims for such an operation. Chloroform is administered, Dr. Sims's duck-bill speculum introduced, and an assistant holds up the right buttock.

The instrument being unlocked, the left-hand blade is passed into the vagina and hooked into the mucous tissue on the right side\* of the fistula, not too near the edge, and rotated from left to right, thus bringing the lock up with the points of the hooks looking toward the right side; and, as the screw of the lock is upon the top of the blade, the handle is held down and the right-hand blade is then passed in over the other, and the hooks are hooked into the left side of the fistula; it is then rotated

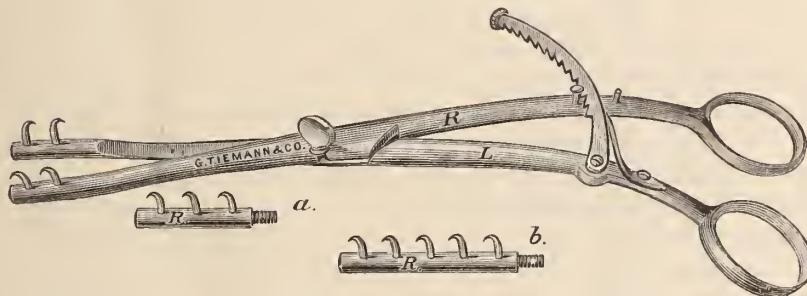

FIG. 1.

locked similarly to the Hodge forceps. One inch of the extremity of each blade is made round, into which are inserted two hooks, three eighths of an inch apart. The hooks are sharp and small at the free end, and thick where they enter the blade, so made to avoid tearing out easily. The shanks, four inches long, bear the screw lock of the Hodge forceps. The handles are five inches and a half long, slightly curved downward, in order to be out of the way of the operator, with a ratchet to hold the blades together, the rotation of the tissue hooked up having a constant tendency to extend the blades. The right-hand blade is marked with an R on the handle, and the left hand blade with an L. In the end of each blade is a female screw. Each blade is provided with two extra blocks, one an inch long, made round, into which are inserted three hooks equidistant, and has a male screw on one end and a female screw on the other end. The other block is an inch and three fourths long, is also round, has inserted five hooks

from right to left, and brought above and across the left-hand blade. The blades are now locked and the handles brought together and fixed by the ratchet. The fistula is thus firmly held, with its edges everted. The next step is to pare the edges, which is best done with Dr. Emmet's straight and curved scissors. This accomplished, pass the needles, armed with silver wire, one in front of the first hook, then one between each two adjacent hooks, and, lastly, one on the outside of the last hook. Twist up the sutures and cut them off, unlock the blades, rotate them in the opposite direction from that in which they were passed in and hooked, thus relieving the hooks, withdraw the blades, and the operation is complete. Fig. 3

\* Right and left as mentioned in this article have reference to the operator's right and left—viz., the right side of the fistula, the right side of the median line, and the right side of the lacerated perineum mean on the operator's right as he faces the parts; so with the left; not with the patient's right and left.

represents the instrument after having been hooked near the edges of the fistula, rotated and locked, holding the fistula open, to show the sutures. To complete the operation, draw

FIG. 2.

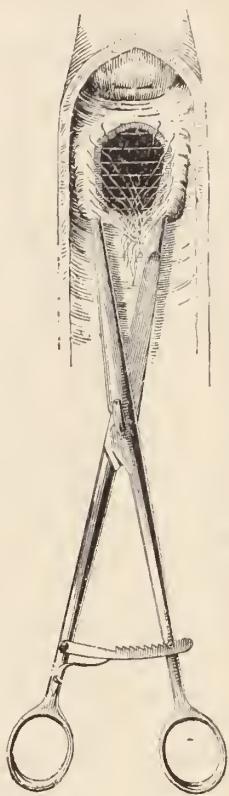

FIG. 3.

the handles together, constricting the fistula, twist up and cut off the sutures, unlock, rotate in the opposite direction from that in which they were applied, and withdraw the blades.

The advantages gained are these: First, by fixing the fistula with the instrument, the operator is enabled to pare the edges at one stroke of the scissors. Second, the blades constricting the pared edges of the fistula furnish considerable support for the passage of the needle, which can be pushed through both sides at once, taking good hold at the same time, and also from this fact the sutures can be better twisted and adjusted. Lastly, the operator has entire control of the parts, for by depressing the handles he elevates the fistula, and during the paring and suturing can bring it clearly into view.

This simple instrument can be used in all operations wherein eversion, elevation, and continuous and perfect adjustment of the tissue are necessary, as in laceration of the perineum, colporrhaphy (anterior and posterior), etc. When performing the operation of clytrorrhaphy, the patient is placed in Sims's position and his duck-bill speculum introduced. The operator, determining his line of operation, passes in the left-hand blade of the "paring and suture clamp forceps," hooks it into the anterior wall of the vagina on the right side of the median line, and rotates the blade from left to right. He then passes in the right-hand blade, over the one already in position, hooks it into the anterior wall of the vagina on the left side, at the same distance from the median

line, and rotates the blade from right to left. The right-hand blade is then brought down upon and across the left-hand blade and locked. The operator can now put the tissue between the blades upon the stretch by separating the handles. He can then bring the mucous membrane so stretched clearly into view by depressing the handles, and is thus enabled to readily cut away or freshen the mucous membrane in any given direction, as in Sims's V-shaped operation for procidentia, apex to vulva, base to os uteri, or Emmet's operation for procidentia. The three points, one in front of the os uteri and the two lateral ones, are easily located and freshened while the tissue is firmly held by the forceps; or, as is suggested by Mundé, all the intervening tissue between the blades can be freshened or denuded and the sutures passed and twisted up. The operator having entire control of the parts, by elevating or depressing the handles of the forceps the blades giving support to the tissue allows him to pass in the needles, armed with sutures, more accurately. The operation is completed by drawing the handles of the forceps together, thus bringing the freshened surfaces into accurate and perfect contact, without any traction upon the sutures whatsoever. The sutures are then drawn up, twisted and cut off, the blades are unlocked and each is rotated in the opposite direction from that in which it was applied, unhooked, and withdrawn.

Emmet's, Mundé's, and Stoltz's operations for cystocele can be greatly facilitated by the use of this instrument; also like operations on the posterior vaginal wall. Emmet's operation for urethrocele is thus performed with the "paring and suture clamp forceps": Sims's speculum is introduced; the left-hand blade is passed into the vagina and hooked into the anterior wall on the right side, parallel to and an inch and a half from the point where the slit in the urethra is to be made, and rotated from left to right and held in this position. The right-hand blade is then passed in and hooked into the anterior vaginal wall on the left side, at a point immediately opposite to the other blade and at the same distance from the median line, and rotated from right to left, bringing it down to and across the left-hand blade; the blades are locked and the handles separated until the tissue between the blades is placed upon the stretch; the handles are then fixed by the ratchet, a grooved sound is passed into the urethra, and the slit is made just in front of the neck of the bladder. "The hyperplastic mucous urethral membrane is drawn through this slit with a tenaculum, trimmed down until the urethral canal appears free, and its border is sewed by fine silk or catgut sutures to the mucous membrane of the vagina." Should the operator desire to constrict the edges of the slit, he can unlock the blades and unhook them, and rehook them on either side of and near the slit, rotating them as before, and hold the edges firmly everted while stitching the urethral mucous membrane to the mucous membrane of the vagina. He then unlocks the blades and, rotating them in the opposite direction from that in which they were applied, withdraws them. Cystocele in many cases can be overcome by paring the tissue and making two longitudinal wounds in the anterior wall of the vagina, parallel to and on either side of the urethra, extending from either side of the os uteri to the edges of the vulva. These,

when sutured and healed, will form two longitudinal cicatrices, which will give support to the relaxed anterior wall.

The posterior wall can be so treated for proctocle, the wounds to extend from either side of the posterior vaginal pouch to the edges of the vulva, parallel to and on either side of the median line. In procidentia, the paring and suturing of both the anterior and posterior walls of the vagina in the directions mentioned, will form, when healed, four longitudinal cicatrices which will act as four splints, preventing the sinking down of the uterus or the shortening of the antero-posterior diameter of the vagina. The width of the denuded surfaces in any of the operations must be determined by the condition of the case. The paring and suturing can be done very readily with the "paring and suture clamp forceps" manipulated as before described.

In perineorrhaphy, Mundé says: "While denudation is under process, the index and middle finger of the left hand of the assistant who holds the left leg, and the right hand of the other assistant, separate the labia by traction on the sound skin, and enable the operator to see the vaginal canal as he proceeds inward; this traction must be uniform, and is regulated by the operator at will during the whole operation, so as to secure the best possible symmetry of the two halves of the wound, and exactly corresponding points of entrance and exit of the sutures." This traction can be made with this instrument with more uniformity than with the hands of an assistant, and the instrument gives the operator complete control of the parts, both when denuding and when suturing. The instrument is applied in this manner: The left-hand blade is hooked into the sound skin on the right side of the lacerated perineum, and rotated from left to right; then the right-hand blade is hooked into the sound skin on the left side of the wound and rotated from right to left. The blades are then locked. The elasticity of the rotated edges causes the handles to be fully extended, and the operator can, by depressing them, draw the sides of the wound tense, and, thus causing the wound to gape at its outer edges, readily bring the tissue at the bottom of the rent to view. The tense condition of the sides allows the operator to pare them with Emmet's flat scissors, kept level with the surface, without any danger to the structures below the mucous membrane. The paring done, the sutures are passed. After this the wound and vagina are thoroughly cleansed. The handles of the instrument are brought together and fixed by the ratchet, which causes the blades to bring the two halves of the freshened wound into close contact and firmly hold them in this position. The operator draws up the sutures one by one and twists them, unlocks the blades, and removes the instrument. There is no traction upon the sutures to bring the edges of the wound together. They are held together by the blades of the instrument, and by so supporting them the operator is enabled to twist up and tighten the sutures with more uniformity than he can possibly do by drawing the wound together by the sutures. Again, when the blades are removed, the strain comes alike upon all the sutures at one and the same time, and greatly diminishes the danger of their tearing out.

Fig. 4 represents the instrument applied as directed to

a lacerated perineum, and shows the rent gaping by the action of the instrument, the tissue pared, the sutures passed. To complete the operation, draw the handles of the instrument together, thus bringing the pared edges accurately into position.

When operating for lacerated perineum, the operator must adapt the instrument to the length of the rent, using the number of hooks which will thoroughly evert and accurately adjust the tissue after it has been pared and the sutures have been passed. He must be careful to see that the instrument, after being applied as before described, will thoroughly and accurately bring the edges together before he commences the paring. In other words, the operator, after hooking the blades on either side of the rent and everting the edges, locks the blades and draws the handles together. He then readily sees if the edges of the rent are brought into proper and exact apposition throughout its entire length; if they are not, he should notice what the difficulty is and overcome it by unhooking the instrument and reapplying it in such direction as will enable him, by drawing the handles together, to make the edges meet at all points. This done, he extends the blades and proceeds with the operation as before described.

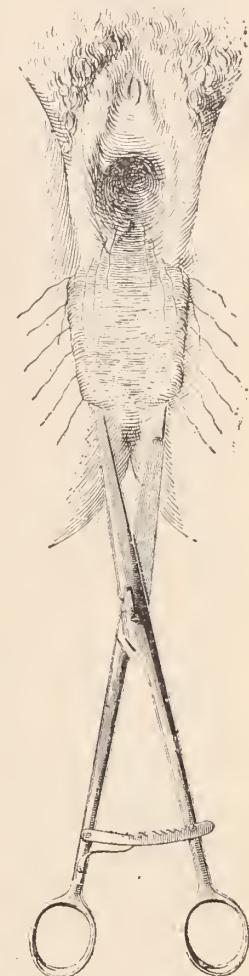

FIG. 4.

## HYSERECTOMY:

### REPORT OF A CASE, WITH REMARKS.

By RICHARD DOUGLAS, M.D.,

NASHVILLE, TENN.,

MEMBER OF THE BRITISH GYNÆCOLOGICAL SOCIETY AND OF THE SOUTHERN SURGICAL AND GYNÆCOLOGICAL ASSOCIATION.

I WAS consulted on December 2, 1888, by Julia H., colored, aged twenty-seven, married, never pregnant; her menstrual flow always normal in quantity, regular and painless. Her symptoms, as related, consisted of great disturbance to digestion, pain and flatulence after eating, most obstinate constipation, dysuria, constant pain, and some tenderness over the lower region of the abdomen.

For the preceding three months, so great had been her distress from these various symptoms, her general health had become seriously impaired, and her weight, formerly 160 pounds, was now reduced to 120 pounds. About five years ago she discovered in the right inguinal region a lump of about the size of an orange. For several years it changed but little; four months ago, however, without any known cause, it was observed to be rapidly enlarging and assuming a more central position;

at times on her turning over in bed the lump seemed to fall from one side to the other. Her general health had been perfect until disturbed by the growth of the tumor. Examination showed the abdomen to be distended to about the size of a six months' pregnancy. The enlargement was most prominent to the right side. The tumor was smooth, globular, hard, inelastic, non-fluctuating, and freely movable—the area of dullness extending from the pubes to the umbilicus, from the right inguinal through the hypogastric to the left inguinal region.

Vaginal examination gave only negative evidence; the cervix was short, conical, and high. Nothing could be felt in either broad ligament. The sound passed four inches forward. Uterine hemorrhage was not and never had been a feature of the case. In fact, there were no uterine symptoms *per se*. The symptoms were constitutional or remote, of which disturbance to digestion and nutrition was the most pronounced. These, together with the history of the growth and the physical signs, led to a diagnosis of subperitoneal fibroid tumor of the uterus, probably pedunculated. These growths ordinarily give rise to but little disturbance; in this particular case quite the contrary was true. Dependent largely upon her own exertions for support, she contemplated with dread a life of forced indolence, if not invalidism. Fortunately, she fully appreciated what the future had in store for her if the tumor was left undisturbed, and urged upon me its removal.

Considering the case favorable for hysterectomy and one in which the operation was clearly indicated, after most careful preparation of the patient I undertook the operation on December 8th last.

An incision about three inches in length was made in the middle line, the abdominal cavity opened, and the tumor with its surroundings explored. To my gratification, the diagnosis had been surprisingly correct. I found a subperitoneal fibroid of about the size of a child's head, movable, free of adhesions, springing from the upper and posterior aspect of the uterus; the attachment was somewhat pedunculated. The tumor had risen almost entirely out of the pelvis, drawing in its upward growth the uterus and appendages. It did not extend between the folds of the broad ligament, and, as before stated, adhesions were very slight—only one of consequence, that being omental.

The bladder in its relation to the uterus was normal; there was no adhesion of that viscous to the tumor. To complete the picture, the left ovary was found lying well up on the side of the tumor, while the right lay in a mass of adhesions low in the pelvic cavity.

This case presented *in toto* all those supposable conditions which Greig Smith takes as illustrative of a typically simple case for hysterectomy. The operative procedure was so simple it is scarcely worth detailing. Enlarging the incision to one inch above the umbilicus, passing my hand from above under the tumor, with the aid of atmospheric pressure thus obtained I turned the mass out, Dr. Buist now holding it well up out of the cavity.

The left broad ligament with its ovary and tube lay high up on the side of the tumor in a position to be easily embraced with a serre-nœud. On the right side affairs were not so simple. The ovary was firmly imbedded in a mass of adhesions, the tube much enlarged; the relations of the appendages of this side were quite different from those of the left side. The right lay too low to be embraced by the wire; fearing too great tension on the ligament would cause it to slip from the grasp of the serre-nœud, which accident would certainly be followed by hemorrhage from the proximal part, I deemed it at least prudent to leave the ovary undisturbed. The greater portion of the tube and broad ligament was doubly ligatured and divided. The left

appendages being held close to the uterus, the wire loop was thrown around the mass, constricting the uterus about at the internal os. The wire was now tightened through Kœberlé's serre-nœud. Sponges were packed around the proposed pedicle, and the mass was cut away an inch and a half above the wire. There was no bleeding from the stump; however, the serre-nœud was immediately tightened by several turns of the screw. The stump was now trimmed of extra tissue. For want of better pins, two steel knitting needles were passed through the pedicle above the wire. The peritoneal cavity having been well protected, there was no need of irrigation or sponging, which is often done to excess. The pedicle was fixed in the lower angle of the wound. The abdominal wound was closed in the ordinary way down to the stump; here the parietal layer of peritonæum was stitched with interrupted catgut sutures to the peritoneal covering of the stump below the wire. The stump was now treated with a saturated solution of perchloride of iron in glycerin. Iodoform gauze was packed under the clamp and pins to protect the cavity from any discharge from the pedicle. The patient was put to bed, having sustained but little shock. For forty-eight hours she suffered some from traction on the stump. The bladder was very irritable. A little morphine was given hypodermatically.

During the first twenty-four hours the clamp was tightened by a slight turn of the screw. On the second day the temperature was 101.8° F., and this was the highest during the progress of the case. On the seventh day the wound was dressed; everything was dry, sweet, and free from suppuration; the stump looked mummified.

On the day following I was surprised to find the dressing moist with the ichorous pus from the stump. There was no elevation of temperature. Her general condition was excellent. The parts were thoroughly cleansed with bichloride solution, dusted with iodoform, and packed well about with gauze to protect the cavity from contamination. The incision had healed beautifully down to the stump. Owing to the quantity of discharge, the pedicle was cleansed and dressed every day. The serre nœud being occasionally tightened, on the twenty-first day after the operation the pedicle separated and the clamp was removed. Upon the separation of the pedicle a funnel-shaped depression an inch and a half deep was left. Through this the ligature applied to the right appendages came away. The hole rapidly filled in by granulation. The subsequent history of the case contains nothing of note. Five weeks after the operation there was a moderate menstrual flow. She recovered rapidly and has continued to improve in health and strength. The tumor weighed six pounds and three quarters. In its center there was a cavity containing about three ounces of clear fluid. I must here express my gratitude to Dr. Buist, Dr. Wion, Dr. Harris, and Dr. Wood, who upon this, as upon many other similar occasions, rendered valuable assistance, and encouraged me by their presence and indorsement.

Since performing this operation it has been my good fortune to observe the methods and results in abdominal surgery of several European operators, but more especially of my distinguished instructor, Dr. Granville Bantock, of London. All his work is characterized by system, simplicity, and dexterity. But it is in hysterectomy for massive fibroids with extensive adhesions and broad pelvic attachments, requiring careful enucleation, that the superior judgment and marvelous skill of this distinguished operator are shown to best advantage.

It is surprising how tolerant the peritoneal cavity is to the presence of large fibroids, even those in which extensive

adhesions are almost certainly known to exist; patients wear their tumors with comparative grace and comfort.

Upon the other hand, in the case here reported, after the rapid growth of the tumor was awakened, its presence caused such distress from obstruction to blood circulation and the channels of nutrition, emaciation was so rapid, and physical pain and mental anxiety were so great, that some active procedure was imperative. True, all these symptoms may be alleviated, but I am convinced this was one of a large class in which total extirpation is the only resort. Yet Mr. Keith's proclamation is in some degree authoritative. He, in a very brief but pregnant communication to the "British Medical Journal," December 10, 1887, says: "I say it deliberately, hysterectomy is an operation that has done more harm than good, and its mortality is out of all proportion to the benefits received by the few."

A word of warning to the rash, a plea for conservatism, is always "vantage ground" chosen by the aged and experienced warrior. To his many successful hysterectomies, as much if not more than to any other operation, Mr. Keith owes his position of pre-eminence. In this same article, above referred to, he indulges in no mean compliment to Apostoli. Was it enthusiasm over electricity rather than aversion to hysterectomy that induced him to utter so condemnatory a speech of an operation which from the point of view of necessity is as justifiable as any major operation?

Carefully study the description of some of Mr. Keith's hysterectomies requiring enucleation, one could never believe he would feel, with H. P. C. Wilson, of Baltimore: "I shrink and have a feeling of terror come over me when I find that I am obliged to perform hysterectomy" ("Trans. of the Am. Gynaec. Soc.", 1886).

Now that Apostoli's method is known to be suitable to only a few carefully selected cases, if not absolutely futile in all, and oophorectomy is unreliable and often wholly impracticable, what are we to do for women dying—and they do die—from fibroid tumors?

Greig Smith, basing his conclusions upon the results obtained by Bantock, Thornton, and Tait, regards it a justifiable procedure. Again, the mere fact that these surgeons are constantly doing the operation speaks for their belief in the necessity and faith in results.

In a study of this operation surgeons are still perplexed as to how best to treat the pedicle. We can affirm upon authority that Keith, Bantock, and Hegar have by the extraperitoneal method attained results unequaled by "any one, or any combination of operators by the intraperitoneal method." Notwithstanding this, Keith says: "The principle of extraperitoneal or clamp method may seem to be the better, but on this point experience has made me change my mind."

Granting the serre-nœud to be crude and unsurgical, and being fully convinced that some method of safe intraperitoneal treatment will be found, one can not study the results at the Samaritan Hospital and question the superiority of the extraperitoneal treatment over any known intraperitoneal ligation and suture, whether it be simply Schroeder's plan; or after the ingenious method of Dr. Polk, in which, when complete, the stump is intra-abdominal yet extraperi-

toneal; or the combined abdominal and vaginal method, accredited, I believe, to Dr. Mary Dixon Jones; or, later, the interparietal method of Hacker; or, still more recent, the new method of Kelly.

One can with comparative ease graphically describe most surgical operations; a nephrectomy or ligation may be depicted step by step, and, whilst no two operations are exactly alike, their details are very similar. Not so with hysterectomy. Note the vast difference between an ordinary supravaginal amputation of the uterus for a non-adherent fibroid and for one growing out in the broad ligaments, rising up into the abdominal cavity, adherent to everything, short at the base, without a pedicle, requiring the elastic ligature and the most difficult enucleation, each step testing the skill, knowledge, and patience of the surgeon. So variable are the complications met with in fibroid growths that the surgeon who attempts their removal by any proscribed plan or principle other than those broad principles upon which all surgical technique is based will find he will often have to abandon his undertaking in despair. Dr. Wylie fully appreciates this when he says: "Each case must be a law unto itself." Experience alone will enable us to cope with the difficulties that are met with.

Without presuming to be in the least critical, I can but remark the sweet simplicity of the ease by which Dr. Howard Kelly illustrates his new method of intraperitoneal and extraperitoneal treatment of the stump ("Am. Jour. of Obstet.", April, 1889).

The special features of the operation for which he claims originality are:

1. The last row of interrupted sutures are left long for the purpose of elevating the stump should hemorrhage occur.
2. The subperitoneal ligation of the uterine arteries as they ascend on the cervix.
3. The important but not original method of closing the abdominal incision about the stump.

"If," says the writer, "the broad ligaments are spread out on the tumor at the side, they are tied off in a double row of ligatures down to the base of the tumor." In my own limited experience and unusual advantages of observing at the Samaritan Hospital, this primary step of freeing the tumor from the folds of the broad ligament which Dr. Kelly treats so lightly is the greatest difficulty and obstacle to the operation. When such a condition is present, enucleation is necessary. A pedicle must be formed; the stump may be from two to four inches in diameter.

Fig. 4 in Dr. Kelly's article is only diagrammatic, of course; quite like the stem of a toad-stool; in no way resembling an ordinary fibroid.

Dr. Kelly treats the stump after Schroeder's plan, except that the last row of sutures approximating the peritonæum are left long. The stump is then held aside while the operator ligates the uterine arteries subperitoneally. Can the surgeon forget that the pathological is but the perversion of the normal; that in so much as the cells and fibrillæ are increased and distorted in the hyperplastic process, just so is the anatomy destroyed?

Given a large, soft fibroid, where are the uterine arteries?

Can it be hoped that one thrust of the needle, one bite of peritonæum, will embrace the artery? Surgery is a science, not a chance shot.

The next step is that of stitching the parietal peritonæum about the stump. This all operators endeavor to do after some fashion, relying, however, upon the clamps and pins to support the pedicle, upon which oftentimes there is great traction. Dr. Kelly relies upon the forceps and sutures to hold the pedicle up. It appears to me that the tension would soon cause the sutures to cut through and the stump, a sloughing mass, to sink down, and that into the peritoneal cavity.

The objections to Dr. Kelly's method are :

1. It is not applicable to a fibroid growing low on the uterus or spreading out in the broad ligaments.

2. Unless the pedicle was unusually long, separation from the parietes would soon occur.

3. The uterine arteries can not be definitely located. In case they were not grasped by the ligature, haemorrhage would certainly supervene.

4. Should haemorrhage occur in spite of precautions taken, forcible elevation of the stump would be attended by obvious dangers.

5. The method is so intricate that the operation would necessarily be a prolonged one.

In a communication to the "Am. Jour. of Obstet." from T. J. Crofford, M. D., commenting unfavorably upon this and all other methods now in vogue of doing hysterectomy, that writer reports a case in which he successfully removed the entire uterus, his aim being to "leave no pedicle of uterine tissue, and there is no necessity to fasten the stump anywhere."

I believe he claims originality for this method. It is nothing more than Bardenheuer's modification of Freund's operation, abandoned on account of high mortality. "Thus, step by step, the way was paved for the vaginal method."—*Sutton.*

No one having had the care of an extraperitoneal stump can fail to wish for some improvement. Dr. Polk, by his modification of Bantock's plan, comes nearer solving the problem. Yet in Dr. Dudley's case, treated after Polk's method, there was slight haemorrhage on the fourth day, and the patient subsequently died.

#### PRACTICAL SUGGESTIONS ON THE REMOVAL OF FOREIGN BODIES FROM THE EAR,

*WITH ILLUSTRATIVE CASES.\**

By ROBERT BARCLAY, A. M., M. D.,

ST. LOUIS,

LATE ASSISTANT AURAL SURGEON, NEW YORK EYE AND EAR INFIRMARY; AURAL SURGEON, ST. MARY'S HOSPITAL, AND CITY HOSPITAL, OF ST. LOUIS; CONSULTING AURAL SURGEON, HOSPITAL DEPARTMENT, MISSOURI PACIFIC, AND MISSOURI, KANSAS AND TEXAS RAILWAY COMPANIES; LATE OF CLINICAL STAFF, BEAUMONT HOSPITAL MEDICAL COLLEGE, ST. LOUIS.

The subject of removal of foreign bodies from the ear acquires its importance from the fact that these cases are frequently met with and that acquaintance with the surgical

anatomy of the external auditory canal and drum-head is absolutely necessary for their proper management. Moreover, the fact that unskillful meddling may at once transform an otherwise comparatively harmless condition into one of great danger calls for a more extensive familiarity with this subject among general practitioners, since to *the family physician first* these patients appeal for relief. To him especially, therefore, these suggestions and illustrations will be offered.

The foreign bodies to be found in the ear may be classified in various ways. For instance, they may be parasitical or non-parasitical; those that do and those that do not swell; animate or inanimate; those produced within the ear or those introduced therein, etc. The brief period of time at our disposal compels me to confine my remarks to the consideration of the removal of foreign bodies of non-parasitical character which have been introduced within the ear. Cases of this kind when first seen, if the foreign body is inanimate, seem simple and without danger, but, improperly interfered with, they become grave in character and difficult of management. If, however, the foreign body is animate—a small bug, for example—its active character and the vulgar superstition of its possible "getting into the brain"—where alone, by the way, a "foreign body" (!) sometimes exists—almost invariably make the case seem from the outset distressing and urgent to an exaggerated degree. One should therefore be upon his guard lest he be either too careless in the former or too hurried in the latter case, yet be alert to the indications of the particular case presenting and active in properly fulfilling them.

*CASE I. A Bed-bug in the Cul-de-sac of the Canal; Instillation of Coal-oil followed by Continuous Pain; Removal of the Bug with a Cotton-wool Brush; an Alkaline Wash gives Instant Relief from Pain.*—A boiler-maker, aged twenty-four, awoke at 3 o'clock A. M. on June 14, 1888, with a fluttering in his left ear "as if a bug were in it." He instilled into this ear, upturned, a few drops of "coal-oil," which at once put a stop to the fluttering. The bug failed to come away with the oil, and, having suffered continuous pain in the ear ever since, he applied to me for relief in the afternoon of the same day. His use of "coal-oil" in this manner had proved efficient several years before in removing a bug from his ear.

Examination showed the tissues covered with oil, and a small dark object in the *cul-de-sac* of the canal, which was afterward removed with a cotton-wool brush, the canal then being syringed with a warm, slightly alkaline aqueous solution, affording entire relief from pain. The dark object proved to be a small bedbug.

*CASE II. A "Candle-bug," having flown into the Ear, causes Impaction of Softened Cerumen against the Drum-head; Removal with a Curette and by Syringing.*—A locomotive fireman, aged twenty-three years, applied for treatment on June 21, 1888. He stated that he had had a bubbling, snapping sound in his left ear, especially on drinking anything, for the past two days. He had slight deafness and autophonous voice in this ear. All these symptoms had developed suddenly two evenings before while he was firing on his engine. His suspicions that a bug had flown into his ear were stated to his mate, the engineer, who had noticed his deafness on this side.

Examination showed cerumen occluding both canals; in the left one it was soft, and imbedded therein was a dark object. The cerumen was impacted against the drum-head. A portion

\* Abstract of a paper read before the Medico-chirurgical Society of St. Louis, September 18, 1888.

of the cerumen was removed with the curette, the remainder by syringing, which brought away the dark object also, a long, black-winged insect, such as is ordinarily called a "candle-bug."

**CASE III.** *A Gnat in the Ear; Abrasions of the Canal Wall and Drum-head by Probing with a Toothpick; Gentle Syringing.*—A cashier, aged twenty-six years, was seen by me late in the evening of July 8, 1887, when he stated that while he was out driving on the afternoon of the same day a gnat had flown into his right ear. This had distressed him so greatly that he had at once probed the canal with a toothpick covered with a layer of his handkerchief. After finishing his drive he promptly repaired to his family physician, who, noting several wounds in his ear, at once referred him to me. When seen he complained to me of tinnitus and tenderness of the right ear.

Examination showed an abrasion of the posterior and anterior wall at the isthmus of the canal, a wound of the membrana flaccida, and a slight one of the anterior-inferior quadrant of the membrana tympani vibrans. A very small, black, seemingly structureless object seen in the *cul-de-sac* was removed by gentle syringing, and the ear then dried with absorbent cotton-wool. A soothing vulnerary was applied to the abraded spots and a mild purgative administered, no further discomfort being experienced by the patient.

These cases fairly illustrate how insects enter the ear. Oil should not be used to kill or remove such intruders. If the insect is very small, it may sometimes be ejected by forcibly blowing into the canal. If the invaded ear is upturned and filled with warm water, the insect will either at once seek the surface or perish for want of air. In the latter case it may subsequently be removed by syringing, which is the preferable method, or with a cotton-wool brush or curette. A little reflection will show the folly of hurriedly probing the ear for the removal of a live insect. Abrasion of the canal and drum-head at least, and very often complete rupture of the latter, is apt to be caused by such a procedure. In many cases the insect will have already escaped from the ear before the remedial attack upon the organ is begun. Should there be any doubt as to the insect still being within the ear, the doubt should first be satisfied by ocular inspection of the canal. If the patient is suffering pain from the movements of a live insect in the ear, unnecessary delay would be cruel, and we should at once upturn the canal and fill it with warm water, proceeding as advised above.

**CASE IV.** *A Clipping of Hair in the Cul-de-sac of the Canal, pressing on the Drum-head, producing Aural and Cerebral Symptoms, with Subacute Catarrh of the Tympanum.*—A clerk, of Jewish parentage, aged sixteen years, applied for treatment on July 24, 1887. He stated that he had had otorrhœa of the left side for two weeks in January, 1887. In April, at one time, he had a spasmodic pain in this ear. After pitching quoits a few days before July 24th he sat down to dinner and was seized with vertigo and headache. At times he had tinnitus. The family physician had been administering internal remedies before referring him to me.

Examination showed evidence of slight catarrhal otitis media; the drum-head was dull, resembling glass covered with condensed moisture; there was not the slightest evidence of former otitis media purulenta. Resting on the floor of the *cul-de-sac* of the canal, extending obliquely inward and upward, and pressing directly against the drum-head, was a clipping of

stiff hair. Removal of this with a cotton-wool brush, slight Politzer inflation of the tympana, and the administration for several days of small doses of mercury, brought about great improvement by July 30th, when the patient was referred to his family physician for tonic treatment.

**CASE V.** *A Splinter of Wood driven into the Ear of a Locomotive Engineer at a Collision, producing Displacement of Cerumen, and, together with the Concussion, producing Deafness, Pruritus, and Tinnitus Aurium; Much Hair growing from the Tragus, obstructing the Meatus; Removal of Hair and Cerumen with Scissors, Curette, and Syringe.*—A locomotive engineer, aged fifty-four years, was first seen by me on March 18, 1888. On December 20, 1887, in a head-end collision with a freight train, he had remained at his post, and sustained a fracture of the left femur about four inches above the knee, the lower fragment being split into the knee joint. His left eye was injured and his thorax partially crushed, so that respiration was painful, and he had slight paresis of the upper extremities. There were also wounds of the neck, tongue, and upper lip. Previous to the accident no aural affection had been recognized, but ever since he had noticed partial deafness and occasional pruritus in both ears. There was frequent tinnitus in the left, occasional in the right ear; sometimes he felt sharp pains darting from the spine to the ear and other distal points. Hearing for a forty-eight-inch watch, a quarter of an inch, each ear; he heard a very low voice with either ear at fifteen feet. Examination showed a small amount of loosened cerumen, together with a fresh splinter of wood in the left ear; cerumen in the right ear; both meatus and intertragal notches closed by a profuse growth of hair from the tragus. The hair was removed with scissors, cerumen and splinter of wood with curette and syringe, followed by Politzer inflation of the tympana. Internal treatment was instituted, and on March 20th the patient reported no tinnitus aurium since the last visit; his head felt less heavy, and a forty-eight-inch watch was then heard an inch distant by each ear, a gain of 300 per cent. in hearing for the watch. Treatment was continued and the patient was soon discharged greatly improved.

These cases show how a foreign body may be within the ear without the person's knowledge. Whenever one is consulted by a patient with persistent "cerebral" symptoms, such as vertigo, headache, etc., a careful and thorough examination for ear disease should be made, especially if these symptoms develop after any occurrence which may have induced ear disease or caused the impaction against the drum-head of an unsuspected foreign body. It is important to note that small foreign bodies in the ear may produce prominent subjective symptoms, and even actual otitis, by prolonged irritation.

**CASE VI.** *A Cotton-wool Wad in the Tympanum; the Drum-head lost by Otitis Media Purulenta of nearly Thirteen Years' Duration; Removal of a Polypus Eleven Years before; Removal of the Wad with Probe and Forceps; Cure of the Otorrhœa in Five Months, with an Intercurrent Attack of Scarletina.*—A school-boy, aged fifteen years, applied for treatment on January 29, 1888. A specialist of this city had removed a polypus from the affected right ear eleven years before, and subsequently treated him for otorrhœa six years. He was then placed under the care of another for a while. After this the patient was creditably treated by the family physician, who saw him at intervals. Upon discovering that a cotton-wool wad had become deeply displaced, he referred the patient to me for subsequent attention. The patient complained of whistling and blowing

tinnitus, deafness, and a mephitic discharge from his right ear. He had no earache.

Examination showed a cotton-wool wad deeply displaced, upward and inward, in the right tympanum. The drum-head was destroyed, except its anterior edge, in which seemed to be imbedded the malleus, its posterior attachments apparently divided long ago. After removal of the wad of cotton-wool with a probe and forceps, the tympanum seemed filled with granulation tissue, pus, and whitish desquamated epithelium. The incus and stapes could not be found. The tip of the promontory was free from granulations. The Eustachian tube was freely pervious. Touching the outer wall of the attic with a cotton-wool brush produced a disagreeable sensation in the right side of the tongue.

Cleansing with peroxide of hydrogen, with local and internal medication varied according to indications, brought about a cessation of the discharge and disappearance of the granulation tissue. On February 3d he heard a forty-eight-inch watch at two inches with the affected ear; hearing for the voice was improving; and the tinnitus had disappeared. In May he contracted scarlatina, and, though he was singularly free from exacerbation of his ear trouble during the attack, yet it was followed by a relapse thereof. Treatment was resumed, and the ear was so far dried and hardened by the latter part of June that he was permitted to visit Europe. He could hear a loud voice at twenty-five feet with the affected ear at this time.

In cases of perforated or lost drum-head a foreign body in the tympanum or attic is a dangerous complication if neglected. In such cases, if the foreign body has reached the inner end of the canal, the syringe, if used at all, must be used with the greatest care, lest the foreign body be driven into the attic or antrum. *En passant*, this advice is apt in cases of cerumen and former otorrhœa. It is better to use some retracting instrument, such as a bent probe or hooked curette, until we have removed the foreign body to a point where it can more readily be seized with the forceps, when we complete its removal with this instrument. Satisfactory illumination of the parts and sight of the foreign body are essential in the performance of this operation.

*CASE VII. Suspected Foreign Body in the Ear; Slight Catarrhal Inflammation; relieved entirely by Treatment.*—A superintendent of a mining company, thirty-six years of age, presented himself for treatment on January 24, 1888. Several days before this he had thrown into his office stove a broken bottle, the crash being followed by a feeling as of a piece of flying glass entering the right ear. He at once unwisely probed his ear with a pin covered with a layer of handkerchief, but brought nothing away. Pressing upward on the lobule of his ear, a feeling of fullness in the ear was felt which had since persisted. He visited two separate physicians, who examined his ear, pronounced it all right, and advised him to let it alone. Upon expressing dissatisfaction with this opinion, the patient was referred by the latter to me, when I also found the canal empty and normal, the drum-head slightly retracted, and somewhat opaque and lusterless. A Politzer inflation of the ear, with mild internal medication, relieved his symptoms permanently.

A patient, his relatives, or his friends, may often insist upon it that a foreign body is in the ear and demand one's interference. Except where there is a live insect moving about in the ear, we should under no circumstances depart from the rule so wisely observed by the two physicians mentioned above: *No matter how positive a patient, his*

*relatives, or friends may be that there is a foreign body in his ear, never attempt the removal of such until you have first provided yourself with satisfactory illumination of the canal with a mirror; examine the ear thoroughly by ocular inspection and convince yourself of the presence of a foreign body.*

*CASE VIII. A Grain of Corn in the Ear; Harmless until disturbed; forced into the Cul-de-sac of the Canal by shifting of the Patient's Head during Efforts at Extraction; Ear syringed; "Blind Groping" with a Probe; Laceration of the Canal and Rupture of the Drum-head; Removal, under Anæsthesia, with a Hooked Curette and Foreign-body Forceps; Otitis Media Purulenta Consequent on Maltreatment.*—A school-boy, about twelve years of age, put a grain of corn into his right ear in the latter part of August, 1886. Upon his confessing this to his parents, they waited patiently for two weeks for its extrusion by decomposition. They then consulted a surgeon in the nearest town. He informed me recently that he found the foreign body well within the canal, but not against the drum-head. Having satisfactory illumination of the parts, he attempted removal with the angular forceps. He had barely touched it when the boy, feeling slight pain in the tender canal, resisted further interference with the forceps. The parents refused to permit the administration of an anæsthetic, and at their solicitation he endeavored, as a last resort, to syringe it out, but failed, telling them that anæsthesia was absolutely necessary, and wisely declined to treat the case further without it. The patient was taken in a few days to a neighboring State, where two separate physicians attempted removal without anaesthesia. It was stated that "they blindly groped for the corn" with a probe. The patient was then referred by them to a medical practitioner of this city, who, after unsuccessful attempts at removal, requested me to perform the operation at his office, which I did as follows: Chloroform having been administered to the resisting, unwilling patient, examination showed the auricle highly congested; the canal greatly lacerated; traumatic inflammation of the entire cartilaginous canal wall; the tegmen of the canal denuded of soft tissues and lacerated to the bone in places; the membrana flaccida scraped, and the pars vibrans membranæ tympani perforated at its posterior-superior quadrant, causing otitis media purulenta; a foreign body in the *cul-de-sac* of the canal lying against the lower half of the drum-head. By carefully cleansing and drying the parts with a cotton-wool brush, and laying back the ragged edges of the lacerations, a speculum was readily introduced through which the deeper parts as described were seen as well as the foreign body, which seemed to be, as stated, a rounded grain of corn. With a hooked curette the foreign body was gently extracted to the isthmus of the canal, where it was seized with a Sexton foreign-body forceps and readily removed. Haemorrhage followed, but was easily checked with a stream of hot water. A cotton-wool wad was temporarily inserted, with the expectation of further cleansing the canal and insufflating some vulnerary powder. No further opportunity of examining the ear was tendered me, but the medical practitioner afterward informed me that the patient was recovering.

In the "Medical News" for March 1, 1884, page 242, was reported by me, from Dr. Sexton's aural clinic, a case very closely resembling this last one, together with eight others of foreign body in the ear, occurring during my service on the surgical staff of the New York Eye and Ear Infirmary. You will find a comparison of these profitable and interesting. Case VIII, which I have just presented to you, shows how harmlessly a foreign body may remain within the lumen of the meatus, provided it is not interfered with. There is always a drooping of the cartilage of the concha

where it joins that of the canal at its superior and posterior rim; this makes a kind of drop-valve which may retain a foreign body when once introduced within the canal. Often, in such cases, simply drawing the auricle upward and turning it forward will open this valve and permit the foreign body to fall out. If this is unsuccessful, when the head is jarred also, the aural speculum should be introduced, and, under illumination and in sight, the bent end of a probe or a foreign-body hooked curette should be carefully passed over the foreign body and then depressed beyond, so that the hook or ratchet-like teeth can seize the intruder and draw it out. With very nervous patients and children, should the foreign body become displaced inward toward the isthmus, the patient's head should be held steady by a strong assistant, and a quick, sharp stream of warm water should be directed above or in corkscrew fashion past the foreign body. This can very readily be done if the stream is directed upward as it enters, for the canal is largest at this point where the foreign body lies loosely, as it does, and the stream of water returning below will carry it toward the meatus, whence it must be removed as directed above. If, however, the stream of water is cast directly inward in the axis of the canal, it will do harm only, and drive the foreign body farther toward or to the drum-head. In steady patients a foreign body on the outer side of the isthmus can be more readily removed with the foreign-body forceps, hooked curette, or bent probe. Whenever the patient is a child or very restless you should not attempt instrumental interference with a foreign body lying near the isthmus unless you are prepared to administer an anæsthetic should your manipulations prove unsuccessful, or the foreign body be forced beyond the isthmus, the narrowest part of the canal, falling into the *cul-de-sac*, since the floor here declines inward. The foreign body will then lie lower in the line of vision and its lowest part will be hidden from sight by the intervening isthmus. It will now rest against the drum-head. Here, then, is a condition of affairs demanding the interference of a *skillful operator only*. No one unfamiliar with the manipulation of instruments in the deeper part of the auditory canal should have the temerity to interfere here except in an emergency, and then by syringing, and that not too forcibly, lest he rupture the drum-head. Should this prove ineffectual to remove the foreign body, the patient should be placed in charge of some practitioner familiar with this operation. If the foreign body is moderate in size and the hooked curette can be passed a trifle over its upper point without touching the membrana tympani, it may be withdrawn thus from the *cul-de-sac*—the most difficult part of the operation—when you should proceed as advised above. If, however, the foreign body is large, or impacted anywhere in the canal, or, as in some cases, can not be passed by a hooked curette, it must then be seized between the teeth of a Sexton foreign-body forceps and withdrawn, at least as far as the outer side of the isthmus. Skill in the use of this, as of every other instrument, is essential to the development of its advantages, as is illustrated by the failure of some in using the Sexton forceps.\*

Every self-reliant physician who has good eyesight, a steady hand, and instruments suitable for illumination of the ear and the performance of this operation, bearing in mind the facts to which I have drawn your attention, should not hesitate to attempt it. *Never introduce any instrument into the ear unless you can see where and how it is acting.* Try to discover the indications in the individual case presenting, determine exactly how you can best meet them, proceed with deliberation and care, and, above all, *hasten slowly.*

## THE PROPHYLAXIS OF RINGWORM OF THE SCALP.\*

BY FREDERICK J. LEVISEUR, M. D.,  
PHYSICIAN TO ST. BARTHolemew's HOSPITAL AND DISPENSARY.

It certainly has not escaped the attention of medical men throughout this country that the number of cases of ringworm of the scalp has very much increased during the last decade. While the governments of European countries use all possible exertion to prevent this contagious disease from spreading, we remain apathetic. America even welcomes to her hospitable shores scores of immigrants whose children bear on their heads the unmistakable signs of this disgusting disease.

If we do not heed (perhaps in a spirit of ideal unselfishness) the danger arising therefrom to our families and ourselves, we ought to take into serious consideration at least the deplorable condition to which those children of the poorer classes are reduced. Breathing the stimulating air of this free country, and surrounded by all the blessings of modern civilization, they find themselves prevented, Tantalus-like, from partaking of what is so liberally offered to all the rest. To these children the schools are closed. Whenever they become sick or destitute, admittance into hospitals and charitable public institutions is often refused and always rendered difficult to them, on account of the contagiousness of their scalp disease. In the dispensaries and outdoor departments of hospitals these little patients are rarely so fortunate as to meet with a physician who has the time and inclination to institute a thorough treatment. It is hardly necessary to point out these evils more minutely. They are so glaringly conspicuous that any suggestion of measures by which they might be remedied will be sensible.

It is the object of this paper to call the attention of the general practitioner, as well as the specialist, to the importance of the prophylaxis of ringworm of the scalp, and to point out a few general measures for the control of the disease wherever it presents itself in public or private practice.

Three points seem to me to deserve special consideration:

*First.*—It is necessary to make a correct diagnosis of ringworm of the scalp as soon as it comes under observation.

*Second.*—The treatment of the disease should contain in itself some elements of prophylaxis.

\* Read at the fortieth annual meeting of the American Medical Association, Newport, June 25, 1889.

\* See "Archives of Otology," June, 1888, pp. 106 *et seq.*

*Third.*—Great care should be exercised before pronouncing a patient cured and fit to go back to school or be admitted into an institution.

A wrong diagnosis, a delay in instituting proper treatment, is frequently the cause of epidemics. In examining cases it will be well to begin with a careful inspection of the hair. As is well known, the hair becomes affected very early in ringworm of the scalp, and its changed condition remains pathognomonic throughout the entire course of the disease. The hairs look as if "nibbled" off close to the scalp, the short portions that remain appearing dry and bent or twisted. On closer inspection with a lens, they are observed to be lusterless, more or less swollen or bulged here and there, and on pulling at them they are found to be quite brittle. They may be surrounded with a white pulverulent matter, which is a compound of epithelial *débris* and fungus. The presence of these short broken-off hairs is very characteristic. The changes affecting the scalp may be looked upon as the results of various degrees of irritation produced upon the tissues, either by the presence of the fungus or by medical interference or by both. The intensity of this reaction, as it were, is in no relation to the quantity or quality of the fungus. It varies according to the individual disposition in every case, and conveys to the observer no intimation as to the severity of the disease proper. In some cases there is no irritation at all, or very little. In others (especially in recent cases), small, rounded or irregularly shaped, dull-red patches are present. These patches are spoken of in most of the text-books as "erythematous"; but in reality their color is of a peculiar kind, which may be described as follows: The redness looks as if painted on the surface of the scalp with a material which has penetrated only the superficial layers of the epidermis. If the hair follicles are the special seat of irritation, pustules or small furuncular abscesses will make their appearance. It may finally come to the formation of "kerion"—inflammatory, œdematosus, boggy, honey-combed tumors, discharging from the follicular openings a mucoid secretion. Viewing these symptoms of ringworm of the scalp in this light, we can readily understand that the disease may be most likely to assume the character of seborrhœa and eczema, passing through all the different stages, from the dry, slightly scaly variety of the former to the pustular, crusted form of the latter. Eczema and seborrhœa, in fact, frequently coexist with ringworm of the scalp, and render a correct clinical diagnosis very difficult, sometimes impossible.

Cases of ringworm of the scalp which have passed through a high degree of irritation and are nearly cured may exhibit the smooth bald patches like those met with in alopecia areata. In France the opinion is prevalent that there exist two forms of alopecia areata—a contagious and a nervous one. It is impossible (so it is asserted) to make a differential diagnosis between these two forms. All persons affected with alopecia areata are consequently subject to strict regulations recently put in force by order of the French government in all schools and military establishments. The identity of the contagious form of alopecia areata and ringworm of the scalp has not been proved; so much, however, is evident, that we should look upon cases

of alopecia areata, especially when occurring in children, as a possible source of infection and danger to others.

I need not dwell upon the differential diagnosis between ringworm of the scalp and psoriasis or lupus erythematosus, because it commonly offers no difficulties. To mistake a case of favus for ringworm, or *vice versa*, would make but little difference in regard to prophylactic measures.

Microscopic examination is indicated in all doubtful cases. A few hairs and scrapings taken from the border of a suspicious patch are soaked in a mixture of equal parts of water and liquor potasse and then examined with a magnifying power of about three hundred diameters. It is advisable to look not for the mycelia of *Trichophyton tonsurans*, which, as you know, are often absent from specimens, but for the conidia or spores. These round little bodies, which are generally present in large quantity, are highly refractive, of a uniform size, and frequently arranged in chains. Besides this, their nuclear contents, their double-contoured outline, their tendency to bud, and their non-alteration by ether, are distinctive features. In making a microscopic examination I usually begin by searching the field with a low power for remnants of broken-off hairs and short stumps, because these are most likely to be found invaded by the characteristic spores.

To the use of the microscope we should resort more frequently than we really do. It must, however, be remembered that the absence of the fungus (microscopically demonstrated) has only a relative value, while the presence of the fungus is the positive and scientific proof of the correctness of the clinical diagnosis—ringworm of the scalp.

Widely varying as are the opinions in regard to the treatment of ringworm of the scalp, there exists one point on which most authorities agree. That is the beneficial action of epilation. The rooting out of the diseased hairs acts as an antiseptic, an irritating, and a prophylactic measure. It combines these very desirable qualities, however, only if it is properly executed. If it is done carelessly or left entirely to hands untrained for the purpose, it will work more harm than good. Instead of acting as an antiseptic, it may give rise to numberless little wounds where septic matter may easily enter. Instead of being the ready means of getting rid of a large quantity of infectious material, the latter may be carelessly strewn about and thus brought in contact with the healthy scalps of other children. Instead of properly irritating or, rather, stimulating the deeper layers of the scalp, it finally may produce severe irritation, requiring temporary cessation of the treatment. The manner in which epilation is practiced is furthermore all-important as to the amount of pain caused. While there is "howling and gnashing of teeth" wherever the epilating forceps is used by an inexperienced attendant, there is generally not a tear in the eyes of the children wherever it is done by an expert. A salve of salicylic acid, in a strength of from ten to fifteen per cent., applied the night before is a good help in rendering epilation easy. It still remains, however, a process which is very tedious and takes up too much of the physician's time. In France, where epilation on a large scale was first introduced in 1855, male and female servants are employed, whose whole duty consists in extracting the

hair of those patients affected with vegetable parasitic diseases. I have seen the *modus operandi* of these *épileurs* and *épileuses* (as they are called) at the hôpital St.-Louis, Paris, while following the service of Dr. Besnier. It is in the main that described by Bazin. "The epilators are seated, and cause the head of the patient to rest upon their knees. With one hand (generally the right) they hold the forceps as one holds a writing-pen; the other hand is applied to the part about to be epilated, with the thumb and index finger of which they put the skin on the stretch so as to keep it steady. They then extract the hairs, pulling them out in the direction of their axis, and only a small number at a time—two, four, six, or at most a small bundle. It is necessary to avoid epilating too quickly or too gently, there being an intermediate point which one can only arrive at after a little practice." The extraction of the hairs at the edges of the patches should first be effected, and from the edges the epilation should be extended inward toward the center.

Dr. Besnier, the eminent French dermatologist, devotes one clinie every week to the special treatment of outpatients affected with ringworm of the scalp. An *épileur* is attached to his service and prepares for treatment a large number of scalps every week. The hair pulled out is destroyed, and the forceps, towels, etc., are carefully disinfected after use. The remaining hair is kept closely cut, every two or three days the scalp being carefully clipped with short scissors. There are three *épileuses* at the "hôpital des enfants malades" and two at the "hôpital Trouseau."

Epilation practiced after this manner has turned out to be a measure not only of great curative but also of high prophylactic value. The extraction of the hair by means of epilating sticks has been recommended by Dr. L. D. Bulkley. It is an excellent means of quickly getting rid of many of the loose and brittle hairs, and, if preceding epilation with the forceps, has proved to be a practical and time-saving measure.

In order to prevent self-inoculation, as well as the infection of others, some physicians keep their patients' scalps soaked with greasy substances containing the antiparasitic remedies, or apply even an impermeable dressing. These measures are liable to cause much undue irritation, which is a great drawback in the treatment of ringworm of the scalp. Salves with pure vaseline as constituents are preferable in this direction. It has been suggested by some authors to apply some of the customary remedies dissolved or suspended in liquor gutta-percha or collodion. These substances form an adhering layer when painted on the diseased spots. Though I do not share the popular idea that they will act by choking the parasite, as it were, I think they are very valuable as precautionary measures. Simple tincture of benzoin, I think, is still more reliable in this regard. It can be applied all over the scalp by aid of a soft nail-brush, and dries quickly into a thin film, which keeps much of the infectious material confined to its place. Besides this, it combines the highly antiparasitic quality of alcohol with that of benzoin. I have used with good success a solution of bichloride of mercury in simple tincture

of benzoin (1 to 300) while treating a large number of cases of ringworm of the scalp. The physician should always insist on his little patients' wearing skull-caps made of linen or some other material which can be washed easily. The use of towels, brushes, combs, etc., by the diseased and healthy in common must be strictly prohibited. We should never weary of laying proper stress on this point, and explain it to the parents and relatives of our patients again and again.

When is a child permanently cured of ringworm of the scalp? This question is not easily answered. "When the formerly diseased patches," says Tilbury Fox, "are covered over with fine, downy new hairs, and all vestiges of the texturally altered ones have disappeared, then a cure may be pronounced, and then only; and this point can only be determined by accurate and minute examination by a lens or the microscope." This is very true in cases where the disease has existed in one or a few circumscribed patches. In cases where the disease has been distributed all over the scalp it will be difficult to select hairs and scales for microscopical examination, and the possibility of some slight signs of the disease escaping detection is very great. The only safe way, therefore, will be to keep the persons under observation for two or three months, making from time to time a careful inspection of their scalps. It may be of importance to trace an epidemic of the disease to its original source. I will therefore not forget to mention the well-known fact that some domestic animals—such as horses, cattle, dogs, and rabbits—may communicate ringworm to man. In Germany, as well as in France, there exist some regulations instructing the veterinary surgeons to seclude from military service those horses affected by the disease. That the air under certain conditions may become loaded with the germs of the fungus and thus spread the disease has been asserted by Tilbury Fox, but lacks the confirmation of others. Some of the prophylactic measures mentioned above find a place in the treatment of ringworm of the body, a disease which, in itself not difficult to cure, may give rise to ringworm of the scalp in the same individual or in others.

Now, in conclusion, what can be done to facilitate the carrying out of these general principles in public practice? We need, I think, a special service for the free treatment of vegetable parasitic diseases of the skin in some of the dispensaries of our large cities. This measure, though constituting a preliminary step only, would undoubtedly result in a great many advantages. It would afford a fine opportunity—

*First.*—For making extempore microscopical examinations for diagnostic purposes.

*Second.*—For studying the vegetable parasitic diseases of the skin, with a special view to their origin, *genus epidemicus*, and general prophylaxis.

*Third.*—For practicing epilation on a large scale by trained nurses.

The physicians in charge of these classes, furthermore, would become most competent in regard to all questions of public hygiene in this direction. They could frame rules as to preventing or checking epidemic outbreaks in

schools and public institutions, these rules to be printed and distributed among principals of schools, teachers, and superintendents. They might finally find it necessary to do what at present would meet with but slight approval—ask for interference by the law.

To these clinics, which need be held but once or twice a week, all the patients suffering from ringworm could be referred. To carry out this suggestion would be connected with little expense, which dwindles into nothing when we come to consider the amount of good which would thus be accomplished in the interest of the common welfare.

If ringworm of the scalp has once been introduced into a school or public institution, it generally spreads like fire. It requires the most energetic treatment and untiring efforts on the part of the physician, who generally has to content himself with keeping constantly under control what he is unable to stamp out. Let us therefore recall to memory the old Latin saying:

“Principiis obsta, sero medicina paratur.”

687 LEXINGTON AVENUE.

**Supra-clavicular Hernia of the Lung.**—“Professor Choré, of Brussels, reports an interesting case of supra-clavicular hernia of the lung occurring in a child of about three years of age. The child came into the hospital for a large cold abscess of the left thigh; this was operated upon by scraping out and subsequent drainage. A short time afterward it was observed that a tumor had formed over the left clavicle, about the size of an orange. The skin covering it was not reddened or discolored. The tumor was not tender; on percussion it gave a tympanitic note, and was found to be completely reducible; on auscultation, a soft vesicular murmur was heard, together with somewhat prolonged expiration, indicating the existence of pulmonary emphysema; the tumor was soft to the touch, giving a sensation of false fluctuation, such as is sometimes noticed in white swelling of the knee. It appeared suddenly, and seemed to be likely to increase in size, as whenever the child cried or moved about it became larger. It was situated immediately behind the clavicle, extending into the space between the scapulae; laterally its boundaries were indistinctly marked; it extended upward to about three fingers' breadth above the clavicle. The diagnosis made was that of pulmonary hernia; the only affection with which it could be confounded was localized subcutaneous emphysema, or a serious congenital cyst; it was, however, quite evident, from auscultation and percussion, as well as from the history and the complete reducibility of the tumor, that it must be a pulmonary hernia. The child, when admitted into the hospital, was very thin and weak, and during the treatment of the abscess chloroform was required, which produced a serious amount of syncope, artificial respiration having in consequence to be kept up for some considerable time. Professor Choré suggests that the energetic movements then made, when the lung was rapidly distended, may have caused it to force its way through the lax connective tissue and the weak and wasted muscles of the supra-clavicular region. The treatment adopted was very simple. Reduction was made, and maintained by means of a piece of card-board well padded and fixed by a spica bandage. In this way a complete cure was obtained. Professor Choré is not aware of any other case of pulmonary hernia occurring in a child. Indeed, the condition is rare even in adults.”—*Lancet*.

**The Hygienic Congress at London.**—We learn from the “Lancet” that the organization committee of the International Hygienic Congress, to be held in London in 1891, has met, Sir Spencer Wells being chairman and Dr. Corfield one of the secretaries. The committee contains among others the names of the following: Sir Douglas Galton, Professor Frankland, Professor Hayter Lewis, Dr. Thorne Thorne, Dr. Mapother, Dr. Mouat, and Mr. Ernest Hart. This committee will presently be enlarged so as to represent the varied interests of public hygiene, and a preliminary circular is in preparation.

D. APPLETON & CO.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JULY 13, 1889.

THE RECOGNITION OF VULVO-VAGINAL INFLAMMATION  
IN CHILDREN.

DR. F. SPAETH, of Hamburg, in an interesting article on this subject, published in the “Münchener medicinische Wochenschrift” for May 28th, arrives at certain conclusions which are of considerable practical interest, especially from a medico-legal standpoint. He shows that since the discovery of Neisser's gonococcus it has been recognized that many cases of vulvo-vaginal inflammation in children which before would have been set down as of unknown origin, or regarded purely as complications of the acute exanthemata, are really due to specific infection. Fraenkel reported eighty-four cases occurring in 1881 in the Hamburg General Hospital during an epidemic of scarlet fever, but did not seem to recognize the specific character of the discharge, although he constantly found in it a coccus that closely resembled Neisser's. Cseir, who observed a similar epidemic, not only found the specific coccus, but proved that the discharge was gonorrhœal, since it produced the characteristic ophthalmia. Hofmokl has recently confirmed the latter's statements. Spaeth's cases were twenty-one in number, the patients' ages ranging from three to eleven years. In fourteen cases Neisser's coccus was found in the discharge, and in every instance the urethral mucous membrane was involved in the inflammatory process, while in the seven children with non-specific leucorrhœa the urethra was not affected. The latter canal seems to be the favorite seat of the gonococcus; hence the inflammation is most severe and persistent here.

In order to establish the diagnosis of gonorrhœa in little girls it is only necessary to irrigate the vagina thoroughly, then to press a drop of pus from the urethra, and to subject it to microscopical examination. The source of infection it is not easy to discover. In one half of the writer's cases the mother had gonorrhœa. There is no doubt that the epidemics which occur in families and hospitals, in which the disease is frequently regarded as a complication of scarlet fever, when it is merely a concomitant, are due to the use of infected clothing, sponges, *pots de chambre*, or thermometers. Impure connection is a comparatively infrequent cause. This is important in view of the fact that suspicion is sometimes directed toward an innocent man, who may have gonorrhœa at the time when he is accused of assaulting a child. Even if the vulvo-vaginal inflammation in the latter is proved to be specific in character, the probability of the infection being transmitted through one of the above-mentioned media should render a medical witness very cautious about giving a decided opinion as to its exact source in a given instance.

## MINOR PARAGRAPHS.

## TOBACCO-SMOKING AS A SAFEGUARD AGAINST INFECTIOUS DISEASE.

At a recent meeting of the Vienna *medicinisches Doctoren-Collegium*, an interesting discussion on tobacco-smoke and diphtheria took place, the impulse toward the discussion having been given by a communication on this subject by Dr. S. Hajek, of Vienna. Induced by the experiments of Tassanari, of Pisa, on the destructive influence of tobacco-smoke on bacteria, Dr. Hajek had made researches in the *Stadtphysikat* of Vienna, in order to determine the proportion of the cases of diphtheria among smokers and among non-smokers. For this purpose he had collected data for the preceding three years, considering all individuals of the male sex upward of twenty-two years of age as smokers. Among all these, three thousand persons had had diphtheria during that time, and the proportion of the smokers to the non-smokers was, on an average, 1 to 2·8. Dr. Hajek, moreover, said that he would discuss this subject more exhaustively in a work to be published shortly, as he was of the opinion that in bacteriological and hygienic questions a certain importance, though a minor one, should be given to statistics. The speaker directed attention to a statistical work by Professor Oser bearing on this subject of the proportion of cases of diseases in men and in women in a certain epidemic of exanthematus typhus. Oser had observed that three times as many women as men were affected by the disease. The explanation of this difference was considered to be that men, in most cases lived for only a few hours in insanitary dwellings, and thus became infected less easily than women. This difference ought also to be taken into account in collecting the data for diphtheria. The speaker wished, moreover, to emphasize the difficulty of determining the exact number of smokers. Dr. Neudorfer called attention to the fact that a real destroyer of bacteria, pyridine, was present in tobacco-smoke. Dr. Schiff added that in all bacteriological laboratories smoking was forbidden, as the smoke undoubtedly hindered the growth of the cultivated bacteria.

## NIGHT TERRORS IN CHILDREN.

DR. G. L. ULLMAN, in the "Albany Medical Annals" for June, treats of *pavor nocturnus*, or "night terrors" in young and excitable children. The causes are various, chief among which are some form of vivid impression, violent play, and great hilarity in the evening or the latter part of the day. He condemns all severity of treatment or harshness of voice on the part of the parents. Soothing measures are the best, and in the event of "spells" recurring with some frequency, he has found the bromides useful, to be given shortly before bedtime. Valerian and asafoetida have been of service. "The charming advice of good nature, coupled with time," always meets his expectations admirably.

## GUY'S HOSPITAL.

This institution has recently undergone a singular experience in its losses by death. Within about a week of one another there have died an emeritus member, ripe in years and honors and known as a "fashionable" practitioner; also another member, a pale, young enthusiast of a student. Death has touched the two extremes of age and service. The death of the younger man is regrettable from every point of view, as he was at the opening of a career that promised to be both brilliant and useful.

Dr. George Owen Rees, F. R. S., consulting physician to the hospital, died on May 27th, aged eighty-four years. He was a

co-labourer with Dr. Bright, and fifty-three years ago published his work on the analysis of the blood and urine. Dr. Rees was physician extraordinary to the Queen. He entered Guy's as a student in 1829, and retired from active duty there in 1873. He was Lettsomian lecturer in 1850 and Croonian lecturer in 1857, and delivered the Harveian oration in 1869. "He was a veritable Nestor of the profession, in the best sense of the term." Dr. Leonard Charles Wooldridge, also of the staff, died unexpectedly on June 6th, at the age of thirty-two years, after eating an anchovy sandwich. An autopsy revealed congestion and ecchymosis of the stomach and duodenum, and numerous follicular ulcers of the colon, with moderate cardiac dilatation. Death had taken place by syncope. Overwork at the hospital had contributed to this untimely ending of a most promising career. The deceased obtained his membership in the College of Surgeons about ten years ago. His medical degree was granted in 1886. In 1887 he became assistant physician at Guy's. He was a lecturer on physiology, and had assisted in the Local Government Board's scientific work. He was the son in-law of Sir Edward Sieveking. The "Lancet" speaks of his "rare genius and sleepless industry," and regards him as the most talented of the men of his own immediate period. His father was Leonard Wooldridge, a surgeon of repute at Overton.

## BADGES FOR PARISIAN STUDENTS.

THE Parisian students have recently decided to wear certain marks of distinction to denote the courses which they are pursuing. Medical students will wear, on a *boutonnière* of red and black, a little violet band with a skull made of some white metal. Army medical students will wear, on a garnet *boutonnière*, the symbol of health—the rod of Esculapius in gold. Students of pharmacy will be distinguished by the emblem of pharmacy, a silver shaft encircled by a gold serpent, worn on a green *boutonnière*.

## GARROD'S SULPHUR LOZENGE.

AN interesting account of the therapeutics of sulphur has lately appeared in the "Lancet," written by Sir Alfred B. Garrod. Dr. Garrod regards small and long-continued doses the best means of securing the remedial influences of this drug; and he has found that a lozenge containing five grains of sulphur with a grain of cream of tartar meets nearly all the indications calling for a long-continued administration. This lozenge, named the "compound sulphur lozenge," is convenient and not disagreeable in taste; patients can ordinarily be readily induced to persevere in using it for an almost indefinite period. The lozenges have been in use about five years, and are gradually growing in popularity. Dr. Garrod has been informed by one of the makers of medicinal lozenges that he has sold and sent out, in the course of six months, as much as three hundred-weight, or at the rate of 220,000 per annum. Dr. Garrod's experience will at least lead many medical men to test the virtues of sulphur in a range of troubles for which it is at present but rarely employed, more especially if they can have access to a form of lozenge as convenient and free from objection as the one described in his paper. If his experience is repeated in this country in regard to "hepatic colic," a term which covers a multitude of the indigestions, we do not require a prophet to forecast that the lozenge will have here a demand as great as, or greater than, in London. It will probably eventually come into the vest-pocket of a great proportion of our countrymen who eat rapidly, and who expect attacks of "colic" from time to time, without appreciating that they are preventable by a proper mastication of food. In hemorrhoidal conditions not

suitable for surgical treatment, and in cases of bleeding from the rectum, benefit has been derived from one lozenge every night for weeks or months. It commonly mitigates the pruritus and the whole chain of accompanying symptoms. So far as we have been able to learn, this compound sulphur lozenge has not yet been made in this country, but it is highly probable that it will be laid before the profession in a short time.

#### SCURVY IN THE RUSSIAN ARMY.

SCURVY having been endemic at some of the garrison towns of Russia, says the "Lancet," an army surgeon, who set himself to the task of locating its causes, has reported that the bad food served to the soldiers will readily explain its existence and increase. He recommends that the army purveyors be discharged and that abattoirs be established in all garrison towns, and that all "superior" flour be excluded from the soldiers' dietary. His scheme for the feeding of the men includes the use of a vegetable soup each day in the following proportions: Twice a week, cabbage soup; twice, potato soup; and one day each, a soup of turnips, peas, and macaroni.

#### THE STOLIDITY OF THE CHINESE.

ACCORDING to the "Deutsche Medizinal-Zeitung," an English physician residing in China points out that the most characteristic difference between the Chinaman and the Caucasian of Europe lies in the former's lack of nervousness. We in America, who have seen the Chinaman working incessantly in his little laundry, shall find no difficulty in believing the statements of the English physician when he says: "The Chinaman can write all day, he can work all day, he can stand for a whole day in one position, weaving, hammering gold, or cutting ivory, without once being attacked by nervousness. This peculiarity makes itself apparent in early youth. The Chinaman can bear any kind of bodily exercise. Sport and play are to him unnecessary labor. He can sleep anywhere and in any position—amid thundering machines, deafening noises, the cry of children, or the wrangle of grown people; on the ground, in bed, or on a chair." In his own innocent way the Chinaman is almost a Sybarite.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 9, 1889:

DISEASES.	Week ending July 2.		Week ending July 9.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	11	3	15	2
Scarlet fever.....	71	7	54	3
Cerebro-spinal meningitis.....	3	3	1	1
Measles.....	88	4	39	3
Diphtheria.....	99	27	84	18

**Recent Deaths.**—Dr. Stephen Wickes died on June 8th, at Orange, N. J., having had an apoplectic seizure about three weeks before. He was born in 1813 at Jamaica, Long Island. He was educated at Union College, graduating when eighteen years of age. In 1834 he was graduated in medicine at the University of Pennsylvania. He practiced in Troy, N. Y., for several years, being associated with the eminent Dr. Thomas W. Blatchford. In 1852 he made Orange his permanent home, and there continued in practice until a few years ago. He was the author of a "History of Medicine in New Jersey and of its Medical Men from the Settlement of the Province to A. D.

1800," also of a monograph on "Sepulture." He had nearly completed a "History of Newark Mountain," to which he had given much of his attention for twenty-five years. He was the editor of the transactions of his State society from 1861. He was physician to the Memorial Hospital from 1873. He was a presiding elder in the Presbyterian Church and president of the Essex County Bible Society. He was a man of decided character, diligent, thorough, fond of research, and independent and original in his form of expression.

Dr. Philip F. Brakeley, of Belvidere, N. J., died on July 3d, aged seventy-five years. He had been for nearly half a century quite a prominent figure in medical affairs in the northern part of the State, occupying a position not unlike that of that other veteran, the late Dr. William Elmer, in the southern section. Dr. Brakeley was for about forty years the secretary of the Warren County Medical Society. Like Dr. Elmer, who was nearly his peer in years, he was an alumnus of the University of Pennsylvania, medical department, of the class of 1842. His death was ascribable to the advancing disabilities of age, hastened by disease of the heart.

Dr. William Robinson Findley died at Altoona, Pa., on July 5th, in his seventy-ninth year. He was a practitioner in Blair County for about fifty-eight years, and had been a permanent member of the State Medical Society since 1863.

Dr. Edward Tobie died on May 12th, at Buffalo, N. Y., at the age of fifty-eight years. He was one of the elders of the profession, and possessed of most noble traits of character. He had built up a very large practice, and his untimely death was seemingly due to the fact that he never spared himself. He was a graduate of the Geneva Medical College in the year 1855. His death was occasioned by a sudden and overwhelming apoplectic seizure.

Dr. John Jordan Brown, of Mifflinville, Pa., a representative in the last State Legislature, died on June 25th. He was found unconscious in his office and did not rally. He was a graduate of Jefferson Medical College, of the class of 1870.

Dr. Charles Bland Radcliffe, of London, died suddenly on June 18th, of bleeding from a varicosity on the surface of an umbilical hernia of large size and long standing. Dr. Radcliffe was well known for his special labor in the field of neurology, for his writings on convulsive disorders, and for his articles in Reynolds's "System of Medicine." He was one of the physicians of the National Hospital for the Paralyzed and Epileptic, and was formerly attached to the faculty at the Westminster Hospital, both as attending and as consulting physician.

Dr. J. Lewis Smith, Jr., a son of the well-known writer on diseases of children, died at his home in New York, on Monday, the 8th inst. The deceased, who was a young man of much promise, was a graduate of Bellevue Hospital Medical College, of the class of 1884.

**The New Hampshire Medical Society.**—At the recent annual meeting of this society the following officers were elected for the coming year: Dr. William Child, of New Hampton, president; Dr. Lyman B. How, of Manchester, vice-president; Dr. Granville P. Conn, of Concord, secretary; Dr. Daniel S. Adams, of Manchester, treasurer; and Dr. Thomas Hiland, U. S. N., of Concord, anniversary chairman. The society was incorporated in 1791, and preparations are in progress for a centennial meeting two years hence.

**The Hospital of Johns Hopkins University.**—Dr. Henry M. Hurd, of Pontiac, Michigan, has been appointed superintendent of the hospital. He is at present the superintendent of the State Asylum for the Insane at Pontiac.

**St. Francis's Hospital, Jersey City.**—The medical board has elected officers for the ensuing year as follows: President,

Dr. Nathan Gross Bozeman; secretary, Dr. Hamilton Vreeland; eurator, Dr. William Perry Watson.

**Change of Address.**—Dr. Frederick Peterson, to No. 201 West Fifty-fourth Street.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 16 to July 6, 1889:*

By direction of the Acting Secretary of War, the following changes in the stations of officers of the Medical Department are ordered: TEN EYCK, BENJAMIN L., First Lieutenant and Assistant Surgeon (recently appointed), ordered to Fort Leavenworth, Kansas; GARDNER, JOHN DE B. W., Captain and Assistant Surgeon, relieved from duty at Fort Leavenworth, Kansas, and ordered to Fort Reno, Indian Territory; Par. 3, S. O. 132, June 8, 1889, A. G. O., is so amended as to direct WALES, P. G., First Lieutenant and Assistant Surgeon, to report to Fort Huachuca, Arizona, for duty in place of Presidio of San Francisco, Cal.; WYETH, M. C., Captain and Assistant Surgeon, relieved from duty at Fort Huachuca, Arizona, and ordered to Fort McDowell, Arizona; Woods, LEONARD, First Lieutenant and Assistant Surgeon, relieved from duty at Fort McDowell, Arizona, and ordered to Presidio of San Francisco, Cal. Par. 2, S. O. 138, A. G. O., June 15, 1889.

FORWOOD, WILLIAM H., Major and Surgeon. By direction of the Secretary of War, the extension of leave of absence on surgeon's certificate of disability granted in S. O. 118, May 22, 1889, from this office, is further extended four months on surgeon's certificate of disability. Par. 14, S. O. 142, A. G. O., Washington, June 20, 1889.

FISHER, WALTER W. R., Captain and Assistant Surgeon. The leave of absence for one month granted by S. O. 30, c. s., Department of California, and extended fifteen days by Par. 3, S. O. 37, c. s., from these headquarters, is further extended fifteen days. Par. 1, S. O. 41, Headquarters Division of the Pacific, San Francisco, Cal., June 12, 1889.

HARRIS, HENRY S. T., First Lieutenant and Assistant Surgeon. By direction of the Acting Secretary of War, leave of absence for two months is granted. Par. 13, S. O. 140, A. G. O., June 18, 1889.

CORSON, J. K., Major and Surgeon. Granted leave of absence for one month, with permission to apply for an extension of one month. Par. 2, S. O. 65, Headquarters Department of the Columbia.

HOFF, JOHN VAN R., Captain and Assistant Surgeon, is relieved from duty at Fort Reno, Indian Territory, and ordered to Fort Riley, Kansas. Par. 6, S. O. 145, A. G. O., Washington, D. C., June 24, 1889.

BACHE, DALLAS, Major and Surgeon, is relieved from duty at Fort Riley, Kansas, and ordered to report to commanding general, Department of the Platte, for duty as Medical Director of that department. Par. 6, S. O. 145, A. G. O., Washington, D. C., June 24, 1889.

WOODRUFF, EZRA, Major and Surgeon, is, by direction of the Secretary of War, relieved from temporary duty at Fort Monroe, Virginia, and will report in person to the commanding officer at Fort Hamilton, N. Y., for duty at that station. Par. 5, S. O. 146, A. G. O., June 25, 1889.

FISHER, WALTER W. R., Captain and Assistant Surgeon. By direction of the Secretary of War, the extension of leave of absence granted in S. O. 41, June 12, 1889, Division of the Pacific, is still further extended fifteen days. Par. 8, S. O. 146, A. G. O., Washington, June 25, 1889.

The leave of absence for one month granted Major J. K. Corson, Surgeon, by Par. 2, S. O. 65, e. s., Department of the Co-

lumbia, is extended one month. Par. 1, S. O. 45, Headquarters Division of the Pacific, June 24, 1889.

Leave of absence for twenty-five days, to commence on or about July 2, 1889, is granted Captain A. R. CHAPIN, Assistant Surgeon. Par. 6, S. O. 145, Division of the Atlantic, June 27, 1889.

GIBSON, R. J., Captain and Assistant Surgeon, reports arrival July 2, 1889, at Camp Lewis, Fisher's Island, New York, in compliance with Par. 5, S. O. 133, Division of the Atlantic, which designated him as medical officer for the encampment (rifle practice) at Fisher's Island, New York.

By direction of the Secretary of War, Captain ANDREW V. CHERBONNIER, Medical Storekeeper, will, in addition to his present duties, take charge of the office and perform the duties of acting assistant medical purveyor in St. Louis, Missouri, during the absence of Captain George T. Beall, Medical Storekeeper. Par. 2, S. O. 151, A. G. O., July 2, 1889.

Leave of absence for one month is granted Captain W. C. GORGAS, Assistant Surgeon, to take effect on the arrival of a medical officer to relieve him. Par. 2, S. O. 84, Headquarters Department of the Missouri, July 3, 1889.

By direction of the Secretary of War, leave of absence for two months is granted Captain GEORGE T. BEALL, Medical Storekeeper. Par. 8, S. O. 148, A. G. O., June 27, 1889.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the two weeks ending June 29, 1889:*

BEARDSLEY, GROVE S., Medical Inspector. Granted a year's leave of absence, with permission to leave the United States.

FEREBEE, N. M., Surgeon. Detached from special duty at Naval Academy and to await orders.

ROTHGANGER, GEORGE, Assistant Surgeon. Ordered to the Naval Hospital at Mare Island, Cal.

SIEGFRIED, C. A., Surgeon. Detached from the U. S. Steamer Quinnebaug, and to wait orders.

CURTIS, L. W., Passed Assistant Surgeon. Detached from the U. S. Steamer Quinnebaug, and to wait orders.

SMITH, GEORGE T., Assistant Surgeon. Ordered to the Army and Navy Hospital, Hot Springs, Arkansas.

#### Society Meetings for the Coming Week:

TUESDAY, July 16th: Medical Society of the County of Otsego (annual—Cooperstown), N. Y.

SATURDAY, July 20th: Medical Society of the New York Post-graduate Medical School and Hospital.

#### Letters to the Editor.

#### SUBLUXATION OF THE HEAD OF THE RADIUS.

133 WEST THIRTY-FOURTH STREET, July 8, 1889.

To the Editor of the New York Medical Journal:

SIR: Answering the letter of Dr. Van Arsdale in your issue of July 5th, please allow me to say that it is a matter of small importance whether my paper brought forward any original ideas. Not knowing of the papers of Moore, Van Sautvoord, and Streubel, I made a few simple experiments upon the cadaver, and published the results for what they were worth in your issue of June 22d. The question as to the real nature of the injury had puzzled me, but the experiments were satisfactory.

The specimen presented by Dr. Van Arsdale, as stated in

his letter, did not illustrate any of the points which I made in reference to the movements of the orbicular ligament, and that is why I did not do him "the credit to refer to it."

In answer to the important points in Dr. Van Arsdale's letter, I would say: 1. In spite of the close attachments of muscles to the anterior ligament, the fibers known as the orbicular ligament can slip over the head of the radius while the anterior ligament remains undisturbed. 2. The fact that in many cases the head of the radius can be felt anteriorly displaced does not speak against the theory of interposition, but rather in favor of it, for, the head of the radius being liberated from the loop of the orbicular ligament, the biceps muscle would naturally be expected to displace the head of the radius anteriorly. 3. If Dr. Van Arsdale will try to produce subluxation of the head of the radius while the biceps muscle of the cadaver is put upon the stretch, he will believe with me that the orbicular ligament can not slip over the head of the radius into the joint space except at a moment when the biceps muscle of the patient is relaxed and "off its guard."

ROBERT T. MORRIS, M. D.

## Proceedings of Societies.

### NEW YORK ACADEMY OF MEDICINE.

#### SECTION IN PRACTICE OF MEDICINE.

*Meeting of April 16, 1889.*

Dr. R. C. M. PAGE in the Chair.

**A Case of Purpura Hæmorrhagica.**—Dr. E. A. BRACKLOW presented a patient. Improvement of some duration had been obtained from the administration of sulphate of quinine in acidulous solution, but the old condition had returned sooner or later after every sort of treatment tried. There was associated kidney disease.

Dr. G. R. LOCKWOOD said he had been struck with the uncertainty in various writers as to what really constituted the morbid state present in or with purpura hæmorrhagia. Many spoke only of the essential cases, to the exclusion of those which were symptomatic—*e. g.*, occurring in scarlet fever, etc. Others associated purpura hæmorrhagia with a general cachexia due to poor food, residence in damp cellars, etc., and with swelling of the gums and loosening of the teeth; still others with anæmia, enlargement of the liver and spleen, retinal hemorrhages, and escape of blood on the mucous surfaces. The pathology, symptomatology, and treatment were not well defined, in other words; the literature on the subject, and especially the reports of cases, needed review and original study. The treatment of the condition had been unsatisfactory with the exception of one instance where the faradaic current, used for the first time when the patient was *in extremis*, had brought about recovery. There was one form of the disease not sufficiently recognized. It was common to hear of mild cases which were recovered from in which there were more or less frequent recurrences. But he referred now to instances where hæmorrhages and acute collapse came on very suddenly, the patient dying in profound nervous depression. Thus a soldier, in good health apparently when such an attack had come upon him, had died after an illness of only eighteen hours. In another instance a young lady had been seized with hæmorrhages into the skin, and from the nose, mouth, bowels, uterus, kidney, and stomach; the temperature had risen to 107° F., and after two days of profound nervous depression the patient had died in coma.

Dr. W. S. GOTTHEIL said he appreciated the confusion now

existing in the descriptions of purpura as distinguished from purpuric diseases, but thought no very marked distinction needed to be made between them. A first class should be made of cases where hæmorrhages occurred into the skin only (in which also recovery always occurred). In a second class should be placed the severe cases where hæmorrhages from the mucous membranes and internal viscera occurred. But, apart from this, he would have the pathological conditions under which the disease occurred studied in themselves, and named accordingly. The connection was the main thing, since purpura was only a symptom of quite a number of different affections.

**The Value of Simulo in Epilepsy.**—Dr. M. ALLEN STARE read a report of the results obtained from the employment of tincture of simulo in a number of cases of epilepsy and hystero-epilepsy. His conclusions were that it was without value in hysterical convulsions of every sort, in *petit mal*, and in procreative epilepsy, and that it was not the equal of the bromides in *grand mal*. But, on the other hand, it caused no general disturbance as the bromides sometimes did, and in such cases might be used to replace them as a means of reducing the frequency of real epileptic seizures. If used, he would advise that the dose be increased daily. The chief objection to the employment of the drug in ordinary practice was its expensiveness.

Dr. E. D. FISHER thought the drug worthy of trial. Some had found that if a third of the ordinary dose of the bromides was replaced by simulo, the effect of each drug was much enhanced.

Dr. L. C. GRAY had tried the drug in five different cases, both in combination and by itself. His experience with it had resulted in his entirely abandoning its use. Any change of treatment was followed by temporary improvement in epilepsy, but a value of this sort simulo had in common with too many other agents to be recognized as having a specific action.

**The Significance of the Crepitant Râle.**—Dr. FRANK W. JACKSON read a paper with this title, in which he had compiled opinions from various standard writers to the effect that the crepitant râle did not occur in pneumonia alone. There was a difference in the definition of the râle by various writers, but all practically followed either Laennec or Walshe. Laennec had located the origin of the sound in the pulmonary cells, believing it due to the breaking of bubbles of air forming in a serous exudation, and described it as a moist sound. Walshe described it as a dry crackling, comparable to the breaking of a fine tissue, and probably produced when stiffened air cells were distended. The reader believed both moist and dry crepitant râles occurred, having noticed them sometimes in the same patient on different examinations. More recent foreign writers made it due to a variety of possible conditions (thus to the tearing loose of the walls of the vesicles from a fluid, beginning edema of the lung, pleuritic adhesions, collapse of air vesicles, edema of the pleura dependent on old lung diseases, and the first stage of pulmonary apoplexy), as well as to the incipient stage of pneumonia. Dr. Leaming, in this country, had sought to enforce the view that all râles were of pleuritic origin, basing his belief on the finding of fibrin on the pleura, in cases where râles had been heard a few hours before death, and when the lung was completely solidified. He considered it a valuable sign of pneumonia and plthisis, but not as a positive indication of either. Dr. Loomis made the crepitant râle due to pleuritis; Dr. Delafield made it a friction sound; Dr. Roosevelt, a sound due most commonly, and perhaps always, to pleuritic rubbing, and occurring in pneumonia, plthisis, and dry pleurisy.

The speaker had a few observations of his own to offer from a strictly clinical point of view. The crepitant râle, in his experience, was not always persistent; that is, it often disap-

peared and then appeared again, from moment to moment. The very fine and dry crackling râles, coming in a gust or shower, were but rarely heard. The crepitant râle was heard in dry pleurisy, in pneumonia, and in phthisis, and in no case could one tell by the râle alone whether the case was one of pneumonia or not. Many patients whose only symptom was pain in the chest had crepitant râles, and this he believed to be due to dry pleurisy alone or to pleuritic adhesions. In œdema he believed the râle was subcrepitant of a very liquid character. There seemed to him a strong probability that the crepitant râle common to pneumonia, phthisis, and dry pleurisy was due to a pleuritic exudation.

His conclusions were that the crepitant râle was not pathognomonic of pneumonia; that it was heard also in phthisis, in dry pleurisy, and in broncho-pneumonia; that there was a strong probability that it was almost always due to pleuritic inflammation; and that the question as to whether it was also heard in œdema of the lung and in pulmonary apoplexy was as yet unsettled.

Dr. J. W. ROOSEVELT thought that among the many loose statements made in explanation of physical signs the loosest had been concerned with the causation of the crepitant râle. We were not yet in a position to say what the cause really was, in his opinion. Some had said that this râle was produced in the air vesicles; others, that it could not be there produced because the air did not move in these spaces. The latter statement he must absolutely deny. The inflation of lung tissue produced by even a small motion of the chest had been proved to the eye experimentally. We were told that the pleural surfaces alone produced this sound. Others said that crepitant râles could not arise in a solidified lung. He saw no reason why they should not be produced in the latter way. We overlooked the fact that a solidified lung moved, or else the pleura did not move with the chest. The solidified lung was capable of expansion, if only by the filling of the bronchi, as could be shown experimentally. Some spoke of it as a curious thing that the crepitant râle was heard only near the seat of pain, but it was equally curious that the pain did not correspond to the seat of the pleurisy and was located sometimes even in the other lung. Sometimes crepitant and subcrepitant râles were heard just before death, and the autopsy showed no pleurisy present. On the other hand, he could say from personal observation that these râles could sometimes be heard in cases of pure pleurisy. It was also heard in pulmonary œdema. If the pleura could produce the sound, why not also a solidified lung? His conclusion, therefore, was that the crepitant râle was valuable as a sign of either pleurisy or pneumonia only in connection with other symptoms.

Dr. W. W. VAN VALZAH agreed that the crepitant râle might appear in each of the several conditions named. A simple means of separating those cases where the source of the râle was in the pleura from those where it was in the lung itself was to fix the lower third of the chest-wall by throwing the arms about the patient's waist, and then having him breathe and cough. If, then, the stethoscope still revealed the existence of a râle, the source of the sound was evidently pulmonary. If, on the other hand, the pain on breathing and the râle were both suspended by thus clasping the chest, both had evidently come from a pleural affection. In pleuritic râles the extent over which they were heard was small, moreover. They were comparatively loud and harsh and the amount of sound varied much. In pneumonia the râle not of pleural origin was comparatively a faint sound, deep-seated, and varying little in amount.

The CHAIRMAN believed that the real crepitant râle originated in the lung, but might be imitated as a result of conditions in the pleura and bronchi, and in some cases indistinguishably.

## Book Notices.

*A Treatise on the Diseases of Women*, for the use of Students and Practitioners. By ALEXANDER J. C. SKENE, M. D., etc. New York: D. Appleton and Company, 1888. Pp. xiv-966.

DR. SKENE's well-earned reputation as one of the leading gynaecologists of America is in itself enough to insure a favorable reception of his book, and this will be the more heartily given after the work has been examined. Like the books published by Emmet and Sims, it voices the author's own ideas and methods of practice—deductions from his own observations to the almost entire exclusion of those of other authorities. All, or almost all, of the many mooted points with which the gynaecology of to-day bristles are not discussed by the author, whose aim has been to present the practical part of gynaecological surgery in brief, concise descriptions of the various disorders of the female sexual organs and of the modes of treatment which he himself follows, rather than a summary of all the methods now in vogue. Illustrative histories of cases are given with a view to the better explanation of details of treatment, as well as of the different phases of the same disease.

A large portion of the work is devoted to the diseases of the bladder and urethra, as one might fancy would be the case, for Dr. Skene has already contributed much to the literature of that subject. Some controversial matter has crept into this section of the work, but its presence is not manifest to a disagreeable extent.

The work shows that its author is nothing if not original, and is replete with practical suggestions and details of operative technique by which other eminent authorities might profit in many instances. The treatment of uterine myo-fibroma by the galvanic current is supported, and some stress is laid upon abnormal invagination of the cervix as a cause of uterine displacements. The chapters relating to the use and abuse of pessaries are most admirable, if one fault, to which subsequent attention will be paid, is ignored. The proper application of these much-abused instruments in the treatment of uterine displacements is clearly defined, as are the injurious effects of careless or ignorant use of the same.

The book will be welcomed by the practitioner of gynaecological experience as a valuable addition to his reference library, but it will be of but little real assistance to the student or tyro, as the fault just mentioned is apparent throughout its extent. This fault consists in the almost absolute neglect of mentioning the contra-indications to the use of the sound as a uterine repositor, and to the performance of operations involving the uterus or the circumjacent pelvic tissues. In gynaecological surgery pre-eminently should care be taken to prepare the patient for operation, and to postpone it until such time as may be required for preparation has elapsed and all evidences of acute pelvic inflammation have disappeared. Yet the only reference to this all-important subject is to be found in the statement, frequently recurring in the histories of the cases cited, that the patient was treated until she was in a condition which was suitable for operation, with no description of that condition and no caution against operating at any time or in any case. To the expert this is of no importance, but to the callow practitioner, who will blindly follow his text-book's directions, it may mean invariable pelvic peritonitis as a complication in his uterine cases. Again, ulceration of the vaginal and uterine walls resulting from the pressure of a neglected or ill-fitting pessary is very uncommon in comparison with the evil effects of the use of even perfectly fitting pessaries when the uterine ligaments are the seat of inflammation, or the enlarged, prolapsed ovary is cruelly pressed upon by the same misplaced instrument.

In general, the work is a concise exposition of the gynaecological surgery of to-day, and, though it treats its subject only from the standpoint of its author's experience and belief, it will well repay him who reads it carefully. Dr. Skene's teachings may be at variance with those of equally eminent authorities, but he adduces enough of clinical proof in support of his methods; and the quality of a pudding is best ascertained by an actual ingestion test, not by theoretical criticism of the recipe after which it had been constructed.

The book, in typography and illustrations, is a credit to the publishers. Numerous woodcuts and several colored plates illustrate the work and testify in regard to the ability of the artist.

*Clinical Lectures on Albuminuria.* By THOMAS GRAINGER STEWART, M. D. Edin., Fellow of the Royal College of Physicians of Edinburgh, etc. New York: William Wood & Co., 1888. Pp. xi-250.

This work is worthy of serious attention. The author details the results of personal observations apparently made with care. However much we may venture to doubt many of his conclusions, we can not overlook the importance of the facts presented. Unfortunately, the tables of statistics are by no means convincing. It is a great pity that more detail is not given. Dr. Stewart first tabulates the incidence of albuminuria in 505 "presumably healthy people," and finds albumin present in 166. Of these, the quantity was sufficient to be shown with cold nitric acid in 76, but in 90 picric acid only showed the reaction. This is a very large percentage, and certainly makes one think that more cases should be studied. Turning to page 37, we find a table of 450 patients with various disorders, of whom 136 showed albumin, 99 with nitric acid and 37 with picric acid. The author says that at first one is surprised to find 32.2 per cent. of presumably healthy people with albuminuria, while only 30.2 per cent. of the patients had it, but calls attention to the fact that of the former 76 and of the latter 99 showed albumin with nitric acid, and that therefore a larger proportion of the sick show a relatively larger *quantity* of albumin than the well. We find, however, in the 99 cases among the sick whose urine reacted with nitric acid, 43 of Bright's disease, 7 of probable Bright's disease, and 9 which were "accidental." Paying no attention to the latter, we have among 450 sick 50 cases of Bright's disease with enough albumin to react with nitric acid. Now, it seems fair to subtract these from the total, and then compare the remaining cases with those in the first table. We have among the healthy 76 in 505 whose urine reacted to nitric acid, while among the sick we have 49 in 400. The rather startling result is that 15.5 per cent. of persons in health have albuminuria, while among the sick only 12.25 per cent. (exclusive of those with Bright's disease) present this symptom! The number of cases examined is far too small. Another criticism which we must make on these tables is that their utility is much reduced by the omission of any statement of the whole number of cases examined in each class. When Dr. Stewart says that nervous affections do not seem a frequent cause of albuminuria, since he finds only 6 among 450 patients, it would be more valuable to us if he had stated the total number of nervous cases examined. The author continually compares his *classes* with the *whole series* of 450, instead of giving the numbers in each class in which there was or was not albuminuria. Two things we would note regarding these tables—first, that not five hundred and five, but at least five thousand cases should be examined before accepting Dr. Stewart's percentage results; second, that among the sick no tables of value can be made unless the number of cases in each class is considered as well as the whole number.

The author considers picric acid and cold nitric acid the most satisfactory qualitative tests for albumin, and seems to think the latter of more clinical value than the former. For quantitative estimation, Esbach's method is stated to be the best for clinical use.

The book, as a whole, is very interesting. The subject is carefully and clearly studied, and the various views of different authorities are fairly presented.

*Lectures to Practitioners on the Diseases of the Kidney amenable to Surgical Treatment.* By DAVID NEWMAN, M. D., Surgeon to the Western Infirmary (Outdoor Department); Pathologist to and Lecturer on Pathology at the Glasgow Royal Infirmary, etc. London: Longmans, Green, & Co., 1888. Pp. xv-472.

THE author has made a careful study of his subject and his book is interesting. It is to be regretted that he has not added a complete list of the authors and papers consulted. There is much to praise in the clearness of his style and the completeness of his descriptions; but we can hardly be satisfied with the paragraphs upon diagnosis. Like so many others, Dr. Newman first states that there is a close resemblance between various diseases, and then proceeds to give descriptions of symptoms which are so absolutely unlike that one wonders how he or any one else could ever make an error, or indeed see any similarity in the disorders. Now, it is not absolutely clear cases which usually cause error. In his description of renal swelling (page 97 *et seq.*) almost every paragraph contains the word "generally." This is well enough, but for the diagnosis of difficult cases we can not rely upon generalities; we want to know what unusual conditions may exist and how they are to be interpreted. We do not "generally" mistake either ascites or an ovarian cyst for a renal tumor or *vice versa*, and when doubt exists as to whether one or another of these is present, we have to deal with conditions which *resemble* each other, not with those which do not.

The book, except for the points noted, is very clear and good. Those who have much to do with surgical cases will find it worthy of study. The pathological descriptions are good. The indications for operations are clearly and rationally given. Rather elaborate statistics are tabulated showing the results of operations as well as other matters.

*Bright's Disease of the Kidney.* By ALFRED L. LOOMIS, M. D., LL. D., Professor of Pathology and Practice of Medicine, New York University Medical College, etc. Detroit: George S. Davis, 1888. Pp. 117. ["The Physicians' Leisure Library."]

In this book Dr. Loomis sets forth his views upon these important subjects in a manner which is disappointing. Although the style seems clear, yet one finds some difficulty in ascertaining exactly what the author means to say. The pathological anatomy given will hardly be accepted by most pathologists. The symptomatology is well handled. The causes of dropsy and albuminuria are not made plainer than has been done by earlier authors. The treatment indicated seems most rational and is worthy of the author. On the whole, the book can not be considered as a very valuable contribution to the literature of the subject.

#### GENERAL LITERARY NOTES.

AMONG recent foreign publications we note the following: ASSELIN & HOUZEAU, Paris.—P. Tillaux, "Traité de chirurgie clinique." Vol. II. 2d fasc. (6fr.) — D. Labbé, "De l'ozone. Aperçu physiologique et thérapeutique." (1fr. 50.)

J. B. BAILLIERE & FILS, Paris.—H. Thompson, "Leçons cliniques sur les maladies des voies urinaires." Transl. by Robert Jamin. (3fr.) —— Borry, "De l'enclavement de l'iris consécutif à l'extraction de la cataracte, principalement d'après la méthode française (historique), pathogénie, prophylaxie." (3fr.) —— E. Gautretet, "Uries (dépôts, sédiments, cailloux). Application de l'analyse urologique à la semiologie médicale, avec une préface de Leeorché." (6fr.)

O. BERTHIER, Paris.—L. N. Worthington, "Chimie inorganique et organique, botanique, zoologie."

CH. BREHM, Montpellier.—A. Jaumes, "La déclaration des causes de décès et des maladies épidémiques."

H. BRIAND, Angers.—G. Dupont, "De la perte de poids que subissent les cadavres dans l'air atmosphérique."

BRISTIND, Havre.—Le Gad, "Observations d'une épidémie de variole jugulée par les revaccinations en masse."

CERF & FILS, Versailles.—S. Y. Ménard, "Note sur la maladie des chiens."

A. COCCOZ, Paris.—L. A. Demelin, "Documents pour servir à l'histoire anatomique et clinique du segment inférieur de l'utérus pendant la grossesse, l'accouplement et les suites de couches." (3fr. 50.)

A. DELAHAYE & BABÉ, Paris.—B. J. Narich, "À propos d'une opération de céphalotripsy sans broiement chez une femme à bassin oblique-ovulaire.—Petite modification dans le cranioclaste."

E. DESHAYS, Rouen.—R. Brunon, "Réflexions à propos d'un nouveau cas de myosite infectieuse primitive."

O. DOIN, Paris.—L. Tripiere, "Guide pratique de petite chirurgie." —— Charlier, "Traitement spécifique de la phthisis pulmonaire par le cuivre." (1fr. 75.) —— J. Ronvier, "Hygiène de la première enfance." —— B. J. Narich, "Expériences avec le cranioclaste de Carl Braun (de Vienne) dans les bassins très retrécis et proposition d'un nouveau procédé d'extraction du fœtus avec le même instrument."

BUREAUX DE L'ENCÉPHALE, Paris.—Rouillard, "Les amnésies (valeur sémiologique, étiologie, classification)." —— H. Savage, "Des troubles d'esprit développés à l'occasion de fiançailles." Transl. by V. Paraut.

BUREAU DU JOURNAL DE MÉDECINE DE PARIS, Paris.—J. Jasenriez, "Quelques considérations sur les stations climatériques françaises."

LECROSNIER & BABÉ, Paris.—J. Renaut, "Le milieu intérieur et le tissu conjonctif lâche et modelé." —— G. Thermes, "Traité élémentaire d'hygiène et de thérapeutique de l'hystérie." —— De Wecker and E. Landolt, "Traité complet d'ophtalmologie." Vol. iv, 3d fascic. (20fr.) —— G. Wickham, "Appareils de Wickham pour le traitement des hernies." (1fr.)

#### BOOKS AND PAMPHLETS RECEIVED.

Lectures on Massage and Electricity in the Treatment of Disease (Masso-electro-therapeutics). By Thomas Stretch Dowse, M. D., Fellow of the College of Physicians of Edinburgh, etc. Bristol: John Wright & Co., 1889. Pp. xix-379.

Synopsis of Human Anatomy, being a Complete Compend of Anatomy, including the Anatomy of the Viscera, and numerous Tables. By James K. Young, M. D., Instructor in Orthopedic Surgery and Assistant Demonstrator of Surgery in the University of Pennsylvania, etc. Philadelphia: F. A. Davis, 1889. Pp. ix, 3 to 393. [Price, \$1.40.] [Physicians' and Students' Ready Reference Series.]

Darwinism. An Exposition of the Theory of Natural Selection, with some of its Applications. By Alfred Russel Wallace, LL. D., F. L. S., etc. With Map and Illustrations. London and New York: Macmillan & Co., 1889. Pp. xvi-494. [Price, §1.75.]

Strathpeffer Spa; its Climate and Waters. With Observations, Historical, Medical, and General, descriptive of the Vicinity. By Forescue Fox, M. D. (Loud.), Fellow of the Medical Society of London. Illustrated. Loudon: H. K. Lewis, 1889. Pp. xvii-165.

Transactions of the American Orthopaedic Association. Vol. I. Published by the Association, 1889.

The Medical Directory of Philadelphia, comprising Lists of Physicians, Dentists, Druggists, and Veterinarians in Philadelphia and Camden. Together with Descriptions and Details relating to Colleges, Hospitals, Dispensaries, Training Schools, Homes, Reformatories, and Charitable Organizations; the Code of Ethics of the American Medical

Association; and Laws relating to the Professions represented. 1889. Philadelphia : P. Blakiston, Son, & Co.

Transactions of the College of Physicians of Philadelphia. Third Series. Volume the Tenth. 1888.

Seventy-second Annual Report of the Managers of Friends' Asylum for the Insane.

The Radical Cure of Hernia. By Thomas W. Kay, M. D. [Reprinted from the "Maryland Medical Journal."]

Constitution and By-laws of the New Mexico Medical Society, with History. Adopted December, 1885 ; revised April, 1889. Las Vegas, New Mexico.

On Unusual Methods of acquiring Syphilis, with Reports of Cases. By L. Duncan Bulkley, A. M., M. D., of New York. [Reprinted from the "Medical News."]

Studies on the Aetiology of the Pneumonia complicating Diphtheria in Children. By T. Mitchell Prudden, M. D., and William P. Northrup, M. D. [Reprinted from the "American Journal of the Medical Sciences."]

Searlatinous Otitis. By Charles H. May, M. D. [Reprinted from the "American Journal of Obstetrics and Diseases of Women and Children."]

The Rational Method of preventing Yellow Fever on the South Atlantic Coast. By J. C. Le Hardy, M. D., Savannah, Ga. (Read before the Medical Association of Georgia, at Macon, Ga., April 18, 1889.)

A Clinical Study on Alopecia Areata and its Treatment. By L. Duncan Bulkley, A. M., M. D., New York. [Reprinted from the "Medical Record."]

De la lobéline dans la thérapeutique de l'asthme. Mémoire présenté au 1er congrès brésilien de médecine et chirurgie et lu devant le même congrès à la séance du 15 Septembre 1888 par le Dr. Silva Nunes.

## Reports on the Progress of Medicine.

### PHYSIOLOGY.

BY LOUISE G. RABINOVITCH, M. D.,  
PHILADELPHIA.

**On the So-called Toxic Antagonism of Some Poisons.**—Besides the physiological antagonism of poisonous substances, researches have been made by some authors to find a toxic antagonism or an antidotal rôle of two poisons taken *vis-à-vis* in the organism. Atropine and morphine have been regarded as toxic antagonists.

M. G. H. Roger ("Jour. des soe. sei.", No. 21, 1888) has experimented on rabbits, with the purpose of determining the existence or non-existence of a toxic antagonism between hydrochloride of morphine, neutral sulphate of atropine, sulphate of quinine, and potassium chloride. To be enabled to draw experimental conclusions, the author determined the poisonous dose of each element, or the toxic equivalent of Bouehard. (This dose is the toxic amount of the substance necessary to be dissolved in 20 c. e. of distilled water.) The intravenous injections were made with a rapidity of 4 e. e. a minute to the kilogramme of the animal's weight. After M. Roger's experiments with mixed injections of morphine and potassium chloride, each substance acted, as regarded its toxic equivalent, as if it had been injected alone. Often both poisons acted synergistically, and their corresponding toxic effects were added to each other (morphine and atropine; quinine and morphine; atropine and quinine). In some cases the toxicity of the mixture was decidedly greater than the sum of the poisonous effects which should be expected to exist (quinine and potassium chloride). In the course of exploration of the substances named the author has never succeeded in finding a toxic antagonism, a more or less complete neutralization of one poison by another.

**The Specific Action of Menthol on the Thermic Sensory Nerves** (Goldscheider, "Archiv fur Anat. und Physiologie").—M. B. ("Journal de méd. de Paris," No. 26, 1888) reports the author's conclusions in

saying that the sensation of cold produced by the application of menthol to the skin or the tongue depends not upon evaporation of the substance, but upon a specific (probably a chemical) action of menthol on the terminal organs of sensation of cold. From the physiological point of view, menthol and phenol are antagonistic. A continual friction performed with a five-per-cent. solution of phenol renders the skin insensible to thermic agents. An application of menthol to such an artificially insensible part makes the sensibility reappear. The insensibility caused by cocaine injections is not remedied by menthol. If menthol acts at all, the phase of excitation may be followed by a paralytic phase. Menthol acts also, to a certain degree, on the nerves of sensation of heat and of tactile sensibility proper.

**On the Chemical Phenomena of the Respiration in Electric Tetanus.**—MM. Hanriot and Ch. Riehet ("Jour. des soe. sci.", No. 9, 1888) give the following conclusions of their work: 1. The normal ventilation in dogs, being twenty-three litres an hour and kilogramme, is doubled by electrization. 2. The weight of carbon dioxide excreted to the kilogramme increases from the normal standard, 1·2, to 4·2. 3. The normal proportion of carbon dioxide contained in the expired air, 2·6 per cent., reaches 4·2 per cent. after electrization. 4. The ratio of the carbon dioxide and oxygen varies little, but may be augmented. 5. The surplus of the heat produced by the muscular overwork goes in part (50 to 75 per cent.) to maintain the animal heat; the remainder is spent on muscular work and radiation.

**The Influence of the Pneumogastric Nerves on the Urinary Secretion.**—MM. Arthaud and Butte ("Jour. des soc. sci.", No. 20, 1888) conclude from their recent experiments that the pneumogastric nerves influence the urinary and, to a certain degree, the other visceral secretions. An excitation of the peripheral end of the vagus caused a diminution of the biliary secretion; the deep vessels of the stomach contracted after an excitation of the same nerve. An excitation of the peripheral end of the cervical pneumogastric, after excision of the branches proceeding from the inferior cervical ganglion, caused a noticeable variation of the cardiac pressure, though the rhythm remained unchanged. The urinary secretion of one kidney is not equally influenced by an excitation of the right and left vagus. An excitation of the peripheral end of the right vagus, somewhat above the diaphragm, gave for a definite length of time in the right kidney zero, and in the left 12 e. c. of urine; the same stimulus on the left side gave 11 e. c. from the right, and 8 e. c. from the left kidney. The conditions were not influenced by whether the stimulus was applied to the vagus above or below the heart. The facts lead the authors to think (1) that the variations of the cardiac rhythm do not influence the phenomena of secretion, and that this is an indirect demonstration of the special vaso-motor action of the pneumogastric on the kidneys; (2) that a crossed distribution of the vagi exists.

**Note on the Modification of the Electric Tension in the Human Body.**—M. Ch. Féré ("Jour. des soe. sei.", No. 5, 1888) calls to mind the fact that certain animals whose skin is remarkably dry, like the cat, have the property of accumulating electricity under certain circumstances (especially under the influence of rubbing), and losing it under the form of a flash; that some individuals present the same phenomenon to a certain degree, especially in dry and cold weather, when the atmosphere is relatively deprived of humidity. The electricity is then said by M. Féré to be seen to discharge from the human body through the hair in the form of flashes or tufts, producing a characteristic crackling sound. The author states some convincing examples, and supposes the fact to be of importance for the theories of hypnotism and the transference of polarization, elective sensibility, and certain actions at a distance.

**Experimental Researches on the Reproduction of Albuminoids in the Blood.**—M. Sophin ("Jour. des soc. sci.", No. 20, 1888) has performed experiments under the directions of M. Dastre. The following are the results: 1. An augmentation of the albuminoids of the blood is noticed after the withdrawal of a given quantity of the same from the blood, the animal remaining in a stage of inanition after the operation. This augmentation is absolute, not merely relative; in three experiments the augmentation was 20, 22, and 29 grammes. 2. The relative and absolute augmentations of the albuminoids are due principally to the growing number of the red globules. 3. The augmentation of the al-

buminoids in the serum is relatively feebler; in the three cases it was 8, 11, and 6 grammes. 4. The fibrin is considerably augmented as compared with its normal amount in the blood.

**The Action of Intravenous Injections of Glucose.**—M. L. Butte ("Jour. des soc. sci." No. 20, 1888) has shown in a previous work that one part of the injected glucose disappeared in the economy and the remainder was eliminated. His late researches, performed to ascertain what became of the glucose retained in the organism, give the following results: The central temperature rises gradually after an intravenous injection of glucose. As regards the modifications of the pulmonary exhalation of carbonic-acid gas, they are constant and in intimate relation with the presiding temperature. In six experiments M. Butte observed constantly an augmented weight of the exhaled carbon dioxide after twenty, thirty minutes, and even an hour, after the injection. The author concludes by saying that the nutrition is evidently augmented after an injection of glucose. The fact is sustained by the rise of the temperature and by the increased quantity of oxygen absorbed and carbon dioxide exhaled in the substance of the tissues. With reference to the overactivity of the nutrition, M. Butte attributes it to the combustion of the glucose, and adds that it must only be an exaggerated physiological phenomenon, as shown previously by Chauveau, who saw in glucose the principal source of animal heat.

**Some Examples of Dynamogenesis in the Centers of the Organs of Special Senses** (Mathias Duval, "Comptes rendus de la soc. de biol.", December, 1887).—Paul Loyer ("Rev. des sci. méd." No. 6, 1888) reports that simple luminous excitations (without any image) of one eye bring about a relatively clearer perception of an image by the other eye. The analogous fact is true of the sense of hearing; some deaf persons hear distinctly sounds pronounced while a noise is being continually produced; the same sounds do not affect the same patient's hearing in an absolute silence. These facts seem to depend upon the general phenomena called by Brown-Séquard dynamogenesis.

**On the Conjoint and Correlative Action of Antithermics and Antipyretics on the Nervous System, and particularly on the Sensory Centers; Relative Deductions on the Seat of Thermogenesis.**—In this note M. J. F. Laborde ("Jour. des soc. sci." No. 21, 1888) shows that M. Lépine's experiments on acetanilide lead to the following law: All true antithermic agents, or agents which reduce the normal animal temperature (the pulse being almost always simultaneously diminished), act at the same time on the sensory function of the nervous system, and attenuate or abolish this function. The statement is thus formulated: All thermic moderators are necessarily moderators of the nervous sensory actions. The facts are important, M. Laborde alleges, from the practical and doctrinal points of view, for they touch directly upon the problem of thermogenesis. Expecting to report in future a thorough study of the subject, the author relates his principal conclusions as follows: 1. The antithermic action is exerted primarily and preferably on the sensory centers of reception and perception in a manner to reduce or annihilate instantaneously the functional activity of these centers; hence thermic depression must be followed by correlative depression of the phenomena of sensibility. 2. It follows that the organic centers of sensibility and those which preside over the dissipation of animal heat are in intimate relation. It results that the location of the thermogenic focus or foci is reduced to the location of the centers of sensibility. 3. It is important not to neglect the fact of the intimate relation existing between the trophic phenomena and those of sensibility. The conscious sensibility which belongs to and must be looked for in the cerebral sphere must be strictly distinguished from the reflex sensibility belonging to the spinal region, since experimental work shows that (*a*) a section or any equivalent lesion of the spinal cord is followed by a progressive thermic reduction, which approximates a warm-blooded to a cold-blooded animal, and this condition interferes with a further production of heat; (*b*) any lesion of the cerebral centers provokes hyperpyrexia, and this implics thermogenesis. In the light of these facts, the focus of thermogenesis must be located in the cerebral regions. The author concludes by referring to the recent works of Schreiber, Ott, Carpenter, Ch. Richet, etc., which have shown the existence of thermic centers in the cerebrum. Gerard's experiments are finally referred to, which confirm the existence of cerebral thermic centers (in the corpus striatum).

**The Influence of the Proportion of the Atmospheric Oxygen on the Respiration** (Speck, "Zeitsch. f. klin. Medicin," Band xii, p. 447-532).—A. F. Plique ("Revue des sci. méd." No. 63, 1888) formulates the author's work thus: The proportion of the atmospheric oxygen may vary within the limits of minimum 9, and maximum 63 per cent. without causing any discomfort in men. But it is necessary to remain motionless at the minimum proportion, all muscular activity increasing the need for oxygen. The acceleration of the respiratory movements and pulse begins at the ratio of 10 per cent. of oxygen. The augmentation and diminution of the production of carbon dioxide are not synchronous with the corresponding phases of the oxygen. The reverse is rather true, *i. e.*, the minimum amount of oxygen being accompanied by a maximum production of carbon dioxide. The utilization of the augmented proportion of oxygen by the economy increases as long as this gas can dissolve in the serum and combine with the haemoglobin; the surplus of oxygen remains indifferent and without chemical action. A diminished amount of oxygen is of no consequence as far as the limit of 9 per cent.; at a ratio of 7 to 8 per cent. labored respiration begins.

**An Experimental Investigation of Strychnine Poisoning.**—At the suggestion of Dr. Henry P. Bowditch, the work was undertaken by Dr. Robert W. Lovett ("Jour. of Phys." Nos. 2 and 3, 1888) to ascertain if the spinal cord showed any special facility in taking strychnine from the circulation and storing it up in its tissues; or, in other words, to determine whether strychnine exercised its peculiar power upon the spinal cord because there was more of the drug present there than in the other organs, or because the cord was more susceptible to its action than muscle, brain, liver, etc. After a careful and minute investigation of the subject the problem is answered in a general way as follows: 1. The spinal cord has the power of selecting strychnine from the circulation and of storing it up in its structure, for at the occurrence of convulsions, or at a definite time after the injection of a certain amount of the drug, the cord is found to contain relatively more than the liver, the muscles, the brain, or the ovary. That the fact is not due to the marked vascularity of the cord is shown by taking into consideration the rich vascularity of the liver, which yet contains a smaller amount of the drug, as compared with that of the cord. 2. At the time of convulsions the relative amounts of strychnine in the blood and in the spinal cord vary with the amount of the drug administered. If it is a large dose, the blood contains overwhelmingly more; but if it is a small dose, a larger amount relatively is found in the cord than in the blood. The amount of the drug in the cord necessary to produce convulsions seems to be more or less constant, independently of the dose, the surplus of the same in the blood being, apparently, in proportion to the size of the dose administered. The author concludes that the spinal cord in cases of strychnine poisoning certainly contains more strychnine than other organs; but whether or no it is more susceptible to the drug than other organs can not be ascertained at present. It is added also that, in a medico-legal sense, the work is of importance as regards the storage power of the spinal cord for strychnine, and especially where the stomach contents can not be relied upon in cases of poisoning by this drug; and in this respect it is an addition to the work of Dr. Chittenden on the "Significance of the Absorption and Elimination of Poisons in Medico-legal Cases."

**The Influence of the Ramus Lingualis Trigemini on the Formation of Lymph in the Tongue** (A. Maracacci, "Arch. ital. de biol." iv, 1).—M. Dastre ("Rev. des sci. méd." No. 63, 1888) reports the author's agreement with Ostromoff's view that a prolonged excitation of the tongue causes edema of the corresponding part. M. Maracacci observed the persistence of the difference in volume of the two halves of the organ after section of it, and also after death by hemorrhage the latter excluding engorgements of the vessels. Anatomical examination by means of Prussian-blue injection enabled the author to find that the larger lymphatics of the tongue reached a ganglion of considerable size in the vicinity of the submaxillary. Excitation caused this ganglion to swell considerably on the side of stimulation. The filling lymph is regarded as originating in the tongue itself, and the fact is ascertained by compressing the organ to interfere with the afflux of lymph from other parts. It is concluded that the lingual nerve has a direct influence on the production of lymph in the tongue.

**On the Resorption of Liquids introduced into the Subcutaneous Lymphatics of the Frog** (J. Archanow, "Archiv für Physiol.", p. 377, 1887).—M. Léon Frédericq ("Revue des sci. méd.", No. 63, 1888) reports the author's experiments on frogs. The lymphatics of the posterior extremity were injected with from 0·2 to 0·3 c. c. of a sodium indigosulphate solution, and a blue coloration of the tongue followed; the beginning of the coloration is supposed to coincide with the moment of absorption. M. Archanow demonstrates that the absorption is performed independently of the lymphatic heart, and that the coloring matter penetrates directly into the blood-vessels at the very seat of injection; that the absorption depends upon the permeability of the blood-vessels, regardless of the conditions of the lymphatic tracts. The absorptive power is augmented with the elevation of the temperature, by the acceleration of the cardiac pulse, and by the movements of the animal. It is not interfered with by the destruction of the central nervous system. The latter is regarded as exerting an indirect influence by governing the heart and the movements of the extremities.

**Experimental Studies on Hyperpyrexia.**—M. Ch. Richet ("Jour. des soc. sci.", No. 20, 1888) has studied the influence of artificial hyperpyrexia, and the result of maintaining the high temperature for a considerable length of time. He says that animals whose temperature attains 45° C. [113° F.], and even 45·6° C. [114° F.], may survive if this thermic stage lasts for a short interval. But an animal succumbs if its temperature is about 43° C. [109·4° F.] for two hours; a crisis occurs before death, the temperature gradually falls, the nervous system seems powerless to generate any more heat, and finally death ensues. Chloralization previous to the artificial hyperpyrexia was found by the author to hasten and assure death. The effect of chloral on the nervous system is considered as that of a depressing agent, which is added to that of the hyperpyrexia. This fact, it is stated, must be of importance in medicine, for the use of chloral seems dangerous in delirium, insomnia, and in other accidents occurring in hyperpyretic patients.

**Apparatus for the Determination with Precision of the Exterior Thoracic Shape, the Extent of the Respiratory Movements, the Profiles and Sections of the Trunk, and the Amount of Inspired and Expired Air** (Presented by M. Marey).—M. G. Demeny ("Jour. des soc. sci.", No. 20, 1888) has shown the permanent modifications of the frequency and amplitude of the respiratory movements which occur in individuals who perform great muscular exertion, and particularly in those subject to the exercise of running. The author finds that after a six months' course at the school of gymnastics of Joinville le Pont, in Paris, the respiratory frequency diminishes to half the normal standard, but the amplitude increases considerably. The apparatus is composed of: 1. A compass scribe to measure the thoracic diameters and to inscribe the variations of these diameters in the inspiratory and expiratory phase. 2. A thoracometer giving the form of a horizontal section of the thorax at a given height. 3. An inscription apparatus for different profiles of the body. 4. A registering spirometer.

**The Influence of the Nervous System on the Collateral Circulation** (A. Stefani, "Accademia di Ferrara," July, 1887).—M. Dastre ("Rev. des sci. méd.", No. 63, 1888) reports the following: The reasons of the formation of a collateral circuit after ligation or obliteration of a main artery are unknown. The old doctrine of the mechanical effect of the augmentation of pressure and dilatation of the collateral arteries has no ground. The author seeks for an explanation of the fact in a nervous influence. In previous experiments the axillary artery in the salamander was ligated. A collateral circulation was found to be established in cases where the nerves were intact; a section of the nerves interfered with the circulation. In frogs the facts were approximately the same, though in some cases the collateral circulation was found in the absence of the nervous influence. Experiments on rabbits were not conclusive, for the ligation of the vessels and section of the nerves induced gangrene of the limbs. Experiments on birds gave results which agreed with the author's views. The author tries to establish that this nervous action is of a reflex nature, having its starting-point in the exsanguinated organ and its cause in the anæmia itself, transmitted to the nervous centers and reflected upon the vessels of the region in which dilatation occurs.

## Miscellany.

### ANSWERS TO CORRESPONDENTS.

**No. 272.**—We have not been able to find anything in literature on that particular point, but we have no doubt of the availability of the dynamo current for the purpose mentioned. We would suggest your writing to the Edison Company.

**No. 273.**—We doubt the possibility of obtaining one, and we very much question the expediency of asking for it. As we understand the matter, the board assumes that an applicant is prepared for any sort of examination, and might conceive an impression against him if he sought to ascertain the scope of the examination in advance; moreover, the examination is not wholly in writing.

**No. 274.**—See Taylor's "Clinicæ Atlas of Venereal and Skin Diseases," part i, page 26, foot-note; also the article there referred to.

**No. 275.**—Much has been published on that subject. Among books that are readily accessible, we would refer you to Creighton's "Bovine Tuberculosis in Man," London, 1881.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

Original Communications.

LABORATORY NOTES OF TECHNICAL METHODS  
FOR THE NERVOUS SYSTEM.

BY IRA VAN GIESON, M. D.,

FIRST ASSISTANT AT THE LABORATORY OF THE ALUMNI ASSOCIATION OF  
THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

METHODS OF OPENING THE BRAIN AT AUTOPSIES AND FOR  
GENERAL DISSECTION OF THE BRAIN.

*1. Meynert's Basal Section of the Brain.*—The ordinary method of opening the brain at autopsies by slitting open the corpus callosum, laying aside the hemispheres, and then making longitudinal and transverse incisions, renders it difficult to handle the brain without tearing it, and, after hardening, the pieces can not be fitted together well, so that the lesions may be accurately localized in conjunction with the microscopical examination. Meynert's section is much more valuable for the purposes of localization after hardening, and is recommended for general use at autopsies and as an instructive method for demonstrating to students the coarser anatomy of the fresh brain. With some modifications of Meynert's original plan, the section is made as follows:

Resting the brain upon its hemispheres and lifting up the cerebellum, the pia mater and vessels are cut above the corpora quadrigemina and around the crura and inner margins of the temporal lobes on either side until the middle cerebral arteries are reached. The incision of the pia then follows the middle cerebral arteries into the Sylvian fissures, and passes to the terminations of the posterior branches of the Sylvian fissure. As the incision of the pia follows in this way, the boundaries of the temporal lobes, the temporal convolutions should be gently separated from the neighboring convolutions and from the base.

The apices of the temporal lobes are then lifted up, and, resting the knife flat on the base, their junction with the base is cut, until the descending horn is opened. Then inserting the knife into the descending horn, the incision passes outward and backward to within an inch of the apex of the posterior horn, or even to its extremity, severing the junction of the occipital and temporal convolutions on the lateral surface of the brain. During this manipulation the cornu Ammonis and posterior pillars of the fornix should not be cut. The temporal lobes are thus freed from the base and folded outward and backward over the occipital lobes, giving access to the island of Reil (Fig. 1). The operculum is then pulled well outward to completely expose the convolutions of the islands, and a slightly curved transverse incision (*a, a*, Fig. 1), with the convexity directed frontally, is made connecting the anterior sulci of the islands on both sides. This incision should be deep enough to pass through the anterior horns of the ventricle to the corpus callosum.

The cerebellum is then lifted up with the left hand, and placing the knife in the ventricle at *c*, Fig. 1, and passing it beneath the rounded posterior extremities of the optic thalami, the internal capsules on either side and the anterior

pillars of the fornix and septum lucidum are cut from behind forward without injuring the basal ganglia. As the

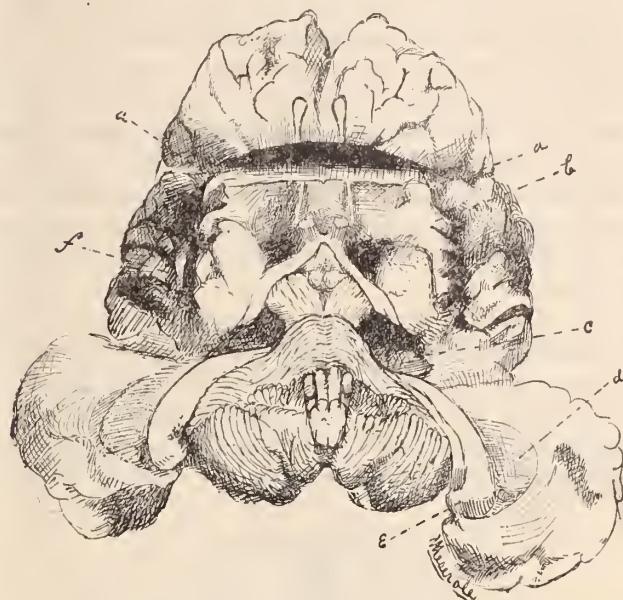

FIG. 1.—Drawing of the brain, showing how the brain axis is exposed before it is cut out. *a*, anterior sulci of the islands of Reil; *b*, convolutions of the island; *d*, descending horn in the reflected temporal lobe; *e*, cornu Ammonis, with the posterior pillar of the fornix passing from it into the ventricle; *f* passes across the convolutions of the operculum to the cut surface of the junction of the temporal lobe with the base.

internal capsules are being cut, the cerebellum is gradually rolled over forward on the base, in order to lift up the basal

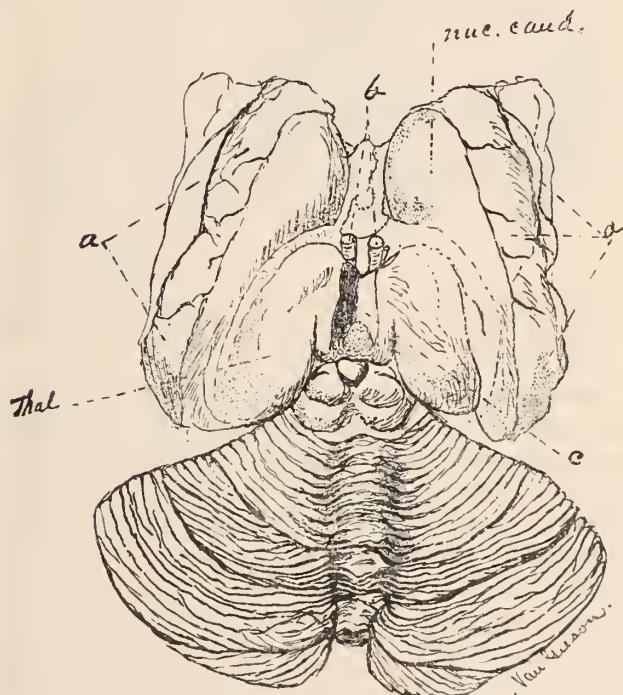

FIG. 2.—Ventricular surface of the basal piece or brain axis. *a, a*, fibers of the internal capsule cut transversely as they enter the basal ganglia; *b*, anterior pillars of the fornix cut across; *c*, third ventricle; *nuc. caud.*, caudate nucleus; *thal.*, optic thalamus.

ganglia from the corpus callosum. A square piece—"the basal piece" (Fig. 2)—is in this way cut out of the base. The fornix is left lying on the corpus callosum.

When the brain is soft, and in children's brains and in cases where the basal ganglia are injured by haemorrhage, the above-described method of removing the basal piece is modified by putting the index and middle fingers of the left hand through a transverse incision of the base (Fig. 1, *a*, *a*) into the anterior horns of the ventricles and raising the basal piece, while the internal capsules, anterior pillars of the fornix, and septum lucidum are cut from before backward. This plan of cutting out the base is not recommended except when the brain is very soft, because the introduction of the fingers into the ventricles is apt to damage the ependyma.

The advantage of this plan of opening the brain is that it uniformly separates the organ into two great anatomical subdivisions. The square basal piece—the *brain axis* (Fig. 2)—includes the island, basal ganglia, internal capsules, crura, pons, medulla, and cerebellum. The remaining piece—the *brain mantle of Burdach* (Fig. 3)—includes the con-

the autopsy unless the integrity of its pontial relations is desirable, so that in hardening the fluid may penetrate into the floor of the fourth ventricle. The cerebellum is removed by cutting away its crura close to the pons. The practice of inspecting the fourth ventricle by splitting the cerebellum in the median line is apt to distort the floor of the fourth ventricle by the traction of the two divergent cerebellar hemispheres.

**2. Division of the Brain into Transverse Segments for Examination at Autopsies.**—This method is used quite frequently at the laboratory in Heidelberg, and consists simply in making serial transverse vertical slices of the brain about three quarters of an inch thick, first having removed the cerebellum and pons by cutting the crura cerebri transversely. When the slices have been hardened they may be easily fitted together for the detailed localization of the lesions. This method is good for the preparation of certain museum specimens and for lantern demonstrations of tumors or cortical lesions by stained sections of the entire brain, made with the Gudden microtome.

**3. Preparation of the Brain for the Dissection of the Association, Commissural, and Projection Fibers, by the Cleavage Method.**—The pia mater is carefully removed from the convolutions, and the brain—suspended in gauze in forty-per-cent. alcohol, which is renewed on the third day—is turned on a new surface each day to avoid flattening. No incisions are made except a small one through the infundibulum to let the fluid into the lateral ventricles. At the end of the first week of hardening, the alcohol is replaced by sixty-per-cent. alcohol; at the end of the fourth week this is replaced by eighty-per-cent. alcohol, and then, for three weeks or a month, the brain is left in strong alcohol. With this treatment the bundles of fibers of the white matter become tough and elastic, and a particular tract may be isolated by pushing and cleaving aside the surrounding structures with a scalpel handle. The same method of hardening may be used if dissoeiation of the tracts is to be practiced in some particular portion of the brain, such as the brain axis or brain mantle.

As an example of how a system of fibers may be dissected out when the brain is successfully hardened in this way, the path of the motor tract in the brain axis is selected. The brain axis (Fig. 2) is hardened as described above, and the pyramids of the medulla are loosened from the olivary bodies, and from each other in the median line to their decussation, with the handle of a scalpel. The superficial transverse fibers of the pons are cut in the median line and pushed away from the pyramids with the scalpel handle inserted in the groove between the inferior pons border and medulla, until they are reflected as two flaps on the middle cerebellar crura. The pyramids are now exposed between the two sets of transpontial fibers, and, when freed from a few interlacing pons fibers, they may be picked up with the forceps and followed up through the middle thirds of the crura into the internal capsules. This method is exceedingly valuable for teaching purposes, and a series of these cleavage dissections is the best way of giving students a clear idea of the various association, commissural, and projection systems. Plates 18 to 22 of Meynert's

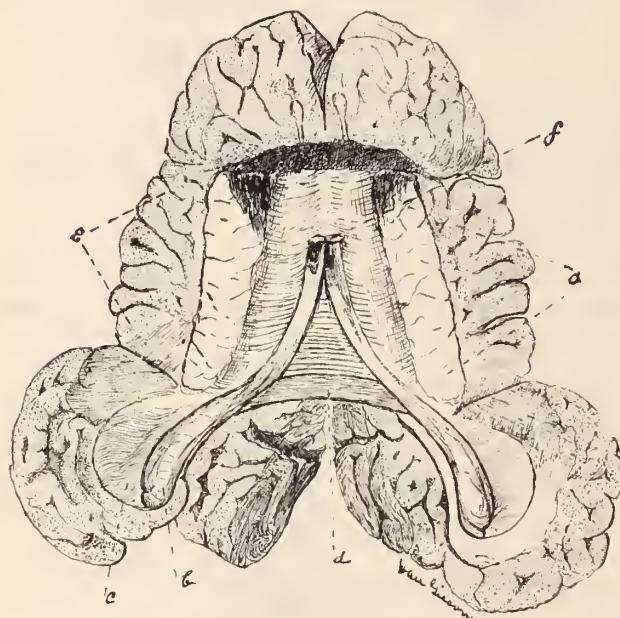

FIG. 3.—Ventricular aspect of the brain mantle. *a*, internal capsule; *d*, posterior border of the corpus callosum; *b*, cornu Ammonis; *c*, descending horn; *e*, operculum; *f*, anterior pillars of the fornix cut transversely.

convolutions, corpus callosum, fornix, and cornu Ammonis. This method also exposes the internal capsule (Figs. 2 and 3) advantageously for the localization of lesions in the internal capsule, because its fibers are cut transversely between their entrance into the basal ganglia and the centrum ovale.

Both these pieces may be hardened *en masse* by making transverse incisions about one half to three quarters of an inch apart in the basal piece, and both transverse and longitudinal incisions into the white matter of the larger piece not quite reaching to the pia mater, which serves to hold the convolutions together for the purposes of localization after hardening. The incisions should be kept open with absorbent cotton, and each piece should be suspended in gauze or laid on absorbent cotton in a large volume of Müller's fluid (five or six times the volume of the pieces), which is kept cool and changed on the second, fifth, and eighth days, and again in the third week. It is best to remove the cerebellum from the rest of the brain axis at

"Psychiatry," translated by Sachs (Putnams, New York, 1885), and Plates 28 and 30 in Edinger's "Zehn Vorlesungen über d. Bau d. nerv. cent. Organe," 1885, may be used as guides for other dissections of the different systems composing the white matter.

#### NOTES ON THE HARDENING OF THE BRAIN.

*Müller's fluid* does not preserve the ganglion cells as perfectly as bichloride of mercury or alcohol, but it preserves the nerve fibers and neuroglia well; it gives the proper consistence for cutting sections, and all the important methods of staining the nervous system depend upon bichromate hardening. The obstacle in getting perfect hardening results with Müller's fluid is the great impermeability of the cerebral tissues. To get the best results in hardening the pieces should not be more than one to two cubic centimetres in volume, and should be left in the fluid at the temperature of the room until they have a dark-brown color, and sections cut by hand do not wrinkle when placed in water. This may take four or five months or longer, and the blocks should be frequently tested to guard against their becoming brittle. Rapid hardening in the thermostat is not often used in this laboratory; it is not so good as slow hardening at low temperatures, or at the ordinary temperature of the room. In hardening with heat, the superficial portions of the specimens become hardened too rapidly, and become dense and prevent the fluid from gaining access to the central portions of the blocks. If rapid hardening is necessary, it is much better to renew the fluid frequently after the first two or three weeks of the hardening, and at each renewal to gradually increase the strength of the bichromate-of-potassium solution up to five per cent. *Erlieke's solution* hardens the superficial portions of the blocks more rapidly than Müller's fluid, and consequently does not preserve the central portions so well. It also has a greater tendency to make the specimens brittle. The bichromate solution should always contain camphor (a piece of the size of a pea to each pint of the fluid) to prevent the development of micro-organisms.

When specimens have become brittle it is very difficult to get them into good condition for cutting. A prolonged immersion of the specimens in equal parts of glycerin, alcohol, and water reduces the brittleness somewhat, but the best results have been obtained by soaking the blocks for twenty-four or forty-eight hours in a fifty-per-cent. or stronger aqueous solution of ammonia. A twenty-four-hours' immersion in peroxide of hydrogen also tends to make the specimens less brittle. When very large segments of the brain are to be preserved for microscopical examination it is best while hardening to keep the bichromate solution cold for the first month or two in a refrigerator.

If specimens are not thoroughly hardened in Müller's fluid, the subsequent permanent preservation in strong alcohol does them considerable injury. The alcohol slowly dissolves out the chrome salts and changes the myelin. In the course of a year or two cholesterol crystals form in the alcohol, and minute cavities and vacuoles appear in the specimens and they do not stain well. If for any reason it is necessary to examine specimens before they are thoroughly

hardened, it is best to keep the material for permanent preservation on the shelves in water containing camphor, or dilute, thirty to forty per cent., solutions of alcohol. In the laboratory even thoroughly hardened material is not kept permanently in strong alcohol. Seventy or eighty per cent. is used, and in certain cases water. Well hardened material kept in water has a tendency to become brittle in the course of years. The structure of the neuroglia never shows so well, and carmine staining is never so successful in sections of material which has been placed in alcohol as in sections cut from specimens while in Müller's fluid, or kept in water slightly tinged with Müller's fluid.

#### DIVISION OF THE SPINAL CORD INTO ITS ANATOMICAL SEGMENTS FOR MICROSCOPICAL EXAMINATION.

The portions of the cord from which each pair of spinal nerves arise are termed the corresponding segments of the cord, and it is desirable to use this well-defined anatomical segmental structure of the spinal cord as a basis for the localization of lesions in the microscopical examination. We can then know exactly from what part of the cord a given section is taken.

The cord may be hardened with the dura mater attached, but is distorted less if the dura is removed. At intervals of little less than half an inch the cord should be traversed by transverse incisions not completely severing the cord, in order that the pia mater may hold the pieces together in their serial order. The cord is then rolled up in a loose spiral and laid in Müller's fluid on absorbent cotton. After the subsequent alcohol hardening the attachments of the nerve roots form a guide for the division of the cord into its proper segments.

To distinguish the spinal segments after they have been taken from their serial order in the hardened cord, I have found it most convenient to mark them by sticking a hot teasing needle in the white matter of one half of the upper surface of each segment. This burns a permanent little hole in the segment, and, by making notes of the different positions of the needle-holes in the different segments, a number of blocks from the cord may be carried through the celloidin imbedding process together and easily identified. If imbedded on pieces of white wood, the number of the segment or portion of the spinal segment to which the imbedded specimen belongs may be written on the wood in pencil. In the sections the needle-hole also indicates the right or left hand side of the cord. When it is necessary to examine the spinal nerve roots, these may be reflected against the corresponding segment and tied in place with thread, and then the segment with its roots is imbedded in celloidin, so that transections of the upper level of the segment will include transections of the corresponding nerve roots. The lumbar and sacral segments are so short that the entire segment may be mounted on the block of wood; but in the cervical and dorsal regions it is more convenient to use only the upper thirds or quarters of the segments for mounting.

#### OSMIC-ACID STAINING OF LARGE NERVE TRUNKS.

Most of the human peripheral nerve trunks are so thick that osmic acid does not penetrate into them when stretched

out in the ordinary way on a bridge, as advised by Ranvier. To stain the human posterior tibial or sciatic nerves affected with peripheral neuritis, the nerve trunks are cut with sharp scissors into segments a little less than half an inch long. One extremity of the segment is held with a forceps, and with a second forceps the protruding funiculi at the other extremity are gently pulled out of their lamellar sheaths and laid in the one-per-cent. osmic-acid solution for twenty-four or forty-eight hours. This manipulation cracks the myelin sheaths transversely somewhat, but the osmic acid penetrates well among the fibers, and stains them quite uniformly. Osmic-acid nerves are kept best in glycerin.

#### NEW STAINING METHODS FOR THE PERIPHERAL NERVES.

*1. Dilute Aqueous Solution of Basic Fuchsin for staining the Connective Tissue of the Peripheral Nerves in the Fresh Condition.*—A slender funiculus of a human nerve, pulled out as described above, or a bit of the sciatic of a frog or mouse (not over half an inch long), is laid upon a slide for twenty to thirty seconds, until its surface begins to stick to the glass. (If the bit of nerve is very wet, it is moved about on the slide until some of its surfaces begin to adhere to the glass.) Then, with two teasing needles, the nerve is rapidly rolled or pulled away from the adherent portion, so that it is spread out into a thin film on the glass. Before it dries—this is to be avoided by breathing on the specimen—a drop or two of an aqueous solution of basic fuchsin, such as is used for bacterial staining (one drop of a saturated alcoholic solution of basic fuchsin in eight or ten c.c. of distilled water), is placed on the specimen. The slide is inspected with the low power, and in two or three minutes the nuclei of the endoneurium will be stained. The specimen may be mounted and studied in the staining fluid, or the dye may be washed with water; the stained nerve is dried in the air on the slide and permanently mounted in balsam. In drying in the air, the endoneurial cells are not perceptibly distorted. Sometimes the dye penetrates through the constrictions of Ranvier for a slight distance between the axis-cylinder and periaxial sheath. I have found this method of service in studying the endoneurium in normal nerves, in experimental nerve lesions, and in peripheral neuritis in the human nerves.

*2. Acid Fuchsin for staining Isolated Hardened Nerve Fibers.*—Nerves are hardened from three to five weeks in Müller's fluid, and then, after washing out some of the Müller's fluid in water, for a week in strong alcohol. A slender strand of fibers, about half an inch long, is teased very finely in water on a slide. The water is then removed, and the specimen covered with a drop of a saturated aqueous solution of acid fuchsin (Grübler's) for two to five minutes. The teased fibers are washed in water, then thoroughly in two alcohols, cleared in oil of cloves, and mounted in balsam. The axis-cylinder, neurilemma, constrictions, incisures of Schmidt, neurilemma nuclei, and branching cells between the fibers have a distinct red color. In successful preparations the incisures show very distinctly. This method is so simple and efficient in demonstrating all the details of the nerve fiber, except the medullary sheath,

that it is recommended for staining specimens for classes in normal histology.

The most convenient nerves to prepare for this method are the spinal nerve roots, because they can be teased more readily than the peripheral nerves, which contain more connective tissue. When nerves have been hardened for a short time (three to eight days) in Müller's fluid and subsequently in strong alcohol, or when they have been placed in ether and then hardened in alcohol, or when they have been entirely hardened in alcohol, the myelin is coagulated in the form of a network—the neuro-keratin network. This method also stains the neuro-keratin network distinctly. Fibers stained by this method may be kept for months in oil of cloves.

*3. Peroxide of Hydrogen for bleaching Peripheral Nerve Fibers stained with Osmic Acid.*—Osmic acid preserves nerve fibers more perfectly than any other reagent, but very often the medullary sheath is stained so dark that the other details are obscured. Peroxide of hydrogen removes the black color from the myelin and makes the fibers transparent, so that they may be examined with high powers. The stained fibers are teased in water, and a few drops of hydrogen peroxide are flowed under the cover glass, while the specimen is being examined with high-power lenses. Sections of osmic-acid nerves may be bleached in the same way, but it is difficult to stain them afterward with the ordinary dyes. If the fibers are treated with strong alcohol after they have been bleached in the peroxide solution, the myelin coagulates in the form of a network. This method is good for studying the incisures of Schmidt and the structure and size of the axis-cylinder, which does not shrink in careful osmic-acid hardening.

#### ACID FUCHSIN AND PICRIC-ACID MIXTURE FOR STAINING SECTIONS OF THE PERIPHERAL NERVES AND CENTRAL NERVOUS SYSTEM.

Sections which have been properly hardened in Müller's fluid and then in alcohol are stained rather deeply with haematoxylin—preferably Delafield's solution—to color the nuclei. They are then washed in water, and left for three to five minutes in acid fuchsin and picric-acid mixture prepared as follows: A few drops of a saturated aqueous solution of Grübler's acid fuchsin is added to one hundred c.c. of a saturated aqueous solution of picric acid, until the mixture has a dark-garnet color. The sections are then rapidly washed in water and in two volumes of alcohol, cleared in oil of origanum, and mounted in balsam. This stain selects the ganglion cells, neuroglia, blood-vessels, and sclerotic areas, distinctly giving them a garnet color. The axis-cylinders are stained red and the myelin is stained yellow. This stain is used considerably in the laboratory in place of carmine.

---

*Transplantation of the Cornea.*—The "Lancet" says that "Dr. Gradenigo, Professor of Ophthalmic Surgery in the University of Padua, has just succeeded in transplanting the cornea from the eye of a barn fowl into the eye of a patient under his care. On the eighth day after the operation the transplanted cornea presented a quite pellucid and convex appearance. Such a result has not yet been recorded in the annals of continental surgery."

## THE GENESIS OF TUMORS.\*

BY THOMAS H. MANLEY, M.D.

ALTHOUGH the title of this essay is suggestive of a discussion of much interest, I may say in the beginning that my efforts will be directed not so much with a view of presenting anything new or original in the study of new formations as to a review of the features peculiar to some of them, and especially important to the surgeon and practitioner to become familiar with and recognize.

The study of the origin, physical properties, special processes, aetiology, and termination of tumors has from the very earliest ages occupied the attention of many of the ablest minds in medicine.

We find in the works of Hippocrates many observations replete with interest in connection with those morbid growths which now, in our days of microscopic analysis, seem rather crude, but are yet not without considerable clinical value.

And so we do in the writings of others, from Galen and Ambroise Paré down.

From all that can be gleaned from the writings of the Greek, Arabian, and Roman practitioners, they always looked on the advent of a tumor with great alarm, classed all in the same category, the benign and the malignant, and never undertook their removal with the knife, but were usually contented with internal medication, which they firmly believed would reduce in volume or wholly dissipate many of great size. Occasionally, however, besides drugs, some used the seton or caustic when the growth was diminutive or very superficial.

For those large and deep seated, or connected with the trunks of large vessels, nothing was promised or attempted in the way of external applications.

With the dawn of dissection, the use of the ligature and of the microscope, and with the flood of light reflected from the brilliant genius of John Hunter, Astley Cooper, Baron Larrey, Dupuytren, Malgaigne, Graafe, Lucitanus, Virchow, Mott, and Physick, besides many others, immense and rapid strides were made in our knowledge of this branch of surgery.

The keen and analytical eye of the early anatomist quickly discerned the wide difference in the consistence, location, and peculiarities of each; and from *macroscopical* observation alone a rather primitive but very useful classification was made.

We had tumors from humors, from injuries, and from heredity. Every kind of sore which had for its characteristics pain and persistence was designated cancer and deemed malignant. Very naturally in the early days of surgery very little use was made of the knife, as complete anaesthesia and the ready methods of controlling hemorrhage were then unknown. The knowledge of the minute physical elements, molecules, or cells, the histology of normal tissue, or the pathology of morbid enlargement, was impossible till the microscope was invented; and we may truly say that all

was conjecture; that we had no real foundation for scientific classification till the latter half of the present century.

At present our classification, though of infinite value, is based mostly on physical peculiarities, on cell elements, on the form and arrangement of the latter, and is not only very imperfect, but in some instances deceptive and delusive, with a tendency to work evil if too rigidly adhered to.

This comes from too much reliance on pathology and an attempt to create a purely artificial distinction in deranged histological changes.

The presence of a certain microbe is held to be enough to decide the true nature of a lesion or growth and to indicate its probable termination.

The aetiology of tumors is still very obscure; about their causes little is positively known. Much time has been spent, extensive research made, and most profound analytical reasoning exhausted in fruitless efforts in this direction. Here, indeed, nature seems to defy art and, as it were, imply that there must be a limit to its advance, though, with the astounding progress made in not only arresting but curing disease by the revelations of Jenner, Pasteur, and Lister, we have good reasons for hoping that this ground will soon be broken, and that many of those now seemingly incurable afflictions will readily yield to scientific management and their nature be better known.

Why an organized structure will at times become the seat of histological derangement—as, for instance, an inward infiltration of epithelial cells penetrating and destroying everything in its destructive march—while at another, under apparently similar conditions, there is a formation of benign variety, we do not understand, and hence can not explain. All we can do is to study the apparent origin, course, and results in each in the way they interest us, and to this end a few considerations are now offered. Broadly stated, all neoplasmata may be divided into two varieties—the benign and the malignant. Each is totally unlike the other in its natural—or, as it is termed, its clinical—history, but with cellular elements or histological structure quite similar.

In tumors we have every kind of organization, development, transformation, disintegration, degeneration, retrogression, and metastasis, the liquids in each at times becoming solids, and *vice versa*, the benign becoming malignant, and the contrary; the hopelessly incurable, for some unknown, inscrutable reason, coming to a halt and making no further progress, or perhaps fading out of sight altogether; while, on the other hand, the apparently innocent are seen suddenly taking on appallingly destructive changes. No race, age, sex, or condition is exempt, but the course of each is markedly influenced by any of the foregoing circumstances. Since the microscope has come into general use many are deluded with the impression that by its use *alone* we can definitely and absolutely recognize the true nature of those morbid formations. By the aid of the lens it is an incontestable fact that we have been able to better see the minute elements of a part; that the field of vision has been vastly extended by its intelligent use; but, no matter how perfect the instrument or well trained the manipulator, there are growths which can not be diagnosed by this sole agency.

\* Read before the Fifth District Branch of the New York State Medical Association, May 28, 1889.

The only manner in which the true nature of a neoplasm can be certainly decided is by cautious, continued clinical observation in conjunction with the aid of this instrument.

I believe, from experience, that in more than ninety per cent. of morbid growths the skilled and careful observer will recognize their character with certainty by their naked-eye appearance, their history, and the condition of the patient.

We all lately saw a most timely and truthful illustration of this in the case of the late unfortunate Crown Prince of Germany. The German doctors met in consultation and unanimously agreed that their august patient was stricken with mortal disease—cancer. This decision was reached without any microscopical examination whatever.

The specialist comes on the scene, slices off a bit of the proliferated tissue and sends it, for examination by the microscope, to the acknowledged father of cellular pathology, Virchow. This was more than a month after the German doctors consulted.

Well! What comes of Virchow's examination? Nothing. He didn't know anything about what it was; or, if he did, he expressed his views in such ambiguous terms and language that his results would quite easily fit either way, and no one knew exactly what real conclusions he did arrive at.

The very perfection of improved vision to which the microscope has brought us has, no doubt, worked much mischief with those operators who rely mainly on its revelations for guidance in diagnosis.

Supposing we do find epithelial hyperplasia with rudimentary embryonic cells, or in another situation the real alveolar structure of malignant disease, must we frighten our patient to death with the announcement that he has cancer? And even if he is so stricken, must we fold our arms and see his malady rapidly sapping and vitiating his vitality without at least making a bold effort to head it off or temporarily arrest its progress?

Pathologists designate tumors homœoplastic or heteroplastic, homologous or heterologous, according to the tissue elements of which they are composed. The term homologous means that the growth is made up of elements similar to the organ or part of the body from which it sprung; heterologous implies that it possesses tissue foreign to that from which it started.

Now, it may seem paradoxical and absurd to so speak, but there really is not, in its fullest sense, such a thing as a foreign or heterologous growth in the human body.

Green\* says, "Every pathological element has its physiological prototype." Hence every deviation from normal form or size is attributable, not to the introduction from without of any new element, but to deranged physiological action. Nothing is elaborated in the body in the most chronic and painful or lingering diseases which can not be found in a person in perfect health. This is quite necessary to bear in mind in dealing with new formations. There is scarcely a tissue but may at some epoch of life

become the seat of adventitious growths, that of which the nerves and brain are composed being most rarely invaded.

Of the organs most frequently attacked and tissues involved in the female are the breast, uterus, and ovary; in the male, the oesophagus, rectum, tongue, and lip. Of tissues, the epithelial, mucous membrane, and cutaneous in one variety of cancer; the parenchyma in cancer of organs. Sarcoma has a special predilection for connective tissue. Of the whole glandular system, the lymphatics are most frequently the seat of enlargement and infiltration. Why this is so does not seem clear, though there are many theories. Some attribute it to their remarkable faculty for absorption, and maintain that they take to themselves and store up in their parenchyma all the deleterious elements abounding in the system.

This will not explain it, though it may in a measure when we speak of cancer, syphilis, and scrofula or tubercle. But there are many well-marked dyserasiae in which they escape any taint, as in sarcoma, senry, pulmonary tuberculosis, and many others.

The lungs, of all the organs, are most rarely the seat of malignant hyperplasia, though it seems rather remarkable that with their constant and unceasing action we seldom find in their composition, except in the bronchial glands, anything undergoing tissue hypertrophy.

So-called benign growths may at times become malignant or menace life by their size and situation, as with the thyreoid gland or with an enormously enlarged uterine fibroid. Some of those neoplasms are not very sensitive, and give no pain except by their impinging on a nerve-trunk or greatly stretching adjacent parts, while others are extremely painful from the beginning.

The malignancy of a growth can not always be estimated by this symptom of pain, though its presence, when of long duration and of a cumulative character, is a cause of much anxiety, and, taken with other indications, is of considerable diagnostic value. Pain is said to be always a warning of the economy that something is going wrong, that a morbid action has commenced. This is undoubtedly true in a general way, but there are so many exceptions to the rule that one may be in doubt whether it is well to place too much reliance on it while there are so many neoplasms in which it may be entirely wanting. It is notorious that with the variety of cancer which for its peculiar histological elements is designated sarcoma there usually is no pain of any moment. I recently had a practical proof of this in a man from whom I removed the left lower jaw for infiltrating round-celled sarcoma. From the beginning of his complaint, which ran a rapid course, he had no pain, and its absence led his family physician to strongly doubt the presence of any malignant disease till the scalpel and microscope satisfied him.

The entire jaw bone, the inferior maxilla, from the symphysis to the articulation, was diseased and broken down, but from the time he first became conscious of any trouble he said he suffered very little. Again, scirrrous epithelial cancer, which usually kills by slow torture, in some situations is entirely devoid of any pain whatever. This, too, was

\* "Pathology," ed. ii, p. 37.

well illustrated in a man whom I was recently called to see in consultation.

He had a large nodular growth at the pyloric orifice of the stomach, and was rapidly breaking down from lack of nourishment and disordered digestion, but had no inconvenience whatever from this new epithelial formation, and would not have known it was there if his attention had not been called to it. This absence of pain is noticeable very often in malignant disease of the viscera. It is strikingly so with cancer of the kidney, œsophagus, liver, and stomach.

It is only when on or near the surface of the integument or a mucous membrane that cancer causes very great agony. However, with innocent growths there may be now and then great pain. Hypertrophy of the papillæ at the meatus urinarius of the female is frequently attended with intense distress, and when not relieved may seriously jeopardize health.

An instance, too, of this came under my notice some time ago wherein a young woman, recently married, was infected with gonorrhœa by her husband. She was treated in the usual way for this, but when the discharge ceased and the inflammation subsided she suffered the greatest kind of torture on urinating. Not that she had to empty the bladder often, as in cystitis, but when evacuating it the pain was dreadful. I knew that this condition was no ordinary concomitant of gonorrhœa, and examined her, when I found, not the condylomata of syphilis, but two or three of those vascular, warty growths just within the urethral orifice sometimes found as a result of the long-continued acrid discharge of gonorrhœa. After they were cut out and the part was cauterized her trouble ended as if by magic.

Many of us have an every-day reminder of the annoyance of those little excrescences called corns, which will not infrequently inconvenience one as much as the gout.

The period of life at which tumors grow and thrive best is somewhat variable, though it may be fairly set down as middle age; at that time at which the vital energies begin to ebb, when degenerative changes are most active, when the hair begins to grow gray and thin, the teeth decay, the muscles lose their earlier tonicity, the arteries ossify, the skin begins to wrinkle and atrophy, and the body grows fat. Usually at this stage less sleep is needed than formerly.

The waste is now more rapid than repair, and, as far as physical strength and vigor go, man, at forty-five or fifty, has seen his best days; some, of course, earlier, and some later, but this rule will stand when we are corporeally considered.

With the mind it is quite different, as we often see the lamentable want of harmony here—this active and buoyant, while the body is rapidly breaking up.

At this epoch of life, and later, normal processes seem to lose their balance or equilibrium, as it were, and the economy sends into diseased or morbid growths which may now appear ample nutritive materials to nourish the whole body, and we witness the ceaseless waste which, unhappily, we are only too often unable to arrest or retard. The body is starved that a useless appendage may thrive; and, even when finally the digestive organs give out, the neoplasm keeps up its ravages till it has at last left the skeleton bared

of everything but ribbon-like muscles and a shrunken, attenuated skin.

While new formations are most frequently encountered at or after the meridian of life and in all conditions, still there is no question but they are markedly influenced by race, age, climate, occupation, and diet.

Strumous growths in the joints and glands are met with chiefly in childhood.

It will be noticed here that I retain the old nomenclature, and do not, as is the custom of the day with most pathologists, classify these as tubercular, for in many of the diseased glands no bacillus is found, and, besides, I believe that this classification has worked much confusion and accomplished more ill than good.

It may be argued that as the bacillus is usually found in the gland, hence the pathological condition should be designated tubercular.

It seems to me just as logical to set every case of simple enteritis down as cholera, because occasionally the microscopist encounters the genuine comma bacillus in the excreta of this bowel trouble.

It would seem best, in this instance, to adhere to the older clinical classification in this species of malnutrition, for we all know, as we always recognized it, that tuberculosis is practically an incurable disease, whereas scrofula, on the other hand, in various degrees and forms, is as peculiar to childhood as measles or varicella, and is readily curable.

Some of the most vigorous and hardy individuals we meet carry the scars of this malady. Hence, though the tubercles of scrofula and pulmonary phthisis are similar and the microbe of each is identical, they differ very widely in their clinical aspects.

I have often thought that the confounding of both as the same, from a clinical point of view, has led to much needless mutilation, especially in dealing with diseased bone.

Sarcoma in youth is rather infrequent, but when met with is terribly malignant, running a very short course.

Syphilitic tumors or glandular enlargements from specific causes may be seen at any age after the contagion is acquired.

The testes are a common seat of this infection and sometimes attain great size, and to one unfamiliar with the pathology of this malady it will be difficult to decide whether or not the enlargement may not be attributable to malignant disease. The testes here are strangely devoid of pain on severe pressure, though, if the patient denies the disease, or there is a strong suspicion, a mercurial course will easily decide the matter. Senn,\* in his article on surgical bacteriology, tells us that, if we are in doubt as to whether a given lesion is syphilitic, cancerous, or tubercular, the question can be readily settled by inoculation. This is denied by Cohnheim, but the experiment is so simple that it is worth trying, at any rate.

There is an undoubtedly connection between certain occupations and habits in the production of neoplasms. It is generally agreed among the English surgeons that cancer of the scrotum is quite peculiar to chimney-sweeps; and when

\* "Transactions of the American Surgical Association," p. 212.

we see cancer of the lip and tongue rarely except in the male sex and in smokers, we must, I think, admit that tobacco has something to do with its development—that it is an exciting cause at least.

We are told that the malady is never seen among natives of the South Sea Islands, be their parents natives or Europeans, and that strumous enlargements are not met with in the primitive tribes of North American Indians.

While malignant formations are very infrequent among the Africau negroes, their women are often afflicted with uterine fibroids.

Darwin and Huxley tell us that no kind of adventitious swelling is often met with in the lower animals in the undomesticated state, or in the uncivilized races of man, but that, when their surroundings and habits change, they soon begin, in common with other beings under similar influences, to show signs of local degeneration.

It would seem that the presence of these neoplasmata is one of the many penalties we must pay for our advanced civilization.

Would it not, indeed, seem absurd to argue to the contrary, to deny that overfeeding with highly nitrogenized food, little or inadequate exercise; "living to eat, not eating to live"; alcohol drinking, in the way of wines, beer, and stronger spirits; venereal excesses, legitimate and illegitimate; residing in the modern city apartment-house, caged and cornered, without ample light or air, like the animals of a menagerie, and with the now almost universal habit of deliberate poisoning of the body with tea, coffee, and tobacco—can it be wondered at, then, that in proportion as we ascend the social scale we and our children degenerate, and that one form or phase of this degeneration or process of decay comes in the way of tumors?

We practitioners, who can take a calm, impartial retrospective view, can see the full force and truthfulness of this in our own country, where, without the constant and unceasing influx of the hardy sons of Europe, many industries entailing toil and hardship, it is feared, would languish.

Diet must have an important bearing in determining the kind of growth and its chemical composition.

It has long been known that, in the cervical lymphomata of children, giving too much animal food or too little vegetable is an exciting cause, in addition to the bad ventilation and herding the little ones together in close quarters.

We most frequently find those stony concretions of the bladder in certain districts where there is an excess of lime in the drinking-water, and in those who over-indulge in certain kinds of wine.

There must certainly be some imprudence in diet at times, for the progress of a growth of a given species may be arrested by restriction to a certain regime.

Every kind of tumor is more frequent in women than in men, and in the single than in the married. Whether this is due to the more confined occupations of the sex and their domestic habits is uncertain. In my experience, the results in treatment are better with them, especially after the menopause. I think this important to bear in mind in giving a prognosis, for a woman's chances of relief are vastly better the older she is, certainly in malignant disease.

Among the early growths in the female, in the order of frequency, the ovarian cyst comes first, which, though devoid of malignant elements, sometimes dangerously threatens health and life by great pressure on surrounding parts and by appropriating from the blood what should go to the body, thereby producing gradual starvation or inanition; for as a growth increases in volume and weight the unfortunate patient emaciates and weakens, till at last the new tenant has won the day.

We can give no rational explanation for the existence of those abdominal tumors. They undergo every kind of metamorphosis in different individuals. At the present time their career is usually cut short by the intervention of the surgeon; and though, if left alone, they usually go on and destroy life, it is evident to any one who has seen many of them and who is familiar with the laws of pathology, that they do sometimes undergo of themselves spontaneous and permanent cure. The process of disintegration in them, in this event, is one of transformation—simply the reverse of development.

Nature goes to work and takes back what she contributed. First, the aqueous elements are taken up by the absorbers; the vessels atrophy and disappear, the sac and loculi contract; the mucous, mucoid, fibrous, and connective-tissue elements undergo fatty metamorphosis, this in turn liquefying, and thus, in the course of time, the whole of this enormous accumulation has dwindled out of sight.

This same process often takes place in every kind of cellular hyperplasia.

I read the report recently of a case bearing so directly on this part of our subject that I can not forbear quoting it here.

It was an ovarian case published by the French surgeon \* Maingault. He tells us of a woman on whom he was called to operate for an ovarian cyst. When he made the opening incision and exposed the tumor, he found a gravid uterus. He decided it unsafe under the circumstances to continue the operation, and sewed up the wound. She was confined three months later, when it was noticed that the ovarian swelling was much diminished in size. Six months after parturition Maingault again examined her and could find no trace whatever of a morbid enlargement. Two years later she died of pneumonia, when at the autopsy the same surgeon could find no evidence of there having been a tumor, except the presence of a small knotty cicatrix extending from the stroma of the ovary into the broad ligament.

I believe a very large number of cases of cystic degeneration undergo spontaneous cure, especially those in advanced life, by the process of retrogression. Nature will sometimes work wonders in this direction.

As it is not within the scope of this discussion to touch on treatment, except inferentially, I will not stop to dwell on what can be done with the intelligent and judicious use of medicines in dissipating many of these formations.

The question has been debated with considerable spirit as to whether or not certain hyperplasiae owe their origin to the mental state, to psychological influences, some

\* "Nouv. élém. de méd. et de chir. opér." Paris.

maintaining that they have seen too many instances directly connected with great tension of mind to regard them as mere coincidences; others, on the other hand, go great lengths to prove the contrary by showing that malignant disease finds its way into the circles of the wealthiest and apparently happiest as well as into the laborer's domicile.

From what I have seen, I must incline to the latter view, though I do think that frequently there is a direct and positive connection between the development of cancer and the state of the mind.

We by all odds find it most frequent in the morose, phlegmatic, and melancholy, and rarely in the gay, cheerful, and buoyant; in fact, in the opposite to those afflicted with tuberculosis, who are usually to the last hopeful.

Though I can not subscribe to the mental condition as a cause of development, I can not say this with respect to its effects on the progress of the disease.

I have seen the fiery heat of a large, fungous, sloughing cancer choked off more than once, as if by magic, by the mere touch of the hand. No one will deny the efficacy of happy and hopeful mental impressions in many of those neoplasms.

We have authentic records of the king's evil, as scrofula was called, because of the manner in which this affliction was once cured by the royal touch. It would really seem that those nomadic, itinerant cancer quacks now and again relieved a case which men who have reached the very summit of fame in their profession had given up as hopeless.

The tumors which they get the greatest credit for curing may not have been of a malignant type; but even if they are not, we see enough in them, and the manner in which they are disposed of, to satisfy us that the relation between mind and matter, mental influence and tissue metabolism, is positive, distinct, and indisputable.

Every kind of emotion, without question, exerts a most remarkable effect in many of the neoplasms or tumor-like formations.

The mention of the knife with the thought of shedding blood will often terrify a sensitive person.

In those large, bulging, inflamed haemorrhoids at the anus where we have tried every expedient short of strangulation, injection, or excision, but without good results, after we speak of operation—which is usually promptly rejected—fear produces wonderful effects. In one night I have seen the whole mass disappear. On more than one occasion I have seen this phenomenon where ocular evidence was obtainable.

It may be said that this can be readily explained on the theory that the sphincter relaxed and permitted the protrusion to disappear up the bowel.

To satisfy myself on this point, I have several times taken the rectal speculum and explored the mucous lining in search for them, but without result.

Nothing whatever remained but the shrunken, withering stalks, which disappeared in a few weeks, leaving no trace of the original lesion.

Like all other ills and ailments of man, those morbid growths are frequently hereditary, and, everything being

equal, they are most likely to occur in the progeny of those who had been similarly afflicted themselves.

Family resemblance is transmissible, as all family traits, virtues, vices, and habits are. We can often recognize a member of a family by his peculiar gait, the poise of his head, or quality of his voice, so that it is but a natural corollary that he should likewise inherit the tendency to malignant disease in the way of new formations. Of course, if our habits, circumstances, surroundings, and climate are different from those under which our parents were bred, so shall we differ vastly in our physical make-up and constitution from them and escape in a measure their infirmities of mind or body, or acquire others of a kind to which they were strangers, so that in this way many escape the effects of heredity.

When we are in doubt about the nature of a sore, however, and there is a distinct family history of a similar taint, it is good confirmatory evidence.

The aetiology of new formations is of far-reaching importance, as it should have a decisive bearing on prognosis and treatment; but, strange to say, we are to-day as much befogged in the matter of causation as ever. Science has been able to assist us here only to a very limited extent.

Are cancerous growths in their beginning due to a local irritation or traumatism, or is there not always, before any outward manifestation of them is seen, thorough systemic infection, giving rise to what is called the cancerous cachexia?

From long and careful observation and the perusal of the works of authorities, ancient and modern, new and old, there seems to be but one conclusion which we can come to in this matter: it is that the disease is always constitutional, usually transmissible, and by no means yet discovered curable.

In some people its energy is spent on an ulcerating sore; this lesion the consequence, not the cause. This will destroy life in itself through pain and drain.

A surgical operation for the removal of the growth will undoubtedly very often give one many additional years, but to effect a cure in its broadest sense—never.

The system is thoroughly saturated with the dire disease, and art is often powerless. How the surgeon will decide the matter as to intervention with the knife belongs to treatment—something very important, which I will not enter into other than to say that it is altogether a different matter now to what it was in the early part of the present century and before it, when so many died of pain and haemorrhage on the operating-table, while to-day, with our perfect anaesthesia and ready methods of controlling haemorrhage in any part of the body and with the use of antiseptics, we may, with reasonable safety, remove almost any kind of new formation without imperiling life.

Tumors of every kind grow not unlike the body—*i. e.*, they sometimes develop rapidly, occasionally very slowly, and not seldom halt, remaining quiescent until they move on again. Many undergo no change in size or appearance for years. Many of the congenital blemishes—such as the naevus and port-wine mark—undergo no visible changes throughout life, though the natural history of every tumor embraces its

transformation or, as it is usually termed, disintegration or obliteration.

The elements slowly take on calcareous or fatty changes, possibly inflammatory and purulent. This latter is the most speedy process. The surgeon will often induce by art changes of structure, ending in the involution and disappearance of the tissue hyperplasia.

This metamorphosis of the molecular elements of a tumor undergoes every kind of mutation, which will occasionally lead to relief or cure, but unfortunately, in certain structures, tends to destroy life. This is seen in the atheroma of arteries, when their coats become the seat of fatty or ossific changes, ending in a dilatation of their lumen, aneurysm, or a bursting of the vessel itself, which, if occurring in the brain, usually ends in death.

This process of degeneration is often met with in connection with development itself, as we so often witness it in connection with ovarian cysts of the multilocular variety, where, while in one loculus or compartment we find mucous, in another serous, in a third dish-water-colored liquid, and again in a fourth, fatty changes commencing.

All this points most beautifully to the great diversity of phenomena of pathological action going on simultaneously—the developmental and processes of decay, each seeming, as it were, to win the mastery.

When spontaneous disappearance of one of those neoplasms does occur, there is no doubt but the first organized tissues to become affected are the blood-vessels, probably becoming affected in a manner not unlike the cessation of the circulation in the umbilical cord at birth.

This gradual diminution of the volume of the blood-current proceeds, probably, from the deeper vessels to the surface capillaries, and from the center toward the periphery.

While the sanguineous supply is being reduced in this manner, the absorbents are actively at work; and the chemistry of pathological transformation, sometimes gradually, again with great rapidity, mummifies, liquefies, and dissipates the remnant or *débris*.

The medical attendant, in imitating this process so wonderfully elaborated by the economy, at one time accomplishes his purpose by making his attack direct through surgical methods; again he will attain the same end, if a well-trained and observant physician, by the aid of change in surroundings, climate, diet, and the intelligent use of electricity and drugs, etc.

It has been curiously noticed that the victims of malignant growths are seldom stricken by prevailing epidemics or maladies peculiar to the changing seasons; but when they are it is said the effect is most salutary, often staying pathological changes indefinitely.

As a rule, independent of the seat of the malady itself, the organs are usually healthy, and the patient expresses himself as being as well as ever if only freed from the localized affliction.

It has been a mooted question what relation the social state as regards marriage or celibacy bears in the production or predisposition to tumors.

No one, I think, conversant with the normal physiologi-

cal phenomena of the female generative system, and who has observed the profound and beneficent effects of maternity, will deny that it seems something more than probable that in the well-developed, hale, and hearty maiden of amative propensities, well fed, and permitted the unrestrained society of the male sex, the prolonged absence of copulation and the penalty enjoined by nature for not giving reasonable vent to pent-up passions may be, and often is, a disordered state of the organs of nutrition, and especially those of the reproductive functions, resulting in a surplus of the formative elements which is made manifest in the way of morbid growths.

Since marriage has been so abused and it has become unfashionable to have large families, it is hardly to be wondered at that the ovary and uterus are so frequently the seat of degenerative changes.

Now, with regard to the tissues which are most liable to transformative changes ending in degeneration, the form, habitat, chemical, histological, or pathological constituents of the various neoplasms—to go into each of them in detail more than has been done would carry us much further than the limits of this essay was intended to reach.

However, in closing, it may be well to epitomize and recapitulate some of the leading features of those growths oftenest seen.

The cancer of former times, the early part of the present century, is now classified in two divisions—the one called cancer proper, which includes all epithelial growths wherever found; and the other designated sarcoma.

In one respect they both are identical: they are both fatal. Sarcomatous growths are quickly and fearfully destructive.

The diagnosis of each may be arrived at with considerable degree of certainty by the clinical history and a competent knowledge of the aetiology of each.

Sarcoma is generally a disease of early age, is seldom accompanied with much pain, and always confines its ravages to the connective tissue at the outset. It is disseminated by the blood-vessels, and, I believe, the *genuine article* invariably returns after enucleation. Microscopically, it is distinguished from true cancer by the shape and arrangement of its cellular elements.

Carcinoma, on the other hand, oftenest comes late in life, and seems to have a predilection for the epithelial elements, when it is known as epithelioma.

In the male, as already stated, the lip, the oesophagus, the tongue, and the rectum are the most often attacked by new epithelial formation.

In the female, the uterus, the mammary gland, and stomach seem specially to invite its attack.

No doubt in epithelial cancer we may stay its progress by operation, but it is doubtful that by any means at our command we can cure it.

The malignant and non-malignant tumors may, by their size and situation, seriously imperil health and life itself, as with a scirrhus of the oesophagus or rectum—the one by shutting off the necessary supply of food and embarrassing breathing, and the other by preventing the free egress of faeces.

The enlarged fibroid, by its great volume, may become a source of distress and annoyance.

Any vessel or duct in the body may have its lumen narrowed or obliterated by these enlargements, which spare no tissue in the body, and, unfortunately, when this does occur in malignant neoplasms, often nothing can be done, as, owing to their invariable tendency to infiltrate, invade, and compromise the integrity of adjacent parts, they can only seldom be displaced.

In innocent tumors, when their cyst-walls have inflamed and contracted extensive adhesions, their enucleation may be attended with great difficulty.

Finally, I think we may summarize as follows:

1. That, of all animal creation, man is most frequently the victim of malignant tumors.

2. That the malignant variety leads toward death, though, by intelligent surgical intervention, life may be prolonged.

3. That, while we know a benign growth may undergo malignant changes, the reverse is seldom known to take place.

4. That habits, diet, climate, environment, and heredity are undoubtedly active factors in causation.

5. The benign, particularly of the skin, remain through life, though they may disappear spontaneously, and they too may be the starting-point of dangerous disease.

6. There are many which develop only in certain organs or tissues—the so-called homologous, which, under certain circumstances, undergo atrophy, or cease to grow.

7. The effect of psychological and physiological influences on the arrest of progress and obliteration of neoplasms is so often seen that it must be admitted.

8. In the diagnosis the clinical history alone is often ample to decide the true nature of the formation, the bacteriological and microscopical revelations being contributory evidence only in themselves, not to be too much relied on.

9. As many tumors arise from defective or perverted nutrition and imperfect metabolism of tissue, they may and should be dealt with by constitutional measures.

10. When, however, it appears that medicine makes no impression, the knife should be recommended early, as at the present time—when modern surgery has reached such perfection that with anesthesia all pain is avoided, with antisepsis purulent infection prevented, and with the aid of the modern clamp-forceps and temporary transfixion ligature hemorrhage impossible—an operation is stripped of all its former horrors and dangers, and can be at least recommended if for no other purpose than the relief of pain and further extension of life.

**Uralium.**—"The latest of hypnotics, 'uralium,' is produced by the combination of chloral and urethan. It is prepared by Signor Gustavo Poppi, of Bologna, a medical student, who declares with all the ardor of youth that it is the best of hypnotics. . . . No doubt the ammonium base of the urethan may counteract in part the depressing action of the chloral, nevertheless the new hypnotic does not recommend itself to us."—*Dublin Journal of Medical Science*.

## THE TIME REQUIRED IN THE STOMACH DIGESTION OF DIFFERENT FOODS IN INFANCY.\*

By MAX EINHORN, M. D.,  
PHYSICIAN TO THE GERMAN DISPENSARY, NEW YORK.

THE digestibility of foods was for a long time judged by the time required for their disappearance from the stomach. The less time a food requires for that object, the more easily digestible is it. I only mention, for example, the scale of digestibility built upon this principle by Beaumont and Riehet, which is cited as standard in Ewald's † book, "Klinik der Verdauungskrankheiten." Although we know that the digestion of food is only partially performed by the stomach—the greater part being done by the intestines—still, the time of retention of food in the stomach is of importance. Besides the work the stomach performs in real digestion, it has an additional task—to prepare the substances contained in it for their entrance into the intestines, and to convert them into a condition suitable to those circumstances. Therefore, the less time occupied by a substance in leaving the stomach, the quicker must it have been converted into that condition. Thus this substance is, so far as concerns the stomach, more easily digestible.

Whereas for adults the normal time of stomach digestion for the most different substances has been determined by many authors, there has as yet been very little done in this respect for infants. Still, the question as to the time of stomach digestion in infants is of great importance, for, whereas, on the one hand, the answer to this question is closely associated with that of how often an infant ought to be fed, on the other hand, the knowledge of the length of time that the various infant foods remain in the stomach is especially important as an indication of the digestibility of these foods.

These points of view decided Dr. J. Rudisch and myself to undertake some investigations regarding the stay of different food materials in an infant's stomach; but, as my colleague and friend has been too busy with his practice, I was forced to take up the work, in fulfilling our mutual idea, alone.

The proposed question I have investigated, thus far, only in infants of the earliest age (three to nine months old). The food materials which were considered in our investigation were:

- A. Mother's milk.
- B. Cow's milk: *a*, undiluted; *b*, diluted with water; and *c*, diluted with barley-water.
- C. Artificial infant foods: *a*, Nestlé's milk food; *b*, malted milk; *c*, Carnick's soluble food; and *d*, Mellin's food.

The investigations were pursued in the children's ward of Randall's Island Hospital, and I am indebted to Dr. Simmons, Dr. Maxwell, and Dr. McCready for their kind permission.

\* Read by title at the fortieth annual meeting of the American Medical Association.

† Ewald, "Klinik der Verdauungskrankheiten," i, p. 95.

The only statements found in literature on our subject are those of H. Leo,\* and treat of the stay of mother's and cow's milk in an infant's stomach. Leo briefly states that one hour after milk feeding, the stomach, in infants a few weeks old, is already normally empty; in somewhat older infants the milk is retained a little longer, the maximum time being an hour and a half for breast-nursed infants and two hours for infants fed on cow's milk. There are no further remarks on this subject, so far as I am aware.

The course of the investigations made was as follows: First, we determined, in a number of healthy breast-nursed infants, in how long a time after the last nursing the stomach became empty; then a number of artificially fed infants were selected, all of them well as regarded their stomach; only two of them lacked somewhat in bodily development, the others being perfectly normal. In these infants, on different days, several food materials were examined with reference to the time of their stay in the stomach. During the days of examination the infants had the usual food of the institution; three hours after the last feeding, usually between five and six o'clock A. M., the infants were fed with the substance to be investigated, and were examined one to two hours afterward with the stomach tube (consisting of a Nélaton catheter, No. 14 A).

Allow me, gentlemen, to describe more fully the *modus operandi*. The introduction of the stomach tube is very easily performed. I have found it more convenient to examine the infant in the recumbent position. A towel is spread around the chest and arms of the child and easily held by the nurse (in this way the child is prevented from interfering with its arms during the procedure). Thereupon the tube is pushed with its oval end into the mouth of the infant. Usually, the child begins to suck and to accomplish several swallowings; both these circumstances facilitate the introduction. One need only push the tube farther into the mouth (without putting his finger into the child's mouth), and it goes quickly through the œsophagus into the stomach. Sometimes the children cry and do not like to suck the tube; the procedure is then somewhat more difficult. You then introduce the left index finger into the child's mouth until the regio epiglottica is reached, slightly depress the back of the tongue, and guide the tube with the right hand along the forefinger and a little to the left. If the child cries or makes a deep expiration, the tube will often encounter resistance at the introitus œsophagi; in this case it is necessary to wait until the child makes an inspiration; then the tube easily goes through the œsophagus and enters the stomach.

The stomach, as well as the other abdominal contents, is under positive pressure during expiration. But, the cardia being slightly closed and the walls of the œsophagus pressing upon each other, the occlusion is thus increased, even during expiration, by the circumstance that by the diminution of the thoracic space a pressure is exerted on the outside walls of the œsophagus. In this way, normally, notwithstanding the pressure exerted on the stomach during expiration, nothing of its contents can come out; but as

soon as there is a communication made by the introduced tube between the stomach and the outside world, any fluid in the stomach will, during a forced expiration, seek the place of less pressure, and will thus make its appearance. Ewald's expression method in adults is founded upon this principle. In infants, the undiluted stomach contents can be obtained in the same way. The expirations of the child are usually sufficient to bring up the stomach contents; but, if the spontaneous expirations of the child exert too weak a pressure to force the contents out, one can make the child cry, and thus increase the expirations and the pressure. After a few seconds the stomach contents, if such exist, always appear. If, in spite of the child's crying, nothing comes out after about a quarter to half a minute, the stomach, as a rule, is empty, or there may exist only traces of contents. One can convince himself more fully whether the stomach is empty or not by blowing air from his own mouth through the tube into the stomach of the child. If there is fluid present in the stomach, the air, striking through and above the fluid, causes a rising of bubbles, which when bursting give a gurgling sound audible to the observer. If there is no fluid in the stomach, one can hear the air striking the stomach walls, but without producing any such sounds. In this way it is possible, without washing out the stomach, to determine whether it is empty or not.

According to the method described I always proceed in making these investigations.

Although the chief object of this investigation was to determine how long after feeding it took the stomach to become empty, or whether after two hours there were yet some contents present; notwithstanding, as a secondary matter, observations were always made upon the physical and chemical qualities of the undiluted stomach contents. Every food to be investigated was given upon two different days to the same children. On the first day the stomach of one part of the infants was examined an hour to an hour and a half after the trial feeding, whereas in the other part the examination was pursued an hour and a half to two hours after the feeding. On the second day the examination was performed just in the same manner, with the only difference that the succession was inverted; in this way all infants were examined once an hour to an hour and a half and the other time an hour and a half to two hours after the feeding. The time counted from the beginning of the trial feeding to the introduction of the tube was always accurately stated and determined, whether the stomach was found empty or not.

The food materials undergoing the investigation were always given in the same quantity—viz., four ounces. As to the artificial food substitutes, the preparation was made according to the receipt accompanying them.

When contents were found in the stomach they were examined for their physical condition; then they were filtered and investigated as to their reaction (acid or not) and as to the presence of free hydrochloric acid; sometimes also as to the presence of lactic acid, propeptone, peptone, and the rennet ferment. As soon as the quantity of the filtrate was sufficient, the degree of acidity was determined. As usual, the determination of the degree of acidity was accomplished

\* H. Leo, "Berlin. klin. Wochenschr.", No. 49, 1888.

by means of a one-tenth standard sodium-hydrate solution and phenolphthalein serving as an indicator. The number of cubic centimetres of the sodium solution used to neutralize 100 c. c. of the filtrate give the figure of acidity. I usually took for this purpose two e. e.; I had then to multiply the obtained number of cubic centimetres of the so-

dium solution by fifty in order to determine the degree of acidity.

In testing for free hydrochloric acid we made use of Günzburg's phloroglucin-vanilline reaction, which is the most reliable; \* but, besides this, we examined also by means of Congo-paper, and, wherever the results obtained with Congo differed from those with Günzburg's test, we mentioned it in the remarks.

As regards the time in which the stomach digestion is finished, one can not always expect repeated experiments to have absolutely like results, for, on the one hand, there are individual peculiarities of the different infants under observation, and, on the other hand, the condition of the stomach in one infant at different times will show some variations. Our conclusions will be derived from the majority of results achieved.

After these remarks I should like to show you, Mr. President and gentlemen, the tables containing the results of our experiments.

From Table I (human breast milk) it is evident that in all breast-nursed infants the stomach was empty two hours after the last nursing. Probably one would find the stomach empty as early as in an hour and a half, but I could not test this question, because of the refusal of the mothers to subject their babies to a re-examination.

The stomach contents obtained an hour after feeding always had an acid reaction, did not give any reaction for free hydrochloric acid with the phloroglucin-vanilline solution, and showed small degrees of acidity; the figures varied from six to thirty. By means of Congo-paper a positive reaction was found in two (Braun and Totten) of the stomach contents, but this positive result of the Congo reaction must have been due to the acid albuminates or to the lactic acid present in these cases. Propeptone was found in most cases and peptone in some of them. The condition of the milk coagula was in two infants very fine, in three pretty fine, and in one infant (Weiss), which was not very well, thick and coherent; besides this, much viscid mucus was also present in this last case.

Table II (cow's milk and barley water) shows that in from an hour and three quarters to two hours after feeding with a mixture of equal parts of cow's milk and barley water the stomach was found either empty or nearly empty. By "traces" I mean that condition where there were found only a few drops of fluid in the tube. The stomach may practically be considered as empty in such cases. The stomach contents obtained an hour after feeding always had an acid reaction, showed degrees of acidity from twenty to thirty-five, and contained no free hydrochloric acid. Only once did I find in the infant Doraw, an hour and fifty minutes after feeding, free hydrochloric acid in the few drops contained in the tube. The coagula flakes were twice very fine, twice medium, and twice thick.

Tables III and VIII (cow's milk and water,  $\ddot{\alpha}\ddot{\alpha}$ ) show that in about an hour and a half after feeding with a mixture of equal parts of cow's milk and water the stomach was found empty. Here also we found in the stomach con-

tents a slight acidity, no free hydrochloric acid, and the condition of the coagula flakes various, fine, medium, and in Rickert's thick.

Table IV demonstrates the behavior of undiluted cow's milk. In an hour and fifteen minutes to an hour and twenty-five minutes after the trial feeding the stomach was empty in most of the infants. Free hydrochloric acid could not be detected. In nearly all the infants the coagula were thick, and only in one fine.

Table V contains the experiments with Nestlé's milk food. Two hours, and even a little longer, after feeding, all the infants, with the one exception of Smith, had still a great deal of the food in their stomach. The flour particles were very minute and well distributed. The acidity was relatively high only in Bernstein and Jackson, whereas in all the others it was low (5 to 12). Free hydrochloric acid was always wanting.

Table VI (maltaed milk). Here we found the stomach empty in three infants after two hours, and in one (Sullivan) after one hour and fifteen minutes, whereas in three other infants the stomach, at the end of the second hour of digestion, was not yet empty. On the second trial day the infants took only half of the food portion given to them. The stomach contents always showed a very minute distribution of the solid particles, only in Jackson (which child was not well at the time) there were somewhat large particles suspended in the fluid; the whole mass looked like water with small pieces of roll swimming in it. The acidity fluctuated from 8 to 45; free hydrochloric acid was not found.

Table VII (Carnrick's food). At the end of the second hour in four infants the stomach as yet was not empty, but contained a considerable quantity of food; in two of the infants (Thompson and Smith) the food had already disappeared from the stomach. The contents showed always a fine, minute distribution of the solid particles, but the same were somewhat coherent in three of the infants. The acidity fluctuated between 20 and 35. Free hydrochloric acid was wanting.

Table VIII (cow's milk and water,  $\ddot{\alpha}\ddot{\alpha}$ ). These results have already been related in conjunction with those of Table III. The reason why we again took up the investigation of equal parts of cow's milk and water after having examined the artificial infants' foods was in order to demonstrate that the functions of the infant's stomach did not suffer much by the long period of experimentation—*i. e.*, that the stomach did not work slower as regarded the transport of its contents to the intestines—and in order to have in this way a better control. In fact, this time also in all infants the stomach was found empty after an hour and a half.

Table IX (Mellin's food). According to the recipe, the preparation is as follows: Two tablespoonfuls of Mellin's food, a quarter of a pint of water, and three quarters of a pint of cow's milk. The mixture is composed in this way in greatest part of cow's milk, and can not be considered, therefore, as an artificial food. Of the infants examined after an hour and three quarters, two infants had already an empty stomach, whereas in the stomach of the third contents

\* Einhorn, "Medical Record," 1888, p. 227.

were present. As regards the condition of the stomach contents, in two the milk was found coagulated in thick lumps, whereas in one the coagula were very fine. Free hydrochloric acid was found in only one, Jackson's.

In making up a short *résumé* of the results obtained in the examination of the stomach contents upon our different trials, we see, first, that even mother's milk can be found under certain circumstances, although very seldom, in a more or less thickened, coagulated condition. The undiluted cow's milk is usually found in thicker coagulated lumps. The diluted cow's milk appears in fine curds, and only occasionally in thicker coagula.

The degree of acidity in the stomach contents was in the milk, as well as in the other food materials, always a low one, and free hydrochloric acid could hardly ever be detected.

The reason why the free hydrochloric acid, although secreted by the stomach—as can be easily seen by the propeptone and peptone formed in the stomach—can not be detected, lies in the circumstance that the albuminates of the milk and of the other food materials combine with the acid to form acid albuminates.

The degree of acidity is not diminished thereby, but the test for free hydrochloric acid will prove negative so long as the latter is not present in sufficient quantities. (One can easily convince himself of this fact in the following way: Add separately to 5 c. c. of distilled water and 5 c. c. of milk 1 e. e. of a one-tenth standard hydrochloric-acid

cretes less hydrochloric acid than that of adults. Leo\* likewise remarked the fact that in milk-feeding the acidity of the infants was a low one.

It has usually been the custom to prescribe hydrochloric acid † in derangements of infants' stomachs, because, upon examination of the vomit, no free hydrochloric acid was found. Inasmuch as, according to my observations, there is no free hydrochloric acid present in the normal stomach contents of infants, it will be seen that there is no indication for supplying the supposed absent hydrochloric acid.

In order to quickly understand the time required for the stomach digestion of the different food materials‡ in the same infants, I made in a comparative table (X), having only reference to the time in which the stomach becomes empty or is yet filled. It is evident from this table that undiluted cow's milk, as well as that diluted with water or barley-water, leaves the stomach in from an hour and a half to two hours, whereas the other artificial food substitutes are still found usually after two hours in the stomach. Milk is in this way the most easily digestible food for infants' stomachs.

Among the artificial food substitutes examined as to the time of their stomach digestion, malted milk seemed to take the first, Carnrick's the second, and Nestlé's food the last place.

As regards the question of artificial infant feeding, since early times mother's milk has been considered as the looked-for ideal; the more we are able to make the food

														1 50	+

solution; the water will give, with the Günzburg solution, a positive characteristic test for hydrochloric acid, whereas the milk will prove to contain no free hydrochloric acid with the same Günzburg's test. But, if we determine the degree of acidity in the water and in the milk, we find the same greater in the milk than in the water.) From the low degree of acidity nearly always found in the normal infant's stomach, it appears that normally the infant's stomach se-

approximate human milk, the better is it. A priori, the milk of mammals shows in appearance as well as in composition great similarity to human milk. Therefore, very

\* Leo, "Berlin. klin. Wochenschr.", 1888, No. 49.

† "Annual of the Universal Med. Sciences," 1889, vol. i, E. 24.

‡ REMARK.—Mother's milk was not added in this table, because the time for mother's milk was taken from other infants being nursed by the breast.

early cow's milk was used as a substitute for human milk. Later on, exact milk analyses were made by different observers, and it was learned that human milk contained less casein and more milk-sugar than cow's milk; furthermore, it was perceived that human milk was coagulated by acids in very fine, small flakes, whereas cow's milk was curdled in thick lumps. In order to make cow's milk more like human milk, it was diluted with water, and milk-sugar was added, first by Biedert \* and then by Raspe; † this diluted milk gives even a finer coagulation.

This simple method of preparing food so nearly approximating human milk certainly merits to be highly recommended, and it is used indeed with the best results in the whole world.

At the last meeting of the New York Academy of Medicine, on June 13th, Professor Rotch, of Boston, in his excellent paper on "Infant Feeding," laid also much stress on using only diluted cow's milk with the addition of milk-sugar, and warned against the use of all so-called patent food materials, because physicians ought to look themselves to the foods they gave, and not rely upon business men to find out foods and to recommend them. Merely from this principle we should not use the artificial foods for infant feeding.

As you have seen before, the result of our investigation is that the time of stomach digestion is much longer for all manufactured artificial foods than for milk (human, cow's undiluted and diluted); in this way it is proved by experimentation that milk should have the preference, and therefore I fully agree with Professor Rotch.

If asked what conclusions we may derive from these investigations, they would be as follows:

1. Infants deprived of human breast milk should be fed, first of all, with (diluted) cow's milk, especially as we are now able to protect the milk by sterilizing it (by means of Soxhlet's apparatus) from decomposition and bacteria.

2. Infants artificially fed should not be fed every two hours, as thus the stomach would be over-filled, but ought to be fed with these foods at greater intervals.

3. In sick infants the absence of free hydrochloric acid in the stomach contents should be no indication for prescribing it.

**The Treatment of Diarrhoea in Phthisis.**—"Dr. Polyák, of Görbersdorf, gives in the 'Orvosi Hetilap' the results of some trials he has made of two recently suggested remedies in the diarrhoea of phthisis—viz., silicate of magnesia in the form of talc, which has been recommended by Debove, and lactic acid, recommended by Dr. Sézary and Dr. Aune. About eight ounces of talc were well shaken up in a pint of milk, and this, or even a larger quantity, was given daily. Dr. Polyák thinks it quite impossible that long-continued use of talc can heal intestinal ulcers. Lactic acid proved in his hands a much more satisfactory remedy. The initial dose employed was thirty grains per diem in four ounces of water; this was increased subsequently, but not more than seventy-five grains per diem were given. On the third day the diarrhoea and the pain were generally arrested, and during the next day or two the stools assumed their ordinary character. It was found advisable to continue to give small doses for some time longer."—*Lancet.*

FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JULY 20, 1889.

THE INFLUENCE OF THE OVARIES ON THE ORGANISM.

In a recent issue we gave an outline of Professor Brown-Séquard's curious investigations into the influence of the testicles on the organism, and further information concerning his ideas will be found in the present issue. In connection therewith, as we suggested in our article of July 6th, it is interesting to consider the significance of the ovaries apart from their reproductive function.

It would be a difficult matter to compute the vast number of cases in which the ovaries have been removed. It is but a few years since the text-books on gynaecology and general surgery could compass in a table of small dimensions the names of those who had performed oophorectomy and the number of cases in which they had operated. Now the number of operators is "like the stars," and not a few have reported series including several hundred cases. A great deal of valuable information has been derived from the publication of these cases, and much more is to come. Glaevecke has analyzed a great mass of data of this character, and his conclusions are suggestive, not to say startling, at least in some respects. Of cases in which the ovaries had been removed, he found that in 88 per cent. menstruation ceased at once or after a short time; in the remaining 12 per cent. it continued at rare intervals and with a much diminished flow. The cessation of menstruation is explained on the theory that the ovary is the source whence the impulse to menstruation proceeds. In about half the cases the molimina menstrualia still recurred in obedience to habit, together with a recurring irritation of the uterus proceeding from the proper nerve centers, and causing hyperæmia. The phenomena of the menopause were present in most cases: flashes of heat, dizziness, headache, leucorrhœa, sweating, etc.

In most cases also the vagina and uterus became atrophied after a short time, uteri that had been enlarged from chronic inflammation or the presence of myomata becoming as small as or smaller than the normal. In 42 per cent. of the cases the body increased in weight and in the supply of subcutaneous fat. In most of the cases the sexual desire was notably diminished and in many it was extinguished. In almost all cases the mind became more or less affected, and not infrequently melancholia resulted.

After the removal of the uterus, menstruation ceased in all the cases analyzed, and atopomenorrhœa or substitutes for menstruation never occurred to any extent. Molimina menstrualia recurred regularly for a short time, with pain and annoyance in the abdomen, this being explained by the continuance of ovarian activity and the reflected pelvic hyperæmia

recurring monthly. Removal of the uterus had no perceptible influence upon the vulva and vagina, and the ovaries did not necessarily undergo atrophy for several years. The influence upon the general nutrition is said not to be so decided as that of removal of the ovaries. Sexual desire is also influenced to a much slighter degree than after oophorectomy. In a third of the cases there was more or less mental derangement.

Thus it will be seen that the conclusions from this analysis are not entirely in accord with general opinion nor with the expressed views of some writers of large experience. In the matter of sexual desire, it has been repeatedly asserted that this was more likely to be intensified than diminished by removal of the ovaries. As to the mental effect, it will doubtless appear too sweeping a statement to be true that all, or nearly all, women whose ovaries are removed suffer unfavorable mental changes. Were this the case, it would be in itself a sufficient reason for the greatest circumspection before performing the operation.

Keith has recently stated that 10 per cent. of his patients who recover from hysterectomy subsequently suffer from melancholia or other form of mental disease. Even if this percentage, much smaller than the proportion stated by Glaevecke, suffered in this way, it should make one hesitate to impose upon a woman the risk of changing the ills she has for others that are worse. What is chiefly required in this matter at the present time is not greater operative skill so much as calmness and clearness of judgment to decide as to cases which are suitable for operation. These cases may be divided into three classes: 1. Those in which an operation is imperative. 2. Those in which the propriety of an operation is questionable. 3. Those in which an operation, for whatever reason, should not be performed.

And we consider it a reasonable proposition that an operation should not be performed, and the life of the patient jeopardized, if moderate relief from her existing evils can be obtained by less dangerous procedures.

#### DOMESTIC AND PUBLIC HYGIENE.

THE women physicians of all schools of practice in the city of Chicago have formed a Woman's Medical Union for the Advancement of Domestic and Public Hygiene. In New York, the Ladies' Health Protective Association, which has done good work in the matter of street cleaning and the abatement of public nuisances, is now investigating matters relating to the management of the public schools that are of sufficient interest and moment to rouse the seven sleepers or any other inert body of indifferent citizens. But the most unique organization for inducing municipal authorities to enforce sanitary laws is a little colony of college-bred women about to be established in Rivington Street. In that unsavory locality, graduates from the leading literary colleges for women, together with a woman physician, are about to take up their abode, and to adopt all the inconveniences of such a life, in the earnest endeavor to convert some of the great unwashed into the washed

by means of baths at five cents each; to interest young girls in the subject of cleaner living; to improve the gutters for those who play in them; and to diminish as far as possible, by a personal statement to the proper representatives of municipal government, the avoidable horrors that they expect to share with the natives of this region, for smells are no respecters of persons, neither is the sight of decaying animal and vegetable matter. This little band of young and pretty women have been told again and again that they need not expect to teach the people anything, but consoled in the same breath by the assurance that they themselves will learn a great deal. The movement is not a so-called religious or intellectual venture. It is a simple scheme of ethical culture, beginning at the foundation of things, without cut-and-dried rules, prejudices, or opinions. Books are wanted for the girls. It is hoped that, if a girl can be induced by personal influence to read one book, she may rise equal to a desire for another. Not even the most sanguine of the Rivington Street colony expect to teach the mature women anything, though they have plans for making the poor souls happy now and then. In a little speech on the subject, a bright and charming Smith College graduate said: "The mothers are always left out. The men have pleasure; they get drunk and fight. The little children can play in the gutter till eleven o'clock at night. Boys and girls have their dance halls. But the laborer's wife signs her death warrant, so far as all pleasure is concerned, the instant she marries. The plush gown that constitutes the wedding garment is her last splurge." The colonists' idea of giving these mothers pleasure is to present them with something good to eat; and our college graduates trust that some listless, weary woman may rouse herself and wish to learn of them how to make it.

Hygiene as the basis of morals is one of the governing principles of modern philanthropy. Every year a disposition to raise the fallen and befriend the friendless by affording them increased material and physical prosperity widens its dominion. Two or three, here and there in little groups, have worked out social problems in this way all over the country. In England, it is said, the strenuous efforts of one woman—she found herself in prison once on account of those efforts—have revolutionized the entire sanitary code. It would seem that there is not a shadow of a chance now for the Circumlocution Office in our large cities. The farmer has decided to cut his corn himself, so the larks must be up and about their business. The nineteenth century is the woman's century, as Goethe has it, and the unprejudiced critic must observe that the nineteenth-century college graduate does her full duty to the times in the matter of domestic and public hygiene.

#### MINOR PARAGRAPHS.

##### A BLACKMAILING PLOT DEFEATED.

MR. MALCOLM MORRIS, a London surgeon, recently the subject of an attempt at blackmail, in the guise of a suit for breach of promise of marriage, has had the satisfaction of seeing two of the conspirators against him sent to prison. The principal offender was sentenced for five years, the other for eighteen

months. The sympathy of the London profession was unanimously in Mr. Morris's favor in the contest, and, now that he has won his cause, he has been presented with an address of confidence and respect. Many of his *confrères* have also subscribed their names to a paper agreeing to make up a fund to reimburse him for a part of the heavy expenses made necessary by the contest, headed by Sir Andrew Clark, Sir James Paget, Sir Alfred Garrod, Dr. Quain, Dr. Ord, Dr. Broadbent, Mr. Critchett, and many other well-known men. The "Lancet" also appears upon the list for five guineas, and its editor congratulates Mr. Morris on the result, and praises him for his courage in making a stout resistance where a weaker man might have been tempted into a compromise with the conspirators.

#### THE NEW BLOOMINGDALE ASYLUM.

It is said that the superintendent of the asylum, Dr. Charles H. Nichols, is about to visit a number of European lunatic asylums, and that the results of his observations will be considered in arranging the plans of the new asylum at White Plains. Dr. Samuel B. Lyon will be acting superintendent during the absence of Dr. Nichols. In view of the fact that the new Bloomingdale will have a fund of a million dollars with which to build, Dr. Nichols's mission will be seen to be a highly responsible undertaking and quite the opposite of a holiday trip. It may, and doubtless will, have a wide-reaching influence upon the future of asylum construction.

#### A REMARKABLE ACCUMULATION OF TRICHINÆ.

It is stated in the "Medical and Surgical Reporter" that Dr. Senator, of Berlin, lately reported an account of the autopsy in the case of a man who had died of cancer of the œsophagus. The body was found to be overrun with trichinæ, every fiber of muscular tissue being inhabited by them by the hundred. One piece of muscle weighing less than two grains contained, by count, two hundred and eighty of the parasites. Inquiry being instituted, it was learned that he had had trichiniasis twenty-seven years before, but had recovered and been able to attend regularly to his duties as a night-watchman until the other malady laid him up, only suffering from occasional pains of a rheumatic character.

#### A QUESTION OF PRECEDENCE.

THE "Lancet" says that a question of precedence between the Royal College of Physicians and the Royal College of Surgeons was brought to an issue lately by Sir Andrew Clark, who is the president of the first-mentioned college. On taking the chair at the beginning of his second term he stated that he had been called upon to sign a document as president which was also signed by the head of the College of Surgeons as well as by the president of the General Medical Council. He insisted that his signature should precede the others, and, the matter having been referred to the heralds' College, it was found that he was in the right, and his name was made to head the list by the Garter King at Arms.

#### THE SEXUAL GLANDS AS SOURCES OF ENERGY.

WE lately gave a summary of an account, published in one of our Paris contemporaries, of M. Brown-Séquard's practical tests of his theory of the influence of the testicle on the economy. Our Paris correspondent, in a letter since received, states that the liquid used in the subcutaneous injections is prepared by adding from two to five cubic centimetres of distilled water to the juice obtained by crushing a testicle and filtering the

mixture. In a note addressed to our correspondent, dated June 28th, M. Brown-Séquard says: "A communication will be made to-morrow by a Paris physician of three cases of weakness due to old age, treated by subcutaneous injections of a liquid extracted from the testicles of guinea-pigs and rabbits. The success was as great in each of these cases as it was in myself." Our correspondent further informs us that M. Brown-Séquard regards it as important to prolong the functional activity of the testicles—a most natural corollary of his theory—and that he has even gone so far as to advise an incomplete form of masturbation, falling short of ejaculation, in two cases where there was cerebral weakness, and with most favorable results. In the article that we published on this subject two weeks ago we suggested that whatever was true of the testicles in respect to their influence over the system might also be true of the ovaries, and our correspondent adds that M. Brown-Séquard also entertains this idea, and has accordingly asked some medical women to test the question in their own persons.

#### THE INCREASE OF LEPROSY.

ONE of the prominent questions of the day is that of the renewal of leprosy. Leper-houses are springing up in one part and another of the English-speaking portion of the world, after an abolition of two centuries or more. There have been frequent allusions to the growth of the disease in the foreign journals. Three cases have lately been brought to light at Cape Breton Island, Nova Scotia, one of the patients being far advanced in the disease and a very repulsive object. This is the report of Dr. Smith, medical attendant at the lazaretto at Tracadie, who was sent to the island by the Canadian Department of Agriculture, in whose jurisdiction rest all like inquiries relative to the public health. The singular feature in the report is that a very advanced case of leprosy should have been permitted to continue unisolated in relatively close proximity to a retreat designed to meet the necessities of just such cases; in a straight line the distance of the leper from the leper-house did not exceed three hundred miles. The boundary line of a province passes between them, however. The three newly discovered cases were in Nova Scotia, but the lazaretto is in New Brunswick. The intervention of a territorial line like that will often prove a serious obstacle to the prompt resolution of a health problem; what disposition the Government will make of these cases has not been announced. It is reported that other subjects of leprosy are at large in the northern part of New Brunswick; they are generally Acadians of French extraction.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 16, 1889:

DISEASES.	Week ending July 9.		Week ending July 16.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	15	2	23	0
Scarlet fever.....	54	3	50	9
Cerebro-spinal meningitis.....	1	1	1	1
Measles.....	39	3	55	3
Diphtheria.....	84	18	76	26

The Orange Mountain Medical Society met on the 12th inst. at the house of a member in Springfield and a committee was appointed, consisting of Dr. Bayles, Dr. Harvey, and Dr. Bradshaw, to report a memorial note concerning the late Dr. Stephen Wickes. The paper of the evening, by Dr. Carl Buttner, was on the "Climatic Treatment of Consumption."

**Recent Deaths.**—Dr. Austin White Thompson, who died at Northampton, Mass., on June 11th, was the well-known proprietor of the "Shady Lawn," in that city. This was a private hospital organized by him over fifteen years ago. He was born in 1834, at Pelham, and was educated at Harvard University, taking his degree in arts, with the salutatory oration, when only twenty years of age. He was graduated in medicine in 1857, from the Harvard school. He was an assistant superintendent at the Insane Asylum at Northampton under Dr. Pliny Earle. He was a member of his State medical society, and an ex-president of the Hampshire District Society. He was in his fifty-fifth year when death, by pulmonary tuberculosis, overtook him.

Dr. Theodoric P. Mayo died on June 20th, at Richmond, Va., in the sixtieth year of his age. He was a native of Virginia and educated at Richmond. He was graduated in medicine from the medical college of that city in 1853. In the late war he served as surgeon of the Virginia contingent in the Confederate army.

Dr. Jonathan Mann died on June 15th at Boston. He graduated in medicine at the Berkshire Medical College in 1843, and became a member of the Massachusetts Medical Society in 1852. He was in his seventy-fourth year when his death took place. About eight years ago he withdrew from active practice.

Dr. Ellwood Wilson, of Philadelphia, has died at the age of sixty-seven years. He was one of the founders of the Jefferson Hospital and for many years a trustee of Jefferson Medical College. He was born in Pennsylvania and graduated in medicine, from the school above named, in 1845. He was formerly one of the lecturers at the Nurses' Home, on obstetrics and diseases of women. He was one of the original members and officers of the Philadelphia Obstetrical Society, and had been a member of the College of Physicians since 1851.

**The New York State Medical Association.**—The seventh special meeting of the Fifth District Branch will be held in Port Jervis (Orange County), N. Y., on Tuesday, August 27th. For those who are willing to spare the time after the meeting, a carriage drive of seven miles along the Delaware River to Milford, Pa., is promised. Members are urged to make an effort to attend this meeting, as the following committee of arrangements are making every preparation to insure an interesting meeting, both scientifically and socially: Dr. J. H. Hunt (chairman), Dr. W. B. Eager, Dr. M. C. Conner, Dr. T. W. Bennett, Dr. W. H. De Kay, and Dr. J. A. Munson. Dr. W. T. Lusk, of New York, is the president, and Dr. E. H. Squibb, of Brooklyn, the secretary.

**The Medical School of Maine.**—The medical department of Bowdoin College, at Brunswick, Me., has only limited resources for the clinical instruction of its students, who are said to show a tendency to desert the school and to take their last year's course in institutions which have hospital privileges. On June 24th the students held a meeting and adopted resolutions in which they suggest that the school could be made more prosperous by being moved to Portland, where there are two hospitals and some other clinical resources.

**The Royal Victoria Hospital.**—The "Montreal Medical Journal" for June announces that the building of the Royal Victoria Hospital has at last been begun. The estimated cost is upward of half a million dollars. The arrangements for the treatment of disease and for the comfort of the patients embrace many modern features. Very special attention has been directed by the architect to introducing into the wards all the modern improvements which tend to facilitate clinical teaching.

**A New Medical College in Tennessee.**—The trustees of the Grant Memorial University have voted to add a medical de-

partment to the university. A full faculty has been selected, with Dr. E. A. Cobleigh as dean. It is expected that the new department will be opened at Chattanooga, Tenn., in September next.

**The University of Buffalo.**—Dr. Charles Cary, professor of anatomy in the university, has been transferred to the chair of *materia medica* and *therapeutics*, made vacant recently by the resignation of Dr. E. V. Stoddard.

**Dr. John Jordan Brown.** a notice of whose death at Mifflinville, Pa., appeared in our last issue, writes from Bloomsburg, Pa., as follows: "In the obituary notices of July 13th you make a note of my death. I wish to make a few corrections. 1. I no longer live at Mifflinville, Pa. 2. I never was a member of the Legislature. 3. I never died. The balance of the notice is correct."

**A Seaside Home for Children.**—Dr. L. Coffin, of the Brooklyn Seaside Home, informs us that arrangements have been made at Coney Island for the reception and care of a class of children heretofore unprovided for—those of the middle and independent classes.

**Change of Address.**—Dr. Edward N. Liell, to "The Wave Crest," No. 39 East Fiftieth Street.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 7 to July 13, 1889:*

McPARLIN, THOMAS A., Colonel and Surgeon. By direction of the acting Secretary of War, the retirement from active service this date, by operation of law, under the provisions of the act of Congress approved June 30, 1882, is announced. Colonel McParlin will repair to his home. Par. 2, S. O. 157, A. G. O., July 10, 1889.

SMITH, ANDREW K., Colonel and Surgeon, promoted surgeon, with rank of colonel, to rank from July 10, 1889, vice McParlin, retired.

TOWN, FRANCIS L., Lieutenant-Colonel and Surgeon, promoted surgeon, with rank of lieutenant-colonel, to rank from July 10, 1889, vice A. K. Smith, promoted.

PERLEY, H. O., Captain and Assistant Surgeon, is ordered to accompany troop from Fort Wayne, Michigan, to Gognae Lake, Michigan, to encamp there with the Michigan State troop from August 8 to 13, 1889. Par. 1, S. O. 154, Headquarters Division of the Atlantic, July 9, 1889.

PERLEY, H. O., Captain and Assistant Surgeon, is granted fourteen days' leave of absence, to commence about July 14, 1889. Par. 2, S. O. 154, Headquarters Division of the Atlantic, July 9, 1889.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending July 13, 1889:*

WHITE, S. STUART, Assistant Surgeon. Detached from the Trenton, July 7, 1889, and ordered to the Naval Hospital, Brooklyn, N. Y.

WHITE, C. H., Medical Inspector. Detached from the Trenton and to wait orders.

NORFLEET, ERNEST, Passed Assistant Surgeon. Detached from the Trenton and ordered to the Monocacy.

AMES, H. E., Passed Assistant Surgeon. Detached from the Monocacy and to proceed home and wait orders.

HARMON, G. E. H., Surgeon. Detached from the Constellation and ordered to the Naval Academy.

LOWNDES, C. H. T., Assistant Surgeon. Detached from the Constellation and ordered to the Naval Academy.

HARVEY, H. P., Surgeon. Detached from the Vandalia July 7th, and to proceed home and wait orders.

**Marine-Hospital Service.**—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service from June 10, 1889, to July 13, 1889:*

FESSENDEN, C. S. D., Surgeon. To proceed to Cairo, Ill., on special duty. July 8, 1889.

LONG, W. H., Surgeon. Granted leave of absence for twenty-eight days. June 18, 1889.

AUSTIN, H. W., Surgeon. To proceed to Cairo, Ill., on special duty. July 8, 1889.

IRWIN, FAIRFAX, Surgeon. Granted leave of absence for ten days. July 6, 1889.

MEADE, F. W., Passed Assistant Surgeon. Granted leave of absence for thirty days. June 24, 1889.

MAGRUDER, G. M., Assistant Surgeon. Relieved from duty at Baltimore, Md., to report to the Supervising Surgeon-General for duty as acting chief clerk and attending surgeon. July 10, 1889.

GOODWIN, H. T., Assistant Surgeon. Granted leave of absence for thirty days. July 8, 1889.

#### Society Meetings for the Coming Week:

TUESDAY, July 23d: Medical Society of the County of Putnam (annual), N. Y.

## Proceedings of Societies.

### AMERICAN NEUROLOGICAL ASSOCIATION.

*Fifteenth Annual Meeting, held at Long Branch, N. J., on Wednesday and Thursday, June 26 and 27, 1889.*

The President, Dr. E. C. SEGUIN, of New York, in the Chair.

**Malaria as a Cause of Degenerative Diseases of the Spinal Cord.**—Dr. MORTON PRINCE, of Boston, presented a paper on this subject in which he spoke of the frequency of tabes and other spinal degenerations in cases which also presented a history of malaria. The first case he had recorded had been one of locomotor ataxia with typical tabetic crises before each malarial chill. Another patient had had gastric crises regularly once monthly, and another crises beginning with rigor and followed by diarrhoea, this occurring every three weeks. The latter case had been diagnosed as malarial by the family physician. Altogether the author reported in detail six cases showing the coexistence of tabes with malaria, and six cases where the malarial history had been associated with disseminated sclerosis. Besides these he had notes of three other cases of multiple sclerosis, two of locomotor ataxia, and one of lateral sclerosis with a similar relation. Generally the malarial poison was present in the system previous to the development of spinal symptoms. He pointed out coincidences in the course of syphilis and malarial poisoning, such as the slowness of action of the poison and its amenability to treatment; and also called attention to the relation of the syphilitic virus to tabes. He had found but little to support his aetiological theory in literature. Erb, following Schulze, had stated that tabes might occur as a sequel to intermittent fever. Tuzek had proved that tabes could be caused by the ergot parasite. Many nervous disorders were undoubtedly due to malaria, such as neuralgias, anaesthesia, severe psychoses, etc. He alluded to the deposition of pigment in the brain in some cases of pernicious malarial fever. It would be very important for many army pensioners if it could be definitely determined that tabes and sclerosis might be sequelæ of malarial disease.

Dr. L. C. GRAY, of New York, saw no reason why the malarial poison should not cause spinal diseases. We did not yet know the exact character of that poison. But there was a sort of periodicity in many spinal and cerebral disorders as well as in peripheral nervous affections which was often as marked as that of fever and ague. He had noticed this particularly in intracranial syphilis. Some of these neuropathies were even relieved by quinine, as he had observed in cases of tabes. When we spoke of latent malarial disease and rested our diagnosis merely upon periodicity, there was danger of error. If Laveran and Councilman were right in their discovery of the malarial germ, this should be looked for in such cases as the author had described in order to corroborate the diagnosis. Improvement or recovery under the use of quinine was no criterion.

Dr. E. C. SPITZKA, of New York, saw nothing in the nature of the case to forbid an aetiological association between malaria and cord disorders, but he agreed with the preceding speakers that sufficient proof of such relation had not been adduced. To show an aetiological significance, it was necessary to present absolute and intrinsic proof of it. If it could be shown that, as in syphilis, there were nervous symptoms at the time of the malarial attack, it would be a different matter. In the secondary fever of syphilis there was absence of the knee jerk. Most nervous symptoms in malarial disease were of a neuralgic character. The anaesthesia differed from those of tabes. It had been found that pigmentary thrombosis or embolism was the most frequent cause of serious nervous disturbances in malarial disease. He believed, however, that, like any other cachexia, antecedent malarial poisoning might predispose to spinal affections. He had observed a case of paretic dementia of the tabetic type which was probably influenced aetiologically by severe malarial infection.

The PRESIDENT could not recall a single case of tabes or multiple sclerosis which presented any relation to malaria.

Dr. PRINCE thought there could be no question as to the correctness of diagnosis as regarded the nervous symptoms in his cases, and as to the antecedent malarial disease; all of his cases had been in men who had been in the army service, and he had documentary proof in the shape of Government records of their having suffered from that poison. The really doubtful question was whether the malarial poison still existed in the system at the time of the development of the spinal disorders. In some of them there had been evidence of its persistence in the shape of typical malarial rigor and pyrexia. He did not consider his aetiological explanation decisive, but merely suggestive.

Dr. SPITZKA thought that there were many cases of nervous disease owing their origin to exposure during the war which were contemptuously rejected by the Pension Bureau. It seemed to him that the association ought to call the attention of the Government to the great injustice which might be done.

**Nuclear Ophthalmoplegia with Poliomyelitis (Poliomyelitis Superior and Poliomyelitis).**—Dr. B. SACHS, of New York, reported a case of this affection. The relation between these two forms of disease, which had been suspected by Hutchinson, Mauthner, and others, was proved by this case. But one other was on record, that of Seeligmüller. The history of the patient was briefly that a ptosis of the right eye gradually developed, followed after a few months by ptosis of the left eye also, and soon after a paresis of all the external muscles of both eyes appeared. This resulted in almost absolute fixation of the right eye, but left a slight inward and upward movement of the left. There was immobility of the left pupil to light, but not to accommodation. The right could not be examined, because of corneal opacity. During the development of this nuclear ophthalmoplegia, a subacute poliomyelitis affecting

the entire right leg supervened. There was now marked atrophy of the entire right leg. The knee jerk was lost on both sides. There were no sensory disturbances, there were no tabetic symptoms, and the patient's condition was normal in all other respects. This case proved that the affection of the nuclei in the floor of the third and fourth ventricles was due to the same pathological process which gave rise to poliomyelitis when it affected the gray matter of the cord.

Dr. SPITZKA said the report of the case had been so complete that, as there was but one other such case on record, it did not admit of either criticism or comparison. He referred to Thomisen's case of unilateral nuclear paralysis, where there had been gummatus infiltration on both sides, the explanation of which was to him quite impossible.

Dr. SACHS asked if fibers could be traced up through the ciliary nuclei.

Dr. SPITZKA answered in the affirmative, and made black-board drawings illustrative of their course.

**Hyperostosis Craniæ.**—Dr. W. N. BULLARD, of Boston, then presented for Dr. J. J. PUTNAM a skull which was a remarkable example of this condition. The case had been reported to the association two years before. The patient was a woman, thirty-one years old at death. The chief symptoms had been headache, broadening of the head, dropping out of the teeth, loss of hearing, and vertigo, beginning gradually some years ago. There had been extreme exophthalmia. There had been no retinal changes. Extensive pachymeningitis had been discovered at the autopsy. There were thinning and atrophy in parts of the skull. The orbital cavities were greatly diminished in size. Virchow considered hyperostosis craniæ due to inflammatory changes. In this case probably the inflammation had originated at the ear. Dr. Putnam had a patient now with similar symptoms, in whom the exostoses were first noticed in boyhood, and desired the opinion of members as to the justifiability of removal of certain exostoses for the relief of pain. Dr. Bullard himself thought it might be difficult to determine which of the exostoses produced the pain. Some of the exostoses were very diffuse, and the operation might have to be extensive.

The PRESIDENT believed that the pain would be more apt to originate from basal lesions, possibly dural inflammation about the issuing nerves. The jaw in this case was interesting because of its senile conformation and angle, despite the patient's youth.

**Spontaneous Degenerative Neuritis of the Brachial Plexus.**—Dr. W. M. LESZYNISKY, of New York, read a paper with this title. The patient was a laborer, aged thirty-eight. He had first had pain in the left shoulder, shooting down the arm, which had been ascribed to exposure to wet. There had been then no involvement of the shoulder joint and the motility of the arm had been unimpaired. All the muscles had reacted well to faradism, except the deltoid, which had been atrophied. There had been no sensory disturbance, but there had been pain on pressure. Gradually other muscles had become paralyzed, until a large number of the arm muscles had been useless. The paralysis had been accompanied by pain, so excruciating that the patient could not sleep at night. A feeling of numbness had extended from the shoulder down the arm over the radial distribution, and a gradual anesthesia and analgesia had supervened throughout the same area. The faradic excitability had disappeared, and there had been galvanic superexcitability. Then he had begun gradually to improve, and would ultimately recover. The case had been remarkable in its severity, in its idiopathic origin, and in the escape of the median and ulnar nerves from the inflammatory process. Not more than one case had to his knowledge been found in literature.

Dr. PRINCE thought it would be difficult in the early stages of such a case to distinguish it from progressive muscular atrophy of the shoulder type. He recalled a case of his own in which there had been every reason for considering it to be neuritis. It had begun with cramps, such as were observed in writer's cramp, and it had been several years before other symptoms proved the case to be one of progressive muscular atrophy. The most common cause in such cases as the author's was traumatic arthritis, but generally the results were slight.

Dr. W. R. BIRDSALL, of New York, had seen this case before, and was impressed with the idea that it might be a periarthritic affection, but the author's careful study of the case seemed to exclude this. He recollects that at that time there had been some ankylosis of the shoulder joint in the case.

The PRESIDENT considered the study of the differing resistances in the healthy and diseased arm made by the author interesting, and asked if any member had had experience in such measurements.

Dr. GRAY had noticed much variation in resistance in many of his patients from day to day.

Dr. M. A. STARR, of New York, had measured the resistance in Basedow's disease, and had found it to vary within a thousand ohms in the same cases from time to time. Electricity was diffused through muscular better than through any other tissue. The chief resistance was in the skin. Probably but little of the current permeated nerves, and hence alterations of nervous tissue would not have much to do with the variations mentioned by the author.

Dr. G. M. HAMMOND, of New York, stated that it was well known that the resistance differed from day to day in animals. He asked if in this case it had been measured for a number of times, and was answered that eight trials had been made.

Dr. BIRDSALL thought the question of resistance had little to do with our study of disease. It was easy to explain the numerous variations by the wide differences in vascularity and moisture of the tissues at different times. It might be due in this case to paralysis affecting the physical condition of the tissues. The saturation of the epidermis by perspiration would explain the variations mentioned by Dr. Gray. He had made measurements in cases of Basedow's disease some time ago, and believed that the diminished resistance found was due to the moisture of the skin. It could not depend on dynamic conditions in the nervous system, but was purely a matter of physics about which there was no great mystery.

Dr. GRAY said the explanation by moisture of the skin was not applicable in his cases. The differences which he had observed had not been owing to the humidity of the atmosphere, although atmospheric conditions might possibly induce dynamic changes in the body.

Dr. SACHS pointed out that on one day the author's patient showed 580 ohms increase on the diseased side, and on another day 1,170 ohms increase on the sound side. Such variations evidently had little to do with the pathological process in the patient. Eelenburg had measured the resistances in cases of paralysis agitans and of Basedow's disease, but without any practical results. As such measurements were very complex, they required exceedingly great care.

Dr. PRINCE objected to the use of the palm of the hand for precise experimentation, owing to the great variability of the thickness of the skin, and consequently of the resistance. He thought the forearm ought to be used.

Dr. LESZYNISKY had not brought forward the question of resistance in this case as a diagnostic symptom. It was increased in the affected arm at every examination. With the subsidence of the symptoms the resistance gradually diminished, but there was a difference between the sound and morbid sides throughout

the disease. As to the question of moisture, there was excessive perspiration upon the paralyzed arm, while the normal arm was dry, in spite of which the resistance was greater upon the former. He thought it better to place the electrode upon the wrist than in the hand. There had been no antecedent traumatism in the case; the roughening of the shoulder joint was the result of the paralysis.

**Interpeduncular Myxosarcoma.**—Dr. M. ALLEN STARR, of New York, presented a specimen of this sort. The growth lay in the middle cranial fossa, in the median line, between the crura cerebri, which it separated. It extended into the lateral ventricles, separating widely the caudate nuclei and optic thalami. The patient had been a male, aged twenty-one months at death. At the age of thirteen months, in October last, a lateral nystagmus had been observed in both eyes, varying from time to time. Dr. Knapp and Dr. Roosa had found a slight pallor of the optic discs, which they had considered normal. Subsequently exophthalmia had developed, gradually increasing until death. Convergence of the eyes had been impossible, although no paralysis of a cranial nerve had been discoverable. The reflexes of the iris had been lost. Toward the middle of April, this year, the child had become unable to walk. The knee jerks had been exaggerated; there had been ankle clonus and typical spastic rigidity. Finally, the back could not be held up, and subsequently the head could not be supported. There had been gradual emaciation. There had been no apparent headache. From time to time the scalp had been congested. About this time the pallor of the optic discs had indicated atrophy. There had been no blindness, no hemiopia, no aphasia, as far as could be ascertained in so young a child. Toward the middle of May ataxia of the arms had developed, but without loss of muscular power. On June 8th vomiting and Cheyne-Stokes respiration had come on, and the child had died in nine hours. The diagnosis of tumor had been made, but the question of localization was of great interest. Nystagmus was not a localizable symptom, but had been found most frequently in lesions of the corpora quadrigemina. The exophthalmia indicated intracranial pressure, the gait disturbance led one to think of a cerebellar lesion, while the ataxia of the hands pointed to a basilar trouble affecting symmetrically either the pons or the medulla. The question of operative interference had been considered, but he had opposed that proposition because of the difficulty of localizing the tumor. The autopsy proved that the pons was not even pressed upon, and that the cerebellum was normal. There were twenty ounces of fluid in the ventricles. He would ask if there was any localizing value in nystagmus or exophthalmia, and what the probable cause of the ataxia had been.

The PRESIDENT, referring to the question of ataxia, recalled a case of remarkable bilateral ataxia with optic atrophy, where a large interpeduncular tumor was found between the crura. He thought such ataxia was to be accounted for by pressure upon the motor tracts or motor nuclei. To him the most puzzling feature of Dr. Starr's case was the absence of blindness. As to the nystagmus, it had as yet, in his opinion, no localizing value. He had seen two cases with lesions of the quadrigeminal bodies, but without nystagmus.

Dr. LESZYN SKY said the child might have had only central vision, which might explain the presence of nystagmus, but Dr. Starr answered that the visual fields were normal.

Dr. SAUNDERS was reminded of Meynert's case of tumor in both optic thalami, with ataxia similar to that in Dr. Starr's case. He thought the thalami might have been pressed upon in the latter, but still was not sure that that would cause the ataxia. He considered nystagmus very frequent in many cerebral disorders of children.

Dr. H. M. LYMAN referred to a case he had seen recently of defective cerebral development in a child where there was also nystagmus.

Dr. GRAY asked how a diagnosis of intracranial tumor had been made so early in this case, and was answered that the diagnosis had not been made until all the symptoms described had made their appearance.

Dr. HAMMOND thought ataxia depended upon injury to the optic thalami or corpora striata, and referred to a case of Weir Mitchell's in which there was a remarkable unilateral ataxia, with a lesion of the optic thalamus and corpus striatum upon the opposite side.

Dr. LESZYN SKY had seen a child, several years ago, with well-marked nystagmus, which had disappeared in the course of time. There had been no discoverable cause.

**A Contribution to the Study of Anæsthetic Leprosy, with Special Reference to Partial Sensory Disorders.**—Dr. GEORGE W. JACOBY, of New York, read a paper with this title. The points to which particular attention should be paid in all cases were the electrical excitability of the muscles, the condition of the reflexes, the presence or absence of fibrillary twitchings, and the condition of sensation. Upon these data depended the diagnosis between anæsthetic leprosy and syringomyelia, as well as that of the central or peripheral localization of the leprous process. The conclusions arrived at by the author, from the analysis of his own and other cases, were that the diagnosis between the two diseases could not always be made; that partial sensory disorders were not characteristic of syringomyelia, but might occur in anæsthetic leprosy as well as in purely peripheral affections; and, finally, that a differential diagnostic point between central and peripheral loss of temperature sense might lie in its complete loss in the one case and its partial loss in the other.

Dr. STARR said that the same question as to the diagnosis between syringomyelia and anæsthetic leprosy had only recently occurred to him. Three weeks ago he had seen a case with Dr. Prince A. Morrow, of New York, in which there had been a gradual onset of an atrophic and anæsthetic affection of the right arm. The patient had come from the Sandwich Islands, and had been exposed to leprosy. There was anæsthesia to temperature and pain, but not wholly to touch, along the hand and part of arm. There were three small, reddish-brown spots on the arm, which Dr. Morrow considered leprous in character. The idea of syringomyelia had at once occurred to the speaker, but the history of exposure in a leprous country sufficed to make anæsthetic leprosy at least the more probable nature of the disease; but without such history it would have been almost impossible to make the diagnosis. As to the matter of partial loss of sensation, in the cases of multiple neuritis and *beri beri* he had seen the sensory loss complete, with the exception, however, of muscular sense.

The PRESIDENT remarked that he had now under observation a case of leprosy, but had as yet made no careful examination of the temperature sense. His case illustrated the ease of diagnosis at an early period, when confusion with syringomyelia could not occur. The patient had a wine-colored eruption on the entire left leg and part of the thigh, the foot being free, and there were three or four similar spots on other parts of the body. There was distinct analgesia with some anæsthesia in these areas, but there was no paralysis or atrophy. The patient had come from the Sandwich Islands. The well-defined limitation of the anæsthetic areas showed that it could not be neuritis. Of late the anterior leg muscles had become paretic, but there was no reaction of degeneration. The left hand was beginning also to manifest similar symptoms. There were no ulcers.

Dr. C. K. MILLS, of Philadelphia, had seen two cases of leprosy. He thought the author's point with regard to partial sensory disorder very interesting, but he did not see why there should not be partial disturbance also in neuritis, and, in fact, in traumatic neuritis it was quite frequent. The nature of the sensory disturbance depended upon the extent of the injury to the nerve. In ordinary multiple neuritis it might be true, as Dr. Starr insisted, that there was complete loss of sensation, through destruction of all the sensory fibers. He did not see, however, why the sensation to cold should not be injured as much as any. It should be borne in mind that in all infectious diseases attacking the nervous system there was a tendency to seize upon the central as well as the peripheral portions at the same time.

Dr. GRAY agreed with the last speaker as to partial sensory disorders met with at times in peripheral neuritis. He had observed them also in multiple neuritis, where, for instance, there was impairment of the touch and temperature senses, yet the pain was excruciating. He did not see that it was easy to diagnose syringomyelia, and Wichmann and Starr had given no rules for diagnosis in their pamphlets. He believed that no one had made a diagnosis of syringomyelia in life.

Dr. STARR stated that Schulze had made the diagnosis in three cases, which had been substantiated by autopsy. The points for diagnosis were the general conclusions drawn from a study of collected cases. Anna Bäumler had brought together one hundred and sixteen cases, to which thirty or more had since been added.

Dr. GRAY thought these diagnostic points would apply to many other spinal lesions.

Dr. BIRDSALL had had ideas similar to Dr. Gray's as regarded the diagnostic indications in syringomyelia until he had read Roth's collection of cases. In a certain number of such cases there were clinical pictures differing altogether from those of other spinal lesions and from that of peripheral neuritis. Disturbance of the temperature sense was the particular characteristic. Still, the testing of this sense had been constantly neglected in studying other spinal cases, and it was possible that it might often be disturbed in other spinal disorders. It was hard to see how any other lesion could produce precisely the same symptoms as those of syringomyelia. It was a question whether tracts for temperature and pain could be localized in the cord. Peripheral nerve lesions might cause injury to some sense fibers and not to others, although generally all were injured, particularly where the inflammation was truncal in character. There might be partial sensory disturbance in dermal forms.

Dr. GRAY said it was easy to localize disease in the anterior cornua, in the lateral and posterior columns of the cord, but the diagnosis of central lesions was very difficult. The fact that out of one hundred and fifty cases of syringomyelia only three had been diagnosed during life proved the truth of his assertion. The diagnostic suggestions given were therefore empirical. The presence or absence of the temperature sense had not been sufficiently tested as yet. How would one distinguish a chronic central myelitis?

Dr. BIRDSALL stated that central myelitis began acutely, and thus differed from the slow advance of syringomyelia.

Dr. MILLS thought the question of partial sensory disorder most interesting. But he thought that there would be more apt to be partial disturbance in a truncal than in a dermal neuritis.

Dr. FREDERICK PETERSON, of New York, asked the president if the tendon reflexes had been exaggerated in his case of leprosy, and was answered in the affirmative. He had asked this because he had recently read an interesting study of the reflexes in anaesthetic leprosy made by Dr. Suzuki, of Tokio, and pub-

lished in the "Sei-a-Kwai" medical journal, in which there was an analysis of seventeen cases. One patient had normal reflexes, while all the others had increased tendon jerks, and in some of the cases there was even ankle clonus. The conclusions arrived at by the author were similar to Dr. Jacoby's.

The PRESIDENT called attention to the fact that so many cases of leprosy were now being continually imported into the United States. It seemed as if the country was threatened with its domiciliation. It was a question whether it was not the duty of physicians having such cases to report them to the authorities.

Dr. WHARTON SINKLER, of Philadelphia, mentioned the recent presence of two cases in Philadelphia. The physician in charge had been fined by the Board of Health for not reporting them.

Dr. PRINCE wondered at the manner in which leprosy patients were allowed to go about, and thought also that the attention of the authorities ought to be called to the disease, and reports to the boards of health be required.

Dr. GRAY knew that in the East, where the disease was prevalent, isolation was practiced. He wished to know what the actual danger of contagion was.

Dr. BRILL said that the attention of the New York Board of Health had already been called to the matter.

Dr. JACOBY said that Schulze was altogether too positive in his assertions. This author went so far as to contend that cases of leprosy, where cavities had been found in the cord, were not leprosy at all, but syringomyelia. As for himself, he thought a central lesion probably often existed in this disease, although it was well known that the essential pathology lay in a truncal neuritis. A simple dermal neuritis could not be assumed in leprosy. In his case, for instance, the indurated and swollen ulnar nerve could be distinctly felt. He did not agree with Dr. Gray that the diagnosis of syringomyelia could not be made. The only danger lay in mistaking it for leprosy. He had only last evening come across the work of Suzuki mentioned by Dr. Peterson, but had noticed the identity of that author's conclusions with his own, although they had been arrived at from different points of view.

**A Description of Two Chinese Brains, and a Note on the Pli de Passage Inferieure Interne in the Human Brain.**—Dr. F. X. DERCUM, of Philadelphia, presented two contributions with these titles. He exhibited the brains described. Dr. Mills had made a morphological analysis of one in 1886, and descriptions of three Chinese brains had been added to literature by Moritz Benedikt. The six brains thus far analyzed exhibited unusual complexity due to excessive sinuosity of the gyri, and a tendency to excessive transverse fissuration. The frontal lobes were especially large and complex. There was unusual confluence of fissures, indicative of a low degree of development, such as was often seen in the negro's and sometimes in the white man's brain. There was unusual length of the parallel and Sylvian fissures, also eversion of the orbital and temporal lobes.

Dr. MILLS said it was very important to keep adding to our morphological descriptions of such brains until accurate deductions could be drawn from a very large number.

Dr. SPITZKA stated that the dictum that a tendency to confluence of fissures indicated a low type of development was not accepted by most anthropologists. The more brachycephalic the skull, the greater was the development of transverse secondary folds. The elephant, which stood among the highest of mammals, had a broad skull and a tendency to confluence of fissures. The Chinese were not low in development. The internal *pli de passage* in the negro and idiot was significant only when the general cortical development was poor. The real cause of the location of the chief sulci lay in the inherent

architecture of the brain, and was due to the arrangement of groups of cells and fibers, but the secondary and tertiary sulci might be influenced by other factors, such as the course of vessels. While we might never be able to localize the higher functions of the mind, there was something in the physiognomy of the Chinese brain which struck him as differing altogether from that of the Caucasian. But it was not the same difference as was noticeable between the negro and Caucasian brains. The peculiar moral attitude of the Chinese pointed to some relation between the structure of their brains and the character of their minds. Still, he had observed a great difference between these two Chinese brains, and there was no feature in them which might not be reproduced in the Caucasian brain.

Dr. DERCUM had not wished to imply that transverse fissuration was indicative of a low type, but thought the unusual confluence showed a lack of cortical development. He did not consider them brains of a low type, but many features such as were found in the brains of the negro and ape were found here also. The excessive sinuosity, however, indicated a higher cortical development. For instance, in one brain there were five well-developed frontal gyri.

Dr. SPITZKA had the same idea as Dr. Dercum. As compared with the Caucasian brain, the Chinese was in some respects inferior, and in others exhibited a superabundance of gyri. He spoke of the resemblance between the negro and ape brains. The differences between the brains of the orang-outang and chimpanzee were greater than those between the brains of the chimpanzee and a human being. There was no uniform appearance of the ape's brain. Vogt and another had classified the human brain into three types—the negro, Mongolian, and Caucasian—corresponding somewhat to the three lower types of the gorilla, chimpanzee, and orang-outang.

**The Pathology of Sensory Aphasia, with an Analysis of Fifty Cases in which Broca's Center was not Diseased.**—Dr. STARR read a paper with this title. In all of these cases collected by the author some form of sensory aphasia had been present, and in all the lesion had lain in the posterior lower third of the brain. In seven of the cases there had been pure word-deafness, and in these the lesion had been limited to the posterior portion of the first and second temporal convolutions. In eleven cases there had been pure word-blindness, and in these the lesions had been found distributed either in the angular gyrus, the occipital lobe, the temporal convolutions, or the inferior parietal region. In seven cases word-deafness and word-blindness had been coexistent, although the use of language had not been lost; and in these the temporal convolutions had been involved, the involvement extending in some to the inferior parietal, angular, and occipital convolutions. The practical application of the localization of aphasia lesions was obvious, for the regions concerned in speech were especially accessible to the surgeon. Another fact of interest was that it seemed to be proved that there was no ideational center. An idea might be impaired, but could not be wholly destroyed, by a single cortical lesion. Thought, being regarded as the play of consciousness along association fibers between sensory centers, could not be localized.

Dr. J. H. LLOYD, of Philadelphia, had now a case of simple homonymous hemianopsia without psychical or word-blindness, and wished to know whether there was any diagnostic importance in this condition as to localization. Was there a preponderance of one hemisphere over another as regarded sensory memories of language?

Dr. STARR said that the matter of psychical blindness had recently been discussed by Wernicke and another. A lesion affecting both occipital lobes or the association tract bilaterally produced psychical blindness, but a lesion along either tract it-

self did not cause this condition. Nine cases of psychical blindness from lesion of one hemisphere alone had been reported.

**Officers for the Ensuing Year** were elected as follows: President, Dr. E. C. Spitzka, of New York; vice-presidents, Dr. Wharton Sinkler, of Philadelphia, and Dr. H. M. Lyman, of Chicago; secretary and treasurer, Dr. G. M. Hammond, of New York; councilors, Dr. Henry Hun, of Albany, and Dr. C. L. Dana, of New York.

**A later History of a Case of Focal Epilepsy for which Trephining and Excision of the Motor Centers were Performed.**—Dr. J. H. LLOYD, of Philadelphia, read a paper with this title. Full details of the case had been reported at the last annual meeting of the association. At that time but three months had elapsed after the operation, and Dr. Ferrier, of London, had stated in the discussion that the time was too short for a decisive result as to the usefulness of the operation. Now that more than a year had passed, further details could be given. Before the operation the patient had had many seizures daily. There was no fit for four months after the operation. Since that time, however, there had been some ten seizures in nine months.

Dr. SPITZKA said there was a minority, but a powerful minority, of clinicians and physiologists who hesitated to accept the dictum that spasms were always of cortical origin when clonic in character and local in manifestation. There were well-authenticated cases of spasm, such as were generally described as cortical, which undoubtedly had their origin in the pons or medulla. He therefore thought it premature to advise a surgical procedure when there was still doubt as to the position of the convulsive center. He was of opinion that the seat of irritation in the great majority of cases of epilepsy was in the lower centers, such as Nothnagel's convulsive center.

Dr. MILLS mentioned the case of a man who had been subject to unilateral convulsions beginning in the hand. There had been a scar upon the head, and trephining had been done at this spot in order to relieve severe pain probably due to trigeminal irritation in the scalp or dura. This operation had relieved the pain, but had caused Jacksonian epilepsy upon the other side. The operation had been repeated in the same spot, the membranes and cortex being removed to some extent, and with great success. It was an apparent illustration of the fact that convulsions might occasionally be the result of operations themselves.

Dr. DERCUM had seen the same case, and stated that the dura had not been opened in the first operation. At the second trephining the membranes had been found united. There had been a pachymeningitis. The patient had had surgical epilepsy. Six months had elapsed between the operations.

Dr. LLOYD said it was a question whether one could have localized epilepsy from irritation of the lower centers, as Dr. Spitzka had intimated. He had always held the idea that such spasm was of cortical origin. In the case that he had just described the absence of fits for four months led him to believe that he had removed the parts concerned in their manifestation. He had been hopeful of the efficacy of this method in the relief of such a disorder, and was not yet willing to give up the idea that something might be accomplished in this way. He thought it would be justifiable to operate again in this same case.

Dr. SPITZKA asked if the cortex removed had been examined microscopically, and what the pathological condition found was.

Dr. LLOYD answered that the microscopist had reported atrophy of the cortical cells.

Dr. SPITZKA remarked that atrophied cells could scarcely be very potent in the production of epilepsy.

**The Diagnostic Signs of Melancholia.**—Dr. LANDON C. GRAY, of New York, presented a paper upon this subject, in

which he called particular attention to the difficulty of diagnosis of simple melancholia at times. It was usually, when in mild degree, confounded with neurasthenia. He had recently made a study of eighteen cases of this form, and pointed out what he considered the three cardinal symptoms—viz.: depression, insomnia, and posterior cervical pain. The last named he thought especially characteristic. This pain was sometimes neuralgic in character, at others vague and continuous. Simple melancholia such as this should not be confounded with neurasthenia or melancholy states dependent upon hepatic or nephritic disease, or with non-typical forms of insanity.

**Multiple Neuritis and Infectious Cerebro-spinal Meningitis.**—Dr. H. S. UPSON, of Cleveland, read a paper in which he considered the relation between these affections. Dr. Mills had first suggested the possibility of a connection between the two. His own case was briefly as follows: A woman, aged twenty-seven, had intense pain and tenderness in the extremities, together with stupor and slight opisthotonus. No electrical examination could be made, because of the extreme hyperesthesia. She had had a multiple neuritis a year before, but recovered. The autopsy revealed congestion of the pia of the brain and cord, with marked serous effusion, and a microscopic examination of the ulnar nerve revealed interstitial inflammation there. In the opinion of the author, the nerve trunk inflammation was not parenchymatous, but rather of the membranes, and was analogous to the process in the brain and cord; the nerve fibers were involved secondarily. He had not looked for bacteria.

Dr. MILLS naturally felt interested in the case. He had had an autopsy in one of his own cases. Portions of nerves and sections of the brain and cord had been examined by Dr. Gray, of Washington, and this examination had proved conclusively the association of neuritis with the cerebro-spinal meningitis.

Dr. SPITZKA referred to the vacuoles in the author's sections, and said retarded lymph outflow might be important in causing the death of tissue and the formation of gas bubbles which these vacuoles must be considered to represent. He had noted also two bodies in the section larger than ordinary leucocytes, very delicately stained, which the author should have carefully delineated.

**Case of Abscess of the Brain; Operation; Death on the Ninth Day.**—Dr. C. K. MILLS, of Philadelphia, gave an abstract of a paper on this subject by Dr. J. T. ESKRIDGE, of Denver. The patient had had typhoid fever. Two months later there was purulent inflammation of the middle ear, and not long after symptoms of brain irritation followed, such as headache, delirium, and persecutory delusions, together with paralysis of the right hand and the right angle of the mouth. The skull was trephined over the face and hand centers, and a purulent inflammation was found under the dura. The wound was then dressed, and the patient died nine days later. A widespread suppurative meningitis was found at the autopsy. Dr. Mills thought the case of great practical value. He thought trephining should have been performed in two places—at the center, which had been properly localized, and also over the mastoid region, where the inflammatory process had originated.

**Peroneal Form of Progressive Muscular Atrophy.**—Dr. B. SACHS, of New York, presented a paper on this subject. The author reiterated his statement of last year that this form was closely related to Duchenne's type. He gave very full details of the cases of two brothers that had recently come under his observation through the kindness of Dr. Gibney. The boys had been thirteen and ten years of age. There had been a gradual development of double club-foot in both at the age of five years, followed by an atrophy proceeding upward, beginning in the leg and toe muscles and spreading to those of the thigh, in one case

also involving muscles of the upper extremities. The knee-jerks had been present. In one there had been general anaesthesia, in the other paraesthesia. There had been full degenerative reaction in some of the muscles in one boy, partial in the other. The progressive wasting rendered treatment of this form of club-foot less satisfactory than that of congenital cases. He would suspect this peroneal form in all cases where acquired club-foot was associated with progressive wasting of the leg muscles, and particularly if heredity or family occurrence of the disease could also be established.

Dr. SINKLER could recall several similar cases, one in particular of two brothers. But doubtless more would be seen if careful attention were paid to the matter.

Dr. BIRDSALL did not think the presence of knee-jerk so important a diagnostic point as the author seemed to regard it. He had seen a few cases of old poliomyelitis where the paralysis and atrophy were below the knee, and yet the knee-jerks were quite active on both sides. It could not, therefore, be an essential point in diagnosis.

Dr. BULLARD had also observed the presence of the knee-jerk in old cases of poliomyelitis.

Dr. PRINCE asked if the author had said that the absence of pseudo-hypertrophy was a diagnostic point between this form and primary myopathies, and was answered in the affirmative. He did not consider this true.

Dr. SPITZKA asked if the symmetry and the coincidence of time and intensity as shown in the photographs were always found, and was answered in the affirmative.

Dr. SINKLER corroborated two of the speakers as to the presence of the knee-jerk in cases of old poliomyelitis, and cited an instance from his own experience.

Dr. GRAY objected to the division of progressive muscular atrophy into groups. Why should there be an arm type, a face type, and a leg type? Such division might be carried out indefinitely. A more useful classification would be upon the pathology of the disease, a division into central, muscular, and peripheral nerve lesions.

Dr. SACHS said he did not lay great stress upon the presence or absence of the knee-jerk. Yet in extreme atrophy of the vasti from poliomyelitis, the knee-jerk was always absent; and if it was present he should consider the ease one of progressive muscular atrophy. He had himself tried to discard subdivisions as much as possible, but the present classification was a clinical necessity. A better one might be made when the pathology was more accurately determined. At present there were spinal and non-spinal cases, but there was no certainty as regarded peripheral nerve cases.

**Pseudo-hypertrophy.**—Dr. PRINCE exhibited some microscopic specimens from the muscles of a patient with this affection. The patient was now twenty-eight years of age. The specimens showed a large quantity of connective tissue, hypertrophy of a few fibers, and great atrophy of many of the fibers. There was also great loss of striation, but no fatty or granular degeneration and no vacuolization.

The following papers were read by title:  
**A Series of Cases of Cerebral Haemorrhage of Unusual Interest.**—By Dr. J. H. LLOYD, of Philadelphia.

**The Histological Examination of Nerves removed for Trigeminal Neuralgia.**—By Dr. J. J. PUTNAM, of Boston.

**The Pathological Anatomy of Chorea.**—By Dr. C. L. DANA, of New York.

**Paranoia in Two Sisters.**—By Dr. FREDERICK PETERSON, of New York.

**Election of Members.**—The following new active members were elected: Dr. W. M. LESZYNKY, of New York; Dr. C. EUGENE RIGGS, of St. Paul, Minn.; Dr. H. S. UPSON, of Cleve-

land, O.; and Dr. HOBART A. HARE and Dr. J. P. C. GRIFFITH, of Philadelphia. Mr. VICTOR HORSLEY and Dr. DAVID FERRIER, of London, were elected honorary members.

#### NEW YORK NEUROLOGICAL SOCIETY.

*Meeting of June 4, 1889.*

The President, Dr. GEORGE W. JACOBY, in the Chair.

#### Alcoholic Paralysis with Central Lesions.—Dr. W. P.

WILKIN reported the history of a case of this affection, and exhibited microscopic sections of the cord. The patient, a woman, aged thirty-one, had died, after four days' stay in Bellevue Hospital, with acute alcoholism and alcoholic paraplegia. At the autopsy the liver was found to be fatty and much enlarged, weighing eight to ten pounds; the kidneys large, the cortex thickened, and the markings indistinct; the brain showed much extravasation around the blood-vessels. There had been a leptomeningitis about the spinal cord, especially marked over the posterior part and involving the posterior nerve roots. Degenerative changes were found in the posterior columns, most marked near the periphery. The interstitial increase had not been confined to one system of fibers; it had extended to a lesser degree through the lateral columns of the cord. In the sciatic and tibial nerves there had been considerable increase of interstitial tissue, and in some places a disappearance of axis cylinders. This case was presented as one of ascending degenerative changes and as showing that alcoholic paralysis might involve lesions not of the periphery only, but also of the central nervous system. The author referred to Schaffer's and other cases corroborative of this statement.

Dr. DANA, who had charge of this case at Bellevue, stated that the cord had been so badly hardened that good sections had been obtained with difficulty. Still the leptomeningitis and ascending degeneration in the cord had been conclusively demonstrated. He held the opinion that central lesions might sometimes occur in alcoholic cases.

**Septic Peripheral Neuritis due to Pyelo-nephritis.—Dr. DANA** then exhibited a case of this disease with the following history: John L., aged twenty one, was admitted to hospital December 13, 1888, with symptoms of acute articular rheumatism affecting all the extremities. There was no history of alcoholism or venereal disease. There were pus and albumin in the urine, continuing five weeks. In the middle of January paralysis came on, the rheumatism abating. There were anaesthesia and burning pains. The nerves affected were the ulnar and median of each arm and the anterior tibial of each leg. Atrophy and degenerative reaction appeared. Improvement began about March 16th. Electrical examinations in April, 1889, showed degenerative reaction complete in the flexors of the right arm and partial in those of the left. The patient was now improving very slowly, but there was still sensory and motor paralysis of arms. The speaker regarded the articular affection as a pseudo-rheumatic disorder due to septicæmia. It had not responded to the usual remedies.

Dr. SACHS said that if there was any question as to the diagnosis of the nervous affection it would lie between peripheral neuritis and atrophy following joint lesions. But the anaesthesia in this case was conclusive in corroborating Dr. Dana's diagnosis.

#### Peripheral Paralyses due to Carbonic-oxide Poisoning.

—The PRESIDENT read a paper with this title. (To be published.)

Dr. SACHS thought that an excellent case had been made out for the author's carbonic-oxide theory. Numerous cases of musculo-spiral paralysis generally credited to pressure might possibly have such an origin. It was a suggestion that ought to be entertained.

Dr. STARR said the cases reported were interesting, and no doubt peripheral in their nature. But we should be cautious in ascribing unilateral paralyses to a general intoxicant in the system. Other poisons occasioning paralysis caused symmetrical lesions, as exemplified in poisoning with alcohol, lead, or arsenic, and in diphtheria, where the injuries were always bilateral. He was aware that of course, as in lead-poisoning, the paralysis was sometimes more marked upon one side than the other. This was, therefore, a presumption against the course ascribed by Dr. Jacoby. What was the cause, then? He described cases of coma of his own, where patients lying for many hours would have pressure-paralysis of the ulnar or other nerves. In another case a patient had paralysis of the adductors of the arm after a uræmic convulsion, which was ascribed to the grasp of the attendant. The speaker thought pressure of some sort more probable as a cause in the cases just portrayed than carbonic oxide.

Dr. SACHS stated that carbonic oxide differed from the other poisons in the rapidity of its effects. Those mentioned by Dr. Starr were very slow. In such rapid cases as these it might not be safe to apply the symmetrical rule.

Dr. DANA regarded the cases as due to the action of both elements. In coma, for instance, very slight pressure might produce paralysis where ordinarily it did not. The paralyses so frequent in alcoholic intoxication were explicable in this way. Carbonic oxide might affect the system in a similar manner.

The President said that the same objections had been made in cases of ether and osmotic-acid injections. He did not consider his position beyond question, but, with the two other cases in literature added to his own, the theory advanced was tenable.

**Examination of the Insane.—Dr. ALLEN FITCH** then read a paper upon this subject, in which he showed that the usual certificates of insanity were not commitments in a correct sense, and that physicians were not responsible for the patient after his entry into an asylum. He considered the physical symptoms of more importance than any other upon which to form an opinion of insanity. It was not always possible to classify the disease in early examinations, nor best to do so in the certificates. He showed that in nearly all cases that came before the courts on writs of *habeas corpus* the persons were discharged, notwithstanding that nearly all were insane. Physicians should have had actual experience in asylums to be competent to examine the insane. He emphasized the value of a physical examination, and said that in feigned insanity there would be little opportunity for mistake were more attention given to these physical peculiarities. He then related numerous interesting cases in illustration of various points in his paper. He thought heredity had no bearing on such kinds of insanity as the puerperal form and general paresis. He then presented for the consideration of the society the "Gallup Lunacy Bill," now in the hands of the Governor of the State of New York awaiting his signature to become law. Some of the bad features of this bill were considerably discussed by Dr. Starr, Dr. Dana, Dr. Douglas, and Dr. Sachs, and a resolution was unanimously passed disapproving of the bill and requesting the Governor to have it carefully reviewed by the Commissioners in Lunacy before signing it.

#### Miscellany.

**The Cartwright Prize.**—At the recent commencement of the College of Physicians and Surgeons of New York it was announced that the Cartwright Prize had been awarded to an essay written conjointly by Dr. Hobart A. Hare and Dr. Edward Martin, of Philadelphia. But

the successful competitors voluntarily surrendered the prize because their essay had just been awarded a prize elsewhere. It appears that the essay had been put into competition for both prizes, with the expectation that the decision of one prize would be made early enough to permit them to withdraw from the second competition in case they were successful in the first. But owing to delay in the decision of the prize which should have been announced first, and to absence of the authors from home when the announcement was finally made, there was no opportunity for the intended withdrawal before the award of the Cartwright Prize was published. The award of the Cartwright Prize has consequently been reconsidered, and the prize has been granted to Dr. Ira Van Gieson, assistant instructor in normal histology in the College of Physicians and Surgeons of New York, for his essay entitled "Studies in Neural Pathology," embracing (1) a Report of a Case of Syringomyelia, and (2) a Contribution to the Pathology of the Laryngeal and other Crises in Tabes Dorsalis."

**The Soden Springs.**—Sir Morell Mackenzie writes, in his "Journal of Laryngology and Rhinology," as follows: "Most of the German saline springs are situated on the range of the Taunus Hills. Of these, unquestionably, one of the very best is Soden. Containing, as it does, some twenty-three springs with a temperature varying between 12° to 18° C., and with one thermal spring of the temperature of 30° C., the waters of which are charged with chloride of sodium in varying degrees up to 116 grammes to the litre, and some of which are further charged with carbonic acid (notably the Champagnerbrunn), the health resort of Soden is, though at present one of the less known of the German spas, unquestionably one of the very best places for the treatment of pulmonary and catarrhal complaints. Additional advantages are the complete protection of the village from north winds, the comparatively great

altitude, and the equable climate, which make it, of all others in Germany, the resort most suitable for the treatment of phthisis, either of the throat or lungs, and catarrhal conditions generally. No spa possesses the peculiar and distinctive advantages of Soden. Though a small amount of iron is present in the waters, they are not on that account contra-indicated in the treatment of incipient phthisis. Compressed pastilles of Soden water are now an article of commerce, as well as the mineral waters. These are made from two of the well-waters, and, containing a large amount of chloride of sodium, are particularly serviceable in pharyngeal catarrhs, and may even in some degree be used where it is desired to obtain the effect of the Soden treatment in persons who are unable to make the necessary journey to the spa itself."

#### ANSWERS TO CORRESPONDENTS.

No. 276.—The region about Tannersville, which is the name of the town you indicate.

No. 277.—Your patient had probably swallowed the ova of some variety of fly, and passed the larvae. The occurrence is not very rare. It sometimes gives rise to considerable irritation.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

**Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.**

**All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.**

**Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.**

**Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.**

**All communications intended for the editor should be addressed to him in care of the publishers.**

**All communications relating to the business of the journal should be addressed to the publishers.**

Tubercular Type of Leprosy.

Mixed Type of Leprosy.

Tubercular Leprosy.

Anæsthetic Leprosy. ~

# THE NEW YORK MEDICAL JOURNAL, JULY 27, 1889.

### PERSONAL OBSERVATIONS OF LEPROSY IN MEXICO AND THE SANDWICH ISLANDS.\*

BY PRINCE A. MORROW, A. M., M. D.

MR. PRESIDENT AND FELLOWS OF THE ACADEMY: I should, perhaps, apologize for not having prepared a systematic paper upon the subject of the evening. I have thought, however, that the result of my personal observations of leprosy, at least so far as its clinical features are concerned, might be more effectively, and at the same time attractively, presented by means of photographic illustrations taken from life. I shall therefore, after a few general remarks, have the pleasure of exhibiting before you lantern slides illustrating not only the typical forms of the disease, but also the various phases which these different forms assume in the process of their evolution.

In the first place, I may remark that by the great majority of the profession leprosy is looked upon as possessing at the present day only a historical interest. It is classed in the same category as the pestilences and plagues which formerly swept away entire populations and devastated countries, but which are now practically extinct. Unfortunately, leprosy can not be relegated to the past; it is still a living, actual reality, and to-day prevails over more than one fourth the habitable surface of the globe. By reference to the map, the red shadings of which indicate the present geographical distribution of leprosy, it will be seen that it extends from the tropics to the arctic regions, embracing every variety of soil and climate and the most diverse races and nationalities. While it affects principally maritime populations, inland countries are by no means exempt; it prevails in both marshy and mountainous regions, in the lowlands of Louisiana as well as in the elevated table-lands of Mexico.

I would call attention to the fact that this extensive distribution of leprosy has a most important bearing upon its ætiology. As is well known, racial peculiarities, conditions of soil, of climate, and especially of food, have been assigned as ætiological factors. It is evident, however, that the widespread and diversified distribution of the disease precludes the possibility of any of these agencies being invoked as efficient causes.

It would not be possible to give an accurate compilation of the number of lepers upon the face of the earth at the present day. In India it has been estimated that there are over two hundred and fifty thousand; in China, Japan, Africa, and Egypt there are large numbers. In Europe the most important center of the disease in the present century is in Norway and Sweden.

The development of leprosy in a country previously exempt from the disease can always be traced to its importation from an infected center. The spread of leprosy through-

out a great portion of Europe early in our present era may be traced along the routes of the Roman armies, and its general diffusion throughout Christendom in the eleventh, twelfth, and thirteenth centuries was materially influenced by the return of the Crusaders. In the Western Hemisphere leprosy was first introduced into Central and South America by Portuguese traders, in Mexico probably by the Spanish, and in Canada by the French *émigrés*. It persists in New Brunswick at the present day, the most important center being at Tracadie.

In our own country the introduction of leprosy may be traced to at least four separate and distinct sources. In Louisiana it was carried by the Acadians, in the northwestern States of Iowa, Illinois, Wisconsin, and Minnesota by the Scandinavian colonists, along the Pacific coast in California and Oregon by the Chinese, and along the southern Atlantic coast it was brought from the West Indies. In Salt Lake City the disease was imported by a colony of Kanaka women brought by the Mormons from the Sandwich Islands.

My own observation of leprosy during the past winter began at New Orleans, where, it will be remembered, Dr. Blanc has recently reported the existence of forty-two cases. I also visited the Tèche River district, where there have long existed two leprous centers—one at St. Martinsville, the other at Bayou Lafourche. I had no opportunity of examining the subjects at St. Martinsville, as they had been subjected to a disagreeable newspaper notoriety and kept themselves secluded from observation. Along the line of the Southern Pacific Railroad, at San Antonio and other points, I learned of the existence of scattered cases. In Mexico I saw a number of cases at the San Pablo Hospital and in the streets of the city. In California I received reports of about twenty cases, but only had the opportunity of examining six which were in the pest-house of San Francisco.

The Hawaiian or Sandwich Islands afford to-day, perhaps, the best field for the observation and study of leprosy of any leprous center in the world. The disease is of comparatively recent introduction. Certain elements of confusion which have surrounded its ætiology in other countries may here be eliminated: the influence of contagion, of heredity, of racial peculiarities, and of certain conditions which have contributed to the rapid diffusion of the disease may be traced with precision. Thanks to the rigid system of segregation enforced by the board of health, the leper settlement of Molokai, in which eleven hundred lepers are gathered, affords abundant opportunities for the clinical study of every possible form and phase of the disease.

Before entering into an exposition of the clinical features of leprosy it may be well to briefly indicate the present status of our knowledge of the disease. It is the reproach of medical science that a disease which has been characterized as the most ancient and the most exclusively human of all diseases should, after centuries of observation, be so imperfectly understood. We know something of its nature, its clinical features and course, its diagnosis and prognosis; but there are many essential points connected with its ætiology, the degree and conditions of its contagiousness, its

\* Remarks made before the New York Academy of Medicine, June 6, 1889, in connection with the exhibition of fifty lantern slides of typical forms of leprosy.

modes of propagation, concerning which our knowledge is incomplete and indefinite.

The facts of our positive knowledge of leprosy may be thus formulated:

Leprosy is a parasitic disease; the bacillus of leprosy has a definite form, a slow rate of development, and is endowed with an extraordinary vital resistance, presenting many analogies with the bacillus of tuberculosis.

Like all specific microbes, it has an elective affinity or predilection for certain tissues and fluids of the organism. The bacilli occur in all forms and stages of leprosy; they are found in both the diffuse and nodular infiltrations of the skin and mucous membranes, in the connective tissue of the peripheral nerves, in the cornea, in the cartilages, and in the liver, spleen, spermatic tubes, and testicles. They are found abundantly in the lymphatic glands and spaces. They are absent from the blood and the physiological secretions, such as the tears, saliva, milk, semen, urine, etc. It is worthy of note, however, that when the nasal, pharyngeal, and intestinal mucous membranes are the seat of leprous lesions the secretions from these surfaces swarm with bacilli.

Leprosy has an exclusive origin; it is invariably derived from the lesions or secretions of a person similarly diseased; it never originates spontaneously, nor does its virulent principle attach to the soil, the water, or the food. Its origin and spread can always be traced to human contact. It is not inoculable to the lower animals, as is abundantly proved by the negative results of numerous experiments. The question of its inoculability to man has until now always been decided in the negative, as the inoculation experiments made by Campana and others have invariably failed, the only result being a septic lymphangeitis. In September, 1884, Dr. Arning inoculated a Hawaiian convict, Keanu, previously free from all leprous taint. This man had been condemned to penal servitude for life, and special care was taken that he should not be exposed to contagion by contact with other lepers. For a long time this experiment was regarded as a failure, but a few months ago Keanu developed unmistakable signs of tubercular leprosy and was sent to the leper settlement at Molokai. Upon the occasion of my recent visit I excised a small subcutaneous tubercle and a portion of the overlying skin. Numerous sections of this specimen were made by my associate, Dr. Fordyce, and in all, the presence of bacilli was demonstrated. (These specimens were shown under the microscope.)

We know, further, that leprosy has a prolonged but somewhat indefinite period of incubation, a slow and irregular course of development, a characteristic and well-defined symptomatology rendering its diagnosis easy, and that its prognostic significance is most grave: it progresses almost invariably to a fatal termination. The period of incubation of leprosy is generally placed at from three to five years. Examples have been recorded in which this period has been materially lessened or prolonged to seven, ten, and even fifteen years or longer; it depends largely upon individual capacity of resistance. It will be readily appreciated that, since the disease has no initial lesion and the early symptoms are quite indefinite and equivocal, it is difficult, if not

impossible, to determine the exact interval between contagious exposure and the first outbreak of undoubted symptoms.

As there is some confusion in the terms used in designating the different forms of the disease, I may say that by modern authorities three types of the disease are recognized which, while pathologically similar, are clinically distinct. When the morbid deposits occur upon the skin and mucous membranes in the shape of macules and nodules, the form of the disease is termed tegumentary or *tubercular*; when they are centered upon the peripheral nerves, it is termed tropho-neurotic or *anæsthetic*. There is, in a certain proportion of cases, an admixture of both forms in the same individual, the lesions peculiar to one or the other predominating; this combination constitutes what is known as the *mixed type* of leprosy.

In addition to these two typical forms of leprosy and the series of symptoms common to both which make up the mixed form, certain writers have described a macular form. There is, however, no good basis for this further division; macular lesions may be met with in any of the forms of leprosy; they do not constitute a type, but simply represent a phase in the evolution of the disease.

The relative frequency of these three types varies in different countries and under different conditions. In the Sandwich Islands about one half the cases are of the tubercular type, about one third are *anæsthetic*, and the remaining one sixth represent the mixed form. The tubercular form is most progressive and rapidly fatal, the *anæsthetic* the least so, and the mixed form intermediate between the two.

As the clinical appearances of the different forms of leprosy will be fully illustrated in the lantern slides presently to be shown, I shall not occupy your time with a verbal description.

Having thus summarized the facts of our positive knowledge, I may briefly refer to certain moot points connected with leprosy. When we come to the consideration of the question of its contagiousness, the precise conditions under which contagion takes place, the various modes of infection, the influence of heredity, etc., it must be confessed that the teachings of science are by no means fixed and definite.

As regards the first point, it may be said that a belief in the contagiousness of leprosy has been universally held from the earliest ages until within recent times. All the prophylactic measures contained in the Levitical regulations, as well as those enforced in mediæval times, for the suppression of the disease, were based upon the recognition of the fact that every leper was a possible source of danger to all with whom he came in contact.

About thirty years ago the contagiousness of leprosy began to be questioned, and in 1867 the Royal College of Physicians of London formulated the dogma that leprosy was not a contagious disease. This opinion was generally accepted by the profession in Europe, although it may be said that the dermatologists of this country have never subscribed to this doctrine. In 1885, when the famous discussion upon the contagiousness of leprosy took place before

the French Academy of Medicine, it transpired that only three physicians in France upheld the doctrine of contagion. In 1888, when this discussion was again reopened, the partisans of contagion were much more numerous, but among the non-contagionists were numbered some of the most distinguished members of the French Academy.

It will, of course, be impossible, within the brief time at my disposal this evening, to enter into a consideration of the various arguments *pro* and *con* which have been advanced toward the determination of this question. As I propose to submit only the results of my personal observations, I may say that the facts of the development and spread of leprosy in the Sandwich Islands furnish the most abundant and conclusive proof of its eminent contagiousness. Upon no other possible ground can be explained the remarkable and rapid dissemination of the disease which, within the short space of a single generation, has decimated the population of these islands. At the present day from five to ten per cent. of the entire native population are affected with leprosy, while many foreigners coming from countries where leprosy is not endemic, and in whom no hereditary taint can possibly be alleged, have fallen victims to the disease.

In my examinations of numerous cases there was afforded in almost every instance a history of known exposure by sexual or other intimate relations with lepers. Another proof of contagion may be found in the fact that of the Kokus who go to the leper settlement at Molokai as helpers or nurses, a large percentage contract the disease. To take only the statistics of the past two years, the president of the board of health in his report for 1888 states: Of sixty-six Kokus who went to the settlement presumably healthy and free from all manifestations of the disease, twenty-three were found to present unmistakable signs of leprosy, and eleven more presented symptoms which caused us to declare them "suspected lepers."

On the other hand, it must be admitted that there are numerous instances of Kokus living in prolonged and intimate contact with lepers who have not developed the disease. In Dr. Mouritz's report for 1886, forty-eight cases are cited, giving an average exposure of fifteen years to intimate contact, in which the subjects remain entirely exempt from all manifestations. This prolonged exemption does not, however, guarantee an absolute immunity for the future. One of the cases cited was that of the washerwoman of the hospital, who had washed the soiled clothing of the worst patients for seventeen years. In addition, she had lived with two leper husbands in succession, and yet in 1886 she was hale, hearty, and apparently healthy. Upon the occasion of my recent visit to the settlement this woman was suffering from undoubted manifestations of the disease.

The negative proofs of contagion are, however, so overshadowed by the immense mass of positive clinical testimony that they fall to the ground. They simply prove that there is nothing constant in contagion; that infection is not inevitable; that, in order that contagion may operate, a susceptibility or receptivity on the part of the individual is essential; and, further, that, owing to individual peculiarities, some persons are endowed with a capacity of resistance

which renders them absolutely refractory to its contagious activity.

As regards the modes of infection, our knowledge is by no means definite. It is probable that in the immense majority of cases the disease is propagated through sexual intercourse. This mode of infection is rendered almost certain by the observed fact that healthy individuals having sexual relations with lepers almost invariably become contaminated. The liability to the disease from exposure of this kind is so generally recognized that the husband or wife of a leper, though apparently sound, is readily admitted to the leper settlement as a Kokua, on the presumption that the germs of the disease have already been implanted in his or her system.

It is also probable that the virulent principle of leprosy may find entrance to a healthy organism through cracks, fissures, or abrasions of the integument or mucous membranes. It may possibly be inoculated by means of the bites of insects, such as flies or mosquitoes, or by animal parasites, such as the *Acarus scabiei*. This mode of infection is well attested in the case of elephantiasis Arabum. It is worthy of note that the latter disease prevails extensively in the Samoan Islands, while it is unknown in the Sandwich Islands.

Inhalation is another assumed mode of contagion, but it rests upon presumptive rather than positive proof.

Vaccination is believed by the natives as well as by many intelligent physicians to be a potent agency in the rapid diffusion of leprosy through the islands. It must be remembered that until recently vaccination was performed by unskillful persons, human virus was used, and no distinction was made between a healthy person and a leper as the vaccinifer. The fact is incontestable that, after the general vaccination of the natives, numerous leprons centers developed in various parts of the islands where the disease had previously been unknown. Arning demonstrated the plentiful presence of bacilli in the lymph and crusts of vaccine pustules in lepers.

There are many other interesting points in connection with contagion to which I might refer did time permit; thus, for example:

At what period in the evolution of leprosy does the system become endowed with contagious activity? Is it during the prodromal stage or during the eruptive stage, or is it delayed until the tubercles have softened and broken down?

Are the lesions of the anaesthetic form contagious? The bacillus is not found in the chronic sores or the necrosed tissues and bones of the anaesthetic leper. Numerous and repeated examinations of sections of an amputated finger showed no bacilli.

Another point of interest: A woman may have several husbands in succession who become lepers and she remains apparently exempt. Is the disease latent in this woman, powerless to produce general accidents, yet sufficiently active to contaminate others?

Finally, there remains to be considered the question of heredity. The traditional belief in the hereditary transmission of leprosy has rarely been questioned. It has gen-

erally been regarded as the principal mode of the propagation and perpetuation of the disease. In all ages and in all countries marriage has been prohibited between lepers, and its development in one partner has been accepted, not only as a sufficient pretext, but an urgent argument, for the dissolution of the marriage tie.

The history of the development of leprosy in the Hawaiian Islands would seem to show that here at least heredity has played an insignificant if not an inappreciable rôle in the propagation of the disease. The following facts may be stated: There is no authentic record of a congenital case of leprosy. I secured the placenta, cord, and portions of the body of a child still-born at full term, of leprous parents. Repeated examinations of these specimens made by Dr. Fordyce showed the absence of bacilli. Leprosy never develops until the third or fifth year, a period which corresponds to the classic period of incubation of the acquired disease. In the immense majority of cases the first manifestations of leprosy occur from the thirtieth to the fiftieth year. In the next place, lepers are almost always sterile. Only two children were born in the leper settlement in the first five years after its establishment; in the next five years only three children were born of parents both leprous. In 1886 Dr. Mouritz collected statistics of twenty-six children born in the settlement, whose ages ranged from three to fourteen years. Of these, nine had become lepers, while seventeen showed no signs of the disease. Considering the multitudinous chances of post-natal contagion from intimate contact with their leprous parents, it seems altogether probable that if these nine children had been immediately removed they might have escaped the disease.

The exemption of the offspring of leprous parents from the parental disease was so frequently observed that in 1885 the Kapiolani Home was established at Honolulu, where these children might be cared for and kept under surveillance as "suspects" until evidences of the disease might be manifest. I am unable to give the statistics of this Home, but they are sufficiently favorable to justify the wisdom of this step.

My observations would seem to justify the conclusion that the influence of heredity in the transmission of leprosy must be regarded as an open question. It is probable that, as in tuberculosis, with which leprosy presents certain analogies, a predisposition to the disease rather than the actual germ is transmitted from parent to offspring.

Finally, there remains to be considered the practical question of the danger of the spread of leprosy in this country. As my remarks have already extended much beyond their proposed limit, I shall refer to this important subject but briefly.

In the determination of this question the facts of the development and spread of leprosy in other countries can not be ignored. The teachings of observation and experience show that in all countries invaded by leprosy its first approaches have been slow and insidious. To take the Sandwich Islands, for example, we find that for twenty years after the first case of leprosy was identified the disease spread slowly, without making sufficient advance to attract the attention of the health authorities. When they awak-

ened to the realization of the danger which threatened the public health, the disease had already gained such headway that they found it impossible to arrest its progress even by the most rigid system of segregation. It has continued to spread until now it threatens the ultimate extinction of the Hawaiian race.

Can any one doubt that if the disease had been promptly dealt with upon its first appearance, every leper removed or isolated from contact with the healthy, it might have been easily eradicated?

Its development may be aptly compared to a slow conflagration, easily extinguished at first, but which, neglected, gains such force and headway that it becomes uncontrollable and can not be checked until it exhausts the materials upon which it feeds.

Unquestionably, leprosy is slowly gaining ground in this country. The existence of forty-two cases in New Orleans, unearthed by Dr. Blanc, was a revelation and a surprise to the entire profession. It is quite significant that a large proportion of these cases were in natives of Louisiana who had never been outside the State. The report by Dr. Berger (in the "New York Medical Journal" of Jan. 5, 1889) of one hundred cases at Key West, where the existence of the disease was scarcely suspected, is no less significant. A rigid investigation would doubtless disclose numerous cases outside the several leprous centers I have located, but which, for obvious reasons, are concealed, or their true nature unrecognized.

Do these facts portend the spread of leprosy in this country? The seeds of the disease are sufficiently abundant; the only question is whether the conditions of soil are suitable for their germination. Either we must admit that this danger exists, or we must assume that, owing to the better physical stamina of our people and the improved hygienic conditions under which we live, the soil is sterile and the seed will fail to propagate. We are not justified in the assumption that susceptibility to leprosy is extinguished by civilization, or that its potentiality for mischief is enfeebled or destroyed by improved modes of living. It is to be remembered that the spread of leprosy in the Sandwich Islands has been coincident with an advanced civilization of the natives. The average Hawaiian of to-day is more cleanly in his person, better fed, and better housed than the majority of the tenement-house population in our large cities.

After all, the danger of the spread of leprosy in the United States resolves itself into a question of the contagiousness of the disease. If leprosy is a communicable disease, then it follows that every leper must be regarded as a possible source of danger to every one with whom he may come into intimate contact. The question to be decided is not the fact, but the degree of danger—whether it rises to the magnitude of a serious menace to the public health and demands State legislation for its suppression.

My own personal belief is that the extensive spread of leprosy in this country must be regarded as a possibility, rather than a strong probability. Still, in dealing with a disease with which medical science has shown its utter inability to cope, except by prophylactic measures, it becomes

the manifest duty of the medical profession, in their capacity as guardians of the public health, to enlighten our legislative authorities as to this possible danger, and urge them to adopt measures for the isolation of every leper in our midst, and especially to prevent the immigration from foreign countries of those who bear in their systems the seeds of this frightful malady.

### NERVOUS SYMPTOMS CAUSED BY FUNCTIONAL GASTRO-INTESTINAL DISORDERS.

BY W. W. VAN VALZAH, M. D.,  
FORMERLY DEMONSTRATOR OF CLINICAL MEDICINE,  
JEFFERSON MEDICAL COLLEGE.

AND CHARLES R. CRANDALL, M. D.

THE following clinical history is, in many respects, a good illustration of a group of cases characterized by gastro-intestinal disturbance and marked nervous symptoms. It tends to show in an interesting manner how imperfect digestion may, in a neurotic patient, cause most persistent and alarming manifestations. As will be seen, these symptoms and nervous phenomena may be very numerous and, in aggravated cases, may display themselves throughout the entire system. This is possible because of the intricate relations and the mysterious sympathies existing between the processes of organic life, the nervous system, and the mind. Hence it is not uncommon to meet with cases in which a large number of nervous symptoms, as well as a perverted state of the emotions and mind, are chiefly due to irritation by improper foods and the effects of gastro-intestinal disease. These cases are most common among city business men who, by improper food, irregular and hurried eating, and intense and prolonged mental strain, bring on nervous excitability, indigestion, and subsequent exhaustion of vital power.

These preliminary remarks will be largely confirmed by the history of a case in which functional gastro-intestinal disorder and many forms of reflex nervous irritation prevailed for a long time, and were finally brought under control by a proper regulation of diet and treatment of the organs of digestion.

Mr. C., aged forty-six, of a bilious nervous temperament, of good habits of life, and a lawyer by profession. His father suffered from catarrh of the stomach and bowels for many years, and then died of consumption. His mother is still living, about sixty-five years of age, and in fair health. The patient himself was healthy during childhood, but subject to pain in the limbs. When about fifteen years old he had diphtheria, which was followed by measles, and then very poor health, emaciation, and debility. He gradually recovered and worked on the farm, taught school, and attended college. About this period he experienced his first occasional suffering from indigestion, which seemed to be due to overeating or improper food. When twenty-two years of age he went into the army, and there suffered still more from indigestion, characterized by intestinal flatulence and pain. Two years later, while still in the army, he had typhoid pneumonia, which left him in poor health and with great weakness of the nervous system for nearly five months. Within six months he had another attack of typhoid pneumonia, and it was six months more before he completely

recovered. These attacks left him with a greatly enlarged liver, and it was nearly three years before the organ returned to its normal size. After the war he returned to civil life, his health improved very much, he engaged in the study of the law, and subsequently became a lecturer on that subject. After two years of hard work his nervous system broke down, and he suffered from general weakness, loss of appetite, and indigestion. Hoping that a change of climate would be beneficial, he moved to Cheyenne, Wyoming, and engaged in the practice of law. From 1867 to 1875 he had very good health, excepting for some indigestion and occasional temporary nervous "breakdowns" from overwork. During this time he was subject to frequent colds and bronchitis, which made him sick for a few days, and finally left him with naso-pharyngeal catarrh. In the year 1876 he was elected to Congress, and the circumstances incident thereto proved to be a great strain upon his nervous system. Indigestion, flatulence, and pain became more marked, and he suffered greatly from insomnia and various nervous manifestations. In 1877 he experienced a general breaking-down, characterized by indigestion, prostration, extreme insomnia, nervous irritability, inability to concentrate his mind, and pain and burning in the limbs. These symptoms continued to grow worse even under a more regulated life and medical treatment. Subsequently he took a trip to Europe, and this afforded temporary improvement. Returning to Washington, he soon grew worse, suffered greatly from indigestion, insomnia, pain in his limbs, and a sense of burning or heat in his feet, and finally became unable to attend to his official duties. At the expiration of his term in Congress he went to Hot Springs, Arkansas, where he remained two months and was again temporarily benefited. From there he returned to Cheyenne and resumed his professional work, but soon broke down, suffering from the same conditions and symptoms, but in a still more aggravated form. Hoping to find relief in rest and change, he traveled in California, and subsequently made a second trip to Europe. In addition to travel, he passed months at a time under systematic treatment at the hands of celebrated specialists for the treatment of nervous diseases; but during the last four years there has been but little, if any, cessation from suffering in his bowels and the manifold nervous conditions repeatedly referred to. When he came under treatment he had a tired, worn, and haggard look. He was suffering from aggravated indigestion, great distension and pain in his bowels, burning and lancinating pain in his legs and feet, and most persistent insomnia. As a rule, he was unable to sleep more than from two to four hours out of twenty-four unless under the influence of a hypnotic. Indeed, he had been obliged to resort to almost every form of sedative, including bromides, chloral, sulphonal, and morphine, in order to obtain even a moderate amount of sleep.

In concluding the history of this interesting case it is worth while to note again that, in the first place, there were the usual symptoms of indigestion beginning in childhood and lasting more or less for thirty years. From first to last the patient suffered from distress after taking food, acidity, flatulence, pain, great abdominal disturbance, grinding sensations in the stomach and bowels, constipation, and all the lesser symptoms of indigestion.

In the second place, going hand in hand with the above-described condition, there was a history of "leg-ache" in boyhood, gradually developing into neuralgic pains in the head, persistent insomnia, excessive nervous irritability, inability to concentrate the mind, numbness and tingling of the limbs, lancinating pains in the limbs, and localized burning sensations in the ankles and feet. From first to last he had been conscious of indigestion with its associated symptoms and miseries, and added thereto had been almost every form of suffering due to

reflex irritation of the nerve filaments of the gastro-intestinal tract. All of these conditions and symptoms steadily grew worse despite medical treatment and travel, until the patient became a constant sufferer and utterly unfit for business or the enjoyment of life.

In these mixed cases of indigestion accompanied by marked nervous symptoms it is frequently difficult to decide just what condition one has to deal with. Indeed, it is often a problem calculated to perplex a careful diagnostician and make him appreciate more than ever the mysteries and complications of disease. That doubts should prevail and mistakes should occur is not strange when one considers what a host of symptoms may result from intestinal disorders and from an irritated, excited, impaired, and perverted state of the nervous system. In the majority of such instances, where the above-named conditions are mixed together, the diagnosis is made in favor of some nervous disorder and styled "nervous dyspepsia," "nervous irritation," or "nervous exhaustion." In fact, the prominence, urgency, and distressing character of the nervous symptoms are allowed to overshadow those that really point to the underlying cause. This was well illustrated in the case under consideration, for the nervous symptoms were so prominent and persistent that they misled both the patient and his many different physicians. One of the latter, a neurologist of national repute, treated him for many months for nervous exhaustion and nervous irritability, never giving more than passing attention to the symptoms of persistent functional disorders of digestion. These latter were called "nervous dyspepsia," and the assurance was given that they would pass away with the return of nerve force.

These facts hint at the difficulties attending this line of cases, and plainly indicate the paramount importance of first establishing an accurate diagnosis. This can be done in most instances by a careful analysis of the history of the case by following out certain general principles, and by a frequent study of the products of the system. The utility of such procedure will be seen as we advance in our study of the case under consideration.

1. The history in this case revealed the fact that indigestion had prevailed more or less for many years—indeed, from boyhood. It was the primary functional disturbance, and had always preceded or existed in concurrence with nervous manifestations. Latterly it had become so marked that there were persistent acidity, flatulent disturbance, gripping pains, and undefinable abdominal distress. These facts and symptoms were, to say the least, highly suggestive and merited thorough investigation. Moreover, the patient was of a nervous or neurotic family and had a highly sensitive nervous organization. He was therefore, by virtue of hereditary tendency, predisposed to suffer from either direct or reflex irritation. All that was needed was an abnormal state of the secretions, improper food, acidity, and fermentation to irritate the nerve filaments of the stomach and bowels, and to cause pain and general nervous disturbance. Besides, to these inherent tendencies he had added that irritability frequently caused by hard work, constant anxiety, a great amount of care, professional strife, and business reverses. In such manner, predisposing and exciting causes

prevailed which would, beyond doubt, point to the probability that the seat of his troubles was in the gastro-intestinal tract.

2. In the second place, it is a general principle that a constant cause underlies a constant effect. It was rational to believe that constant disorder of digestion, accompanied by continual abdominal pains, burning sensations and lancinating pains in the legs, irritability of the nervous system, mental confusion, and intolerable wakefulness had a constant cause somewhere. It was equally rational to assign the cause to improper food and imperfect digestion, because the symptoms of each prevailed, and also because it is well known that gastro-intestinal irritation may be reflected to all parts of the body, causing most alarming symptoms. Moreover, it is established that constant acidity and fermentation in the stomach and bowels invariably give rise to lithemia, oxaluria, or phosphaturia. The presence of either of these conditions of the system may so affect a susceptible nervous system as to cause neuralgias, twitching of groups of muscles, shooting and burning pains in the limbs, numbness and coldness in different parts of the body, imitative locomotor ataxia and paralysis, vertigo, violent headaches, and functional derangement of the mind. This fact has been elaborated in a masterly manner by Ralfe in his immensely valuable work on "morbid urine." He shows conclusively that there is a wonderful relation between an acid state of the system and a host of the most common and alarming nervous symptoms and functional nervous affections. It is also proper to add in this place that it is believed by many investigators at the present time that intestinal fermentation produces certain chemical gases and alkaloids which, when absorbed into the blood, make a profound impression upon the nervous system. It is maintained that their absorption practically introduces a poison into the blood, followed by symptoms of disease which are vaguely attributed to various conditions. Brunton well said that "perhaps we are not yet sufficiently alive to the important results produced by the absorption from the intestinal canal of substances generated in it by fermentation or imperfect digestion. We recognize the danger of breathing gas from a sewer, but probably we do not sufficiently realize that noxious gases may be produced in the intestine, and, being absorbed into the circulation, may produce symptoms of poisoning."

3. The prevalence of these general conditions and probabilities pointed to the necessity of adopting all the usual methods of diagnosis—such as inspection, palpation, percussion, and, in addition, an analytical study of the blood, urine, and faeces. Inspection revealed in this case that the abdomen was greatly distended and abnormally prominent. Palpation and percussion disclosed that the stomach and bowels were full of gas and that there were points of tenderness over them. These marked evidences of gastro-intestinal disturbance, together with signs and symptoms of lesser importance, were verified by repeated microscopic studies of the blood. Such method showed the presence of mycoderma aceti, or what are better known as yeast ferment, or the absorbed products of acidity and fermentation. When these are found in the blood they are proof

positive that improper food is being taken, and that digestion is imperfect. In addition to careful and repeated study of the blood there was a thorough and daily examination of the urine. At first its specific gravity was about 1.030, and it contained an excess of phosphates and bile. The microscope showed uric-acid crystals, but no evidence of degeneration of tissue. It is the rule in these cases for the urine to be very dense with phosphates and bile, and to show more or less crystals of either uric acid or oxalate of lime. In this case constipation prevailed and the faecal discharges were variable.

Turning now from this rapid view of the history, causation, and diagnosis of this case, a few remarks will be made regarding the treatment it received.

In the first place, an effort was made to place the patient under the most favorable hygienic and moral conditions. He was located in a large airy room, and attended and accompanied by his wife and child. The help and encouragement of the wife were utilized as far as possible, with a view of steadyng and maintaining a healthful mental condition. It was necessary to meet the tendency to mental irritability and depression in every possible way. With the favorable surroundings went the strictest injunctions as to complete relaxation from work, care, anxiety, and physical fatigue. It is useless to attempt to treat such patients unless the mind can rest and be diverted from the corroding worries incident to domestic and business life. It is safe to say that gastro-intestinal indigestion, accompanied by excessive nervous irritability, will never yield to any form of treatment unless these conditions obtain. The processes of digestion must be allowed all opportunity that is possible, and what nerve power there is must be saved for the promotion of organic functions. The law that rest and sleep, mental relaxation, and composure are absolutely essential to restoration needs to be imbedded in the mind of the patient. The patient must yield to this law in a cheerful, obedient, and helpful manner, as a condition precedent to recovery. In this instance mental and bodily rest was insisted upon, until the system was rested and refreshed. With a view to promoting nutrition, baths, friction, and daily massage were adopted, and served a useful purpose. These methods tended not only to work the nutriment into the system, but also to divert the blood and nerve currents from the brain to the functions of organic life. Afterward the invigorating effects of unobstructed fresh air and sunlight were sought, and the patient was advised to sit out of doors, and to take short walks and an occasional ride whenever the weather would admit. He was always enjoined, however, never to allow diversion and exercise to overtax his nervous system, and thus cause fatigue. It is believed that the attention given to these common-sense moral and hygienic regulations did much to bring about the improvement that soon supervened. In other words, they afforded the conditions that made still other efforts operative and helpful.

The next step in the management of this case was to place the patient on a suitable diet. The indications were for one that was light, palatable, easily digested, non-fermentable, and nutritious. These were cardinal conditions

that had to be met before any progress could be expected. It was not reasonable to try to cure with fermentable foods a case in which acidity, fermentation, and flatulence were sources of intolerable misery. Consequently, all sweet, starchy, and greasy foods, all fruits and vegetables, as well as everything containing acids, were displaced from his diet at the outset. The great object was not only to carefully eschew every indigestible substance, but to avoid the causes of acidity and fermentation. It was believed that the rigid exclusion of such causes would enable the stomach and bowels to regain their normal state, would favor the processes of digestion, and would avoid an immense amount of discomfort. With these definite ends in view, the patient was placed upon a carefully regulated animal diet, composed mostly of beefsteak, and the muscle pulp of beef prepared by a machine made for the purpose. The latter afforded him a simple, concentrated, digestible, and non-fermentable diet, yielding the maximum nourishment from the minimum effort. Of this he was allowed every four or five hours as much as his stomach would easily tolerate and digest. At times, as he became tired of this single preparation, he was allowed choice beefsteaks, which answered much the same purpose but were not so digestible. Besides directing this diet, every effort was made to know that it was completely digested from day to day. In these cases it is not enough to order a particular food, but it must be known that it is being entirely digested. This information should be obtained from day to day by careful inquiry, thorough examination of physical signs, and an analytical test of the blood, urine, and faeces.

As soon as the machinery of the system gets to doing its work well, the physical signs of disease will disappear and the organic products will show good work. On the contrary, if it does not get to working well, physical signs of disease will prevail, the blood will show abnormal elements, the urine will be highly colored and heavy with excrementitious products, and the faeces will show undigested food. It is wonderful how accurately and promptly physical signs and abnormal products will show whether the processes of digestion, absorption, and assimilation are going on as they should. In this case these conditions were watched more or less from day to day until it was found that the food was agreeing with the patient and the organs were doing their work well. Subsequently, as the patient improved, a larger amount and a wider range of food were allowed. At first he was given a small piece of stale bread, then from two to four ounces of milk, then a little game, and ultimately some vegetables. The effect of these additions was carefully watched, and they were continued or dispensed with as he was able or unable to digest and utilize them. As a result of this carefully selected and well-regulated diet, relief from gastro-intestinal pain soon ensued, and the host of secondary nervous symptoms grew beautifully less. In a single month he passed from constant wretchedness to a state of entire comfort. In other words, just as soon as the cause was removed, the miserable effects which had tormented him for years vanished.

The same degree of attention that was given to the regulation of his food was applied also to the regulation of his

drinks. He was at once deprived of such drinks as tea, coffee, milk, and stimulants, and placed upon the regulated use of hot water. He was directed to take a pint of hot water systematically by the clock an hour before each meal and the same length of time before going to bed. Or, in other words, the rule was for him to take his food every five hours and the hot water four hours after taking food. This allowed four hours for digestion without the presence and interference of a great quantity of liquid. Moreover, the use of a large amount of hot water tended to dissolve and wash downward any accumulation of tough, stringy acid and fermented mucus that was left in the stomach, thus preparing the way for the next meal. It also maintained the volume of the blood, stimulated the secretions, and favored a freer action of the liver, kidneys, and bowels. In short, the object was to quench thirst, keep the stomach cleansed of catarrhal mucus, aid downward action of the bowels, "flush out" the liver and kidneys, and maintain the specific gravity of the urine at about 1·015. The great utility of the internal use of hot water in the treatment of gastro-intestinal disease can not be overstated, but, like every other remedial agent, it must be used systematically, persistently, and for a definite purpose.

As regards medicinal treatment in this case, it is to be said that only simple remedies were used, being employed as the need was indicated. No effort was made to cure (?) the patient with medicines, but rather to put him in a condition to receive cure from the great and only sources of health—proper food, pure water, abundance of sunlight, and fresh air. Consequently only such remedies were used as tended to tone up the nervous system, stimulate the organs of digestion to better action, aid the digestion of food, and induce composure and rest of the nervous system. These were the four chief indications, and they were met as demanded from day to day. They pointed to the use of chinchona, nux vomica, damiana, salicin, cascara, pepsin, bromides, and sulphonal, which were about all the remedies required.

In conjunction with medicinal remedies went what may be styled thorough mental and moral treatment. The patient was seen daily, and great and constant effort was made to overcome the tendency to doubt, delusion, morbid imaginings, mental depression, and discouragement, so common to patients suffering from indigestion and nervous exhaustion. He was not only thoroughly examined each day, but also cheered, aroused, encouraged, reassured, advised, and rigidly held to the carefully systematized treatment now found useful in so many instances. The great object was to steady his mind, to appeal to his reason, to explain away doubts and morbid fancies, to insure co-operation in carrying out details, and to inspire hope. In this form of chronic cases, above all others, it is of the highest importance to thus gain control of the patients' emotions and mind, to lift them out of depression and evil apprehensions, and to give them a determinate action toward health. Indeed, satisfactory results are almost impossible unless persistent mental and moral suasion enters largely into the general management of the case.

In conclusion, it can be said that, as a result of this line of treatment, the patient improved from the very first, and

in three months felt able to pass from observation and return to his home, there to continue this treatment. He was not discharged cured, for in a case of such severity and long-standing the patient can not get entirely well in three months. A weakened and unreliable state of the organs of digestion lasts for a long time after the signs and symptoms of indigestion and nervous irritation have been relieved by a regulated diet and various remedies. There needs to be constant watching and judicious caution as to the quality and quantity of food taken, for many months elapse before the stomach and bowels become so strengthened as to manage a liberal mixed diet. Although not cured, he was so well started in that direction that his digestion was vastly improved, he was entirely free from gastro-intestinal pain and nervous irritability, the burning sensations in the feet and limbs had passed away, neuralgic pains in various parts of his body had all gone, mental confusion and depression were things of the past, and he was able to sleep from six to seven hours out of the twenty-four. In other words, removal of the cause, together with well-directed hygienic, moral, and medical treatment, had resulted in producing a satisfactory and comfortable effect.

## NASAL BACTERIA IN HEALTH.\*

BY JONATHAN WRIGHT, M. D.,  
BROOKLYN.

THE position which micro-organisms will ultimately take in their relation to the morbid processes of disease has not been determined as yet. Indeed, we seem now only at the beginning of an unknown region in which possibly lies hidden the mystery of the aetiology of many pathological changes. Encouragement in the region of preventive medicine, under which head we must include all that Listerism has done for surgery, lends zest to the attempts to follow the microbe into the human organism and there annihilate it. The almost complete failure thus far has given professional cynics an opportunity for a somewhat galling criticism. These failures are, no doubt, in a large measure due to our as yet very incomplete knowledge of the varying conditions and influences which complicate the relations of microbes to the human organism. Whatever opinion the clinician may have of the part played by them in the aetiology of the diseases he observes, even the most skeptical must admit that the burden of disproof has been thrown upon the doubters.

With the increased probability that many pulmonary and nasal diseases owe their origin, in a large degree, to micro-organisms, it becomes important that the bacterial contents of the respiratory tract in a state of health should be known. Before we are in a position to investigate a pathological process we must have a firm physiological basis on which to stand. Before we seek for a pathogenic micro-organism in disease we should know what exists in the situation in a condition of health. The ingress of all infective agents must, in the vast majority of cases, be through the

\* Read before the Laryngological Section of the American Medical Association at its fortieth annual meeting.

nose or the mouth; those of the respiratory tract, as a rule, through the former; those of the alimentary tract, as a rule, through the latter. The bacterial contents of the mouth in health have been so thoroughly investigated by Biondi (1), Vignal (2), Netter (3), Fraenkel (4), and others that further researches would seem superfluous when our knowledge of the nasal micro-organisms in health is so slight. As laryngologists we are becoming more and more impressed with the necessity of normal nasal respiration and the harm of mouth breathing. In the further advance of nasal bacteriology we may find another reason to urge the importance of purely nasal respiration. When we remember the apparatus of Hesse (5) for air analysis, the configuration of the internal nose would seem admirably adapted to arrest the progress of microbes carried into it by the air current; and, still further, it has been conclusively proved that bacteria never rise from a damp surface, however strong the blast may be over it, unless carried along by some particle of water or mucus or solid matter. Hence we should expect to find innumerable varieties of bacterial forms derived from the air, and might well despair of reaching any definite conclusions in the matter. Besides the bacteria of phthisis and pneumonia and the microbe of diphtheria, whether it be the bacillus of Löffler or the streptococcus of Prudden, there seems good evidence that some purely intranasal diseases depend upon micro-organisms for their origin or their subsequent course. A perusal of the researches of Löwenberg (6), Klammann (7), Thost (8), Seifert (9), Strauch (10), Valentin (11), Hajek (12), Reimann (13), and others into the aetiology of ozæna and coryza must convince us of the truth of what Walb (14) says of ozæna.

"I am convinced," he says, "that the way opened by Löwenberg will lead to the discovery of the nature of ozæna. Whether the Löwenberg coccus or some other is the cause of ozæna is of no consequence; it must exist, and it is to be hoped that it will be found."

Whether there is a bacterial connection between coryza and pneumonia, as maintained by Thost (8), and further urged by Cardone (15), it is impossible, with our present knowledge, to form any opinion.

Notwithstanding the abundance of the literature to be found on the bacteria of nasal diseases, there is very little, in fact no systematic examination of the normal nasal secretions for bacteria recorded in the somewhat extended range of literature to which I have had access. However instructive the staining of nasal secretions for bacilli and cocci as a matter of technique may be, there is little or nothing else to be learned from it without the aid of the improved methods of cultivation tests. I have therefore omitted extended reference to this class of work. The mere presence of micro-organisms in nasal secretions was established many years ago. Bernard Fraenkel, in von Ziemssen's "Encyclopædia" in 1876, in his article on acute coryza, says:

"A large number of these little structures, recently so much spoken of and called micrococci, may generally be seen also covering the cells."

And he refers to Hucter (16) as maintaining these bodies to be the source of irritation in coryza. Herzog (17) in 1881 found many bacilli and cocci in normal and abnormal nasal

secretions, more abundant in the latter, and especially in foetid nasal catarrh. Eugen Fraenkel (18), on the other hand, in 1882 stated that he could find no bacteria in the normal nose, and his work on ozæna, in the secretions of which he found four kinds of bacteria, has been widely quoted, but, in the light of our present bacterial knowledge, possesses on this point only historical interest. Later observations have all been made incidentally in connection with bacterial investigations of disease. Bernard Fraenkel (19) in 1886 found in the normal pharynx, besides the *Staphylococcus pyogenes aureus* and the *Staphylococcus pyogenes albus*, a micrococcus which often appeared as a diplococcus and did not liquefy gelatin. Probably the same coccus was found in the normal retro-pharynx by Hack (20), and fully described by his pupil Stranch (20). The latter asserts that it is also found in the nose, but less frequently and in smaller numbers. Both Löwenberg (6) and Hajek (12) failed to find micro-organisms at all constant or abundant in normal nasal secretions. Reimann (13), on the other hand, described two forms as nearly always found—one a plump round-ended bacillus, and the other a little coccus which occurred usually in pairs but often in longer chains. Considering the extensive and very thorough work done upon the bacterial contents of the mouth in health, it is singular that there should be such a lack of it in the nose.\*

My own observations have been made during the last two years in the laboratory of the Alumni Association of the College of Physicians and Surgeons under the direction of Dr. T. M. Prudden, to whose kindness and careful oversight the little which may be of value in them is due. The material was drawn from the Dispensary of the Roosevelt Hospital. Although a number of other cases were examined, it is my purpose to record here only those investigations made in fairly normal cases, leaving the examinations in the other cases for further amplification and another occasion. The method of work was as follows: Portions of the nasal secretion were removed from the mucous membrane covering the turbinated bones and adjacent portions of the septum, in the loop of a long platinum needle previously sterilized in the flame. This was immediately plunged into two gelatin tubes, and streak cultivations were made upon two agar-agar plates. Thus, four inoculations were made from different portions of the nasal chambers in each case. Besides this, a number of dry cover-glass preparations were made of the nasal secretion in each case and stained by Gram's method and by simple double staining. These last frequently showed no bacteria when the cultivation tests proved their presence in great abundance. The gelatin tubes were plated according to Koch's method and pure cultivations obtained

\* At the last meeting of the Russian congress in St. Petersburg, Besser reported having examined the nasal secretions of 81 patients, the bronchial secretions of 10, and the secretions of the frontal sinuses in 5. Out of the nasal and bronchial secretions he cultivated the Fraenkel-Weichselbaum diplococcus of pneumonia in 14 cases, the *Staphylococcus pyogenes aureus* in 14 cases, and the *Streptococcus pyogenes* in 7 cases. Unfortunately, I have not been able to procure the original article, and the reference in the "Centralblatt für Bacteriologie," Bd. v, No. 21, is incomplete, not giving the conditions under which they were found.

and transferred to cultivation-media tubes of agar-agar, five-per-cent. glycerin-agar, gelatin, bouillon, milk, and potatoes. The same was done with pure cultivations obtained from the streak cultivations on the agar plates. The growth characteristics were noted and compared with descriptions in the works of Flügge, Fraenkel, Eisenberg, and others, and where close correspondence was observed their denominations were accepted. Those forms found not to correspond to any descriptions were, as a rule, carefully worked out and the records preserved, but it is unnecessary to describe them here, as they were only found in isolated cases. All the usual precautions were taken against contaminations and, in addition, only those colonies selected from the plates which were in sufficient numbers to preclude the possibility of contamination and to eliminate, as far as possible, those microbes which had only recently become nasal inhabitants and had not yet grown in the nasal secretions to any considerable numbers.

When one remembers the multitude of air bacteria which would naturally lodge against the nasal mucous membrane, and be only accidental visitors to a soil unsuited to them, this precaution will not seem uncalled for. In all cases care was taken to ascertain that no nasal douches of any kind had been previously used. Any one, even those unfamiliar with the technique of bacterial analysis, will appreciate the amount of work required where so many different forms had to be carefully worked out, and that may be pleaded as an excuse for the limited number of cases brought forward. In the ten cases mentioned, the condition of the mucous membrane was as nearly normal as possible, and even where insignificant changes were observed they are noted. The class of cases was not so diversified as would be desirable, as they were all in dispensary patients. I made several bacterial analyses of the air of the dispensary from time to time by Petri's and Sedgwick's methods and by exposure of agar plates. At no time was there any growth but those of simple air bacteria noted. The nasal bacterial forms were found to vary markedly with the state of the weather and of the streets. High winds and dry and dusty streets were sure to fill the noses with air bacteria. In rainy weather, or after several days of calm, or when snow was on the ground, aerial forms were much more rare. It seems to me there can be only one cause for this—viz., they tend to disappear because they have found a soil unfitted for their growth, and, according to the universal law of natural selection, give way to microbial forms more favored by the conditions. It certainly is not because they blow away in the secretions, because it is not only their absolute frequency which varies, but their frequency relative to other forms. The reaction of the secretion of the normal nose was found to be neutral or slightly alkaline.

CASE I.—A young man in fair health, with the exception of slight cough. No pulmonary lesion; slight hypertrophy of one turbinated bone; nose otherwise normal. A short, plump bacillus looking at times like a diplococcus; slow white growth on gelatin which it does not liquefy. Same on agar, spreading slightly on surface.

CASE II.—A young girl with slight tonsillar enlargement; nose normal; general health good. Bacterial analyses were

made on three separate occasions, and twice was found a nearly pure cultivation of the *Staphylococcus pyogenes aureus*. The tonsils were examined and the same growth was found there. Inoculations of pure bouillon cultivations in the jugular of rabbits set up purulent pericarditis and endocarditis, of which the animals died. The pus swarmed with the cocci.

CASE III.—A boy of seventeen who had a perforation of the septum and hard palate from a syphilitic process. All ulceration had long healed and the mucous membrane was normal in appearance. The *Staphylococcus pyogenes aureus* was found in large numbers and a moderate growth corresponding to the *Bacillus lactis aerogenes*.

CASE IV.—A man of thirty-five, who a few weeks previously had been discharged from Roosevelt Hospital after a severe operation for the removal of a thyroid tumor. The wound had healed by first intention. Left laryngeal paralysis resulted. The nose was perfectly normal in every way. The *Staphylococcus pyogenes aureus* and *albus* were both found, and abscesses were caused by the injections of pure bouillon cultivations of each beneath the skin of rabbits. From these abscesses new cultivations of the same growths were obtained in each case.

CASE V.—A child ten years old. No subjective nasal symptoms, but the mucous membrane of the nose was slightly hyperemic. In this case also both the *Staphylococcus aureus* and *albus* were found, and positive results obtained from animal inoculations.

CASE VI.—A seamstress, aged sixteen. She had had considerable post-nasal catarrh, but no purulent secretion. Nose normal and health good. Two examinations six weeks apart were made. Each time in the nares there was found an abundant growth of the ordinary mold, the *Penicillium glaucum*. Each time pure cultivations of the *Streptococcus pyogenes* were obtained from the post-nasal space. A pure bouillon cultivation was injected beneath the skin of rabbits' ears and an erysipelas-like inflammation produced, from the sanguous pus of which cover-glass preparations were made showing abundant cocci in chains. At the second examination a cultivation of a gas-producing bacillus was also made from the tonsils. The most careful questioning could elicit no history of exposure to contagion of any kind. She herself was in the best of health except for the discomfort from her post-nasal catarrh.

CASE VII.—A girl, aged sixteen, cigarette-maker. There was slight hypertrophy of the nasal mucous membrane with some tonsillar injection. The *Staphylococcus pyogenes citreus* was found in the nose.

CASE VIII.—A child, aged four. Slight post-nasal catarrh and slightly enlarged tonsils. Nose normal. In it was found the *Micrococcus flavus desidens*.

CASE IX.—A man, aged nineteen, with follicular amygdalitis and post-nasal catarrh. This case presented considerable structural change, and I insert the record here because, in spite of the large amount of secretion present, only aerial forms were found. They were the *Micrococcus flavus desidens* and *Micrococcus cereus flavus*, and an undetermined coccus with a curious growth on agar and gelatin, a description of which would be out of place here.

CASE X.—A woman, aged twenty, with a slight attack of laryngitis. She was recovering from coryza and there was some mucous secretion in the nose. The bacterial contents were as follows:

1. *Staphylococcus pyogenes aureus*.
2. *Micrococcus flavus desidens*.
3. A tetrad resembling closely the descriptions of the *Micrococcus tetragenus*.
4. An undetermined coccus, with a white non-liquefying growth on gelatin and agar.

The three last cases were examined during windy, dusty weather, and illustrate well, especially in the last case, the unreliability of cover-glass preparations alone of the nasal secretions in determining bacterial species, as the morphological appearance in four out of the five organisms was the same.

To summarize: In six cases, the *Staphylococcus pyogenes*; in three cases, the *Micrococcus flavus desidens*; in one case, the *Bacillus lactis aerogenes*; in one case, the *Penicillium glaucum*; in one case, the *Micrococcus cereus flavus*; in one case, the *Micrococcus tetragenus*; once in each of three cases, different undescribed forms.

The air forms may be dismissed without further consideration. The *Micrococcus tetragenus*, found in only one case and in small numbers, need only receive a passing mention. In Case VI the only organism in the nasal chambers proper which was made out by two careful examinations at different periods was the ordinary mold—the *Penicillium glaucum*. It was in such great numbers that it possibly may have overshadowed the growth of other forms. Considering its great aerial frequency, it is singular that it was not oftener found. In this case the *Streptococcus pyogenes* was twice found in the naso-pharynx, which was the seat of a chronic catarrhal inflammation, but which showed few changes in the mucous membrane besides the reddening of the surface and the increased secretion of mucus. For its pathogenic significance in the air-passages the works of Netter (3 and 22), Prudden (21), and others may be referred to.

Our attention is therefore directed to the *Staphylococcus pyogenes*; the three varieties *aureus*, *albus*, and *citreus* need only be considered as one in their pathogenic significance. We know as yet too little concerning the conditions under which this organism exerts its characteristic influence to draw conclusions. It may be well, however, to refer to the statements of a few of the various workers in this field.

Ullmann (23) found the staphylococcus in the air in different situations and under varying conditions, as well as in the water of the river Spree. He and others found it in the earth, on the streets, and on the walls of various rooms and buildings. As to man, he says: "Fürbringer found it in the dirt under finger-nails, and Bumm in the folds of the nipples. Biondi obtained cultures of it from the saliva, and Fraenkel from the tonsils. I have found it not only on the buccal mucous membrane, in the saliva, the tonsils, the

pharynx, and vagina of healthy people and of animals, but in the œsophagus, intestinal tract, and bladders of recently killed animals. Lustgarten and Mannberg found it constantly in the urethra. These investigations show that the staphylococcus is very widely distributed, and that it is found wherever living beings are."

From this we see that its very frequent occurrence in the nose forms no exception to the rule. It will require investigation of many more cases than those here cited to prove that it is the most frequent and abundant micro-organism in the nasal chambers. Netter (22), speaking of the influence of pathogenic micro-organisms in the mouth, nose, and ears, says: "The presence of the microbes is not enough. It is necessary that they should be present in sufficient quantity to triumph over the resistance which healthy anatomical structures offer them. It is necessary that their virulence should be sufficiently great, and we know that their virulence is not always the same."

He might have also said that the resistance offered them was not always the same. On this head the work of Bujwid (24) is suggestive. He found that, in round numbers, a billion *Staphylococci aurei* for a rabbit, a hundred millions to a billion for a rat, and a hundred millions for a mouse, could be injected beneath the skin of a healthy animal without result, no abscess forming. When, however, grape-sugar had been previously introduced into the animals' systems, they succumbed.\*

Ribbert (25) and his pupils, Fleck (26) and Laehr (27), caused a catarrhal inflammation of the bronchi, with more or less broncho-pneumonia, by injections of pure cultivations of the staphylococcus into the trachea. Their investigations, as well as those of Wyssokowitsch (29), tend to show that the lungs or the adjacent bronchial lymphatic glands act as a sort of filter or as a place of destruction for the microbes, preventing their further penetration into the human organism.

Prudden (21) repeated the experiments of Fleck and Laehr, with like results. He also succeeded in causing broncho-pneumonia by injections of pure cultivations of the *Streptococcus diphtheriae* and by injections of ammonia.

Lübbert (28) caused fibrino-purulent tracheitis and bronchitis by injections of a pure cultivation of the staphylococcus into the trachea. It is asserted by many investigators, and their assertions are based upon extensive experiments, that it is the pavement epithelium which prevents the entrance of various microbes into the subjacent structures and thence into the general system. The very general experience of laryngologists would hardly bear this out as regards the staphylococcus, since tonsils and uvulae are cut without a fear of septic invasion, and in all the operations upon the mucous membranes of the mouth and nose this is the least danger we fear. If, however, a patient bites the operator's finger so as to break the skin, unless the wound is thoroughly washed out with an antiseptic, local suppuration

\* Since this paper was written, the very valuable papers of Buchner ("Ctbl. f. Baet," iv, 25, v, 1) and Nissen ("Ztschr. f. Hygiene," vi, 3) have come under my observation. They give convincing proof that it is the albumin in the blood plasma that exercises the destructive influence on bacteria in the circulation.

tion often follows, and, occasionally, from this general sepsis.

I have mentioned these facts and observations in order to show how little we know as yet and how vastly much more we have to learn about this comparatively well-known microbe so often found in the upper air-tract of healthy people.

Before closing I wish to make mention of some investigations, as yet very incomplete, which I have been engaged upon during the last two months, more in the hope that others with more leisure and better opportunities will continue them, than from an expectation of adding much to our knowledge. I refer to the nasal chambers as a bacterial filter of the air passing through them.

It has been definitely proved by the investigations of Grehant (30), Paulsen (31), Aschenbrandt (32), and Bloch (33) that the nasal chambers not only are warmers and moisteners of the inspired air, but act also as a filter for dust particles. The latter observer experimented with many substances in fine powder, and came to the following conclusion, as did Grehant and Aschenbrandt:

"A certain part of all kinds of dust, even the finest, is held back; the larger part of the formed substances which float in the air do not reach the entrance of the larynx or even the choanae; but it is impossible for the nose, even with the help of the naso-pharynx, to completely free the air even from the coarser kinds of dust."

Now, a bacterium, whatever its relative proportions to other divisions of matter with which we are familiar, is a ponderable substance, heavier than air, water, or any of the animal fluids. It is therefore subject to the same physical laws. It is yet an unsolved mystery how the *Bacillus tuberculosis* reaches the most frequently chosen seat of its selective action in the apices of the lungs, and how the pneumococcus usually reaches the lower lobes before a lobar pneumonia occurs. To a bacteriologist it is almost inconceivable how a microbe entering the anterior nasal meatus with the tidal air should go through the tortuous, moist passage of the nose, past the broad surface of the palate and the post-pharyngeal wall, into the larynx between the false and true vocal cords, down the long tubes of the trachea and bronchi, and finally find a lodging place on the walls of the bronchioles and air cells. The chances of its being arrested before it reaches them seem almost infinite, especially since the tidal air must stop at a comparatively high point in the respiratory channel in inspiration, and flow upward again on expiration. Neither does it seem probable that, becoming arrested at some higher point, it flows downward with the bronchial secretions, when we remember the ciliated epithelium and its function. The lymph channels have been strongly urged as an explanation; but, although our knowledge of the pulmonary lymphatics is very limited, there are many objections to this vague theory which will occur to every one. The day for theorizing has gone by. A theory nowadays should be considered as little better than confession of ignorance.

However small and insignificant an addition to our knowledge the ascertaining of the capacity of the nose as a place of arrest for microbes may be, it seemed so easy of demon-

stration that I have attempted it. The technical difficulties were many, but have been fairly overcome, though it needs a much more extended and varied research than I have yet made to draw conclusions. The task is easily stated: Ascertain the bacterial contents of the air before and after it has passed through the nose. Glass tubing, of a caliber of one eighth to one fourth of an inch and six inches long, was filled with granulated sugar for three inches and a half of its length, held in place at the bottom by a piece of rolled copper gauze, tightly fitting the tube, leaving enough space at each end for the insertion of a cotton plug. The sugar grains were of a uniform size of forty to the inch. This part of the apparatus was copied from that of Professor Sedgwick and G. R. Tucker, of Boston, to whom I am greatly obliged for a description of their method of air analysis kindly sent to the college laboratory some time before it was communicated to the Society of Arts, in whose proceedings for 1887-'88 it may be found. Their rules for sterilization of the sugar and the apparatus were also followed. For reasons which I need not stop to explain here, it was found best to vary their procedure considerably and adopt, to some extent, the method of Petri (34) with sand. After proper sterilization, the glass tubing was attached by means of stiff rubber tubing to an air-exhaust apparatus. As there was a good head of water in the laboratory, a Sprengel's air-pump was principally used, by means of which one litre of air could be drawn through the three inches and a half of sugar in from forty seconds to a minute. Usually, however, a very perfect air-exhausting apparatus may be obtained by making use of the Allen surgical pump, of the size used for veterinary purposes. About a hundred revolutions of the handle of this instrument, which can be made in forty-five seconds or a minute, will exhaust one litre of air. With either contrivance it is perfectly easy to ascertain the rate at which air will pass by means of a litre flask inverted in water.

It has been proved by Sedgwick, and I have verified the statement, that air passing at about this rate will deposit all its bacterial contents in the sugar.

With this apparatus, then, ten litres of air are drawn through the filter after the cotton plugs used during sterilization have been withdrawn. Then ten litres of air at the same time and in the same locality are drawn through the nose and also through the filter. This is accomplished as follows: The glass tubing with its load of granulated sugar, all thoroughly sterilized, is inclosed by means of a perforated rubber cork in a larger piece of glass tubing and the space between the two loosely packed with absorbent cotton. The end of the smaller tube does not reach to the end of the larger. The filter thus protected from the buccal secretions is put into the mouth and the lips are closed firmly around the outside tubing. If it is held in a horizontal position in the mouth, nothing but air can enter the filter when the suction is begun. During alternate periods of fifteen seconds each the person is directed to hold his breath, making the thoracic walls rigid. Thus practically all the air drawn through the filter must have first passed through the nasal chambers and the post-nasal space. During the fifteen seconds of respiration the air current is shut off by compressing the rubber

tube between the filter and the suction apparatus; consequently the time consumed in the examination of the nasal air is twice that consumed in the control examination. The plan adopted by Aschenbrandt and others of drawing the

precautions taken in sterilizing, controlling, and guarding against aerial contaminations, which belong to the technique of careful bacterial analysis.

The colonies developed after several days in the two sets

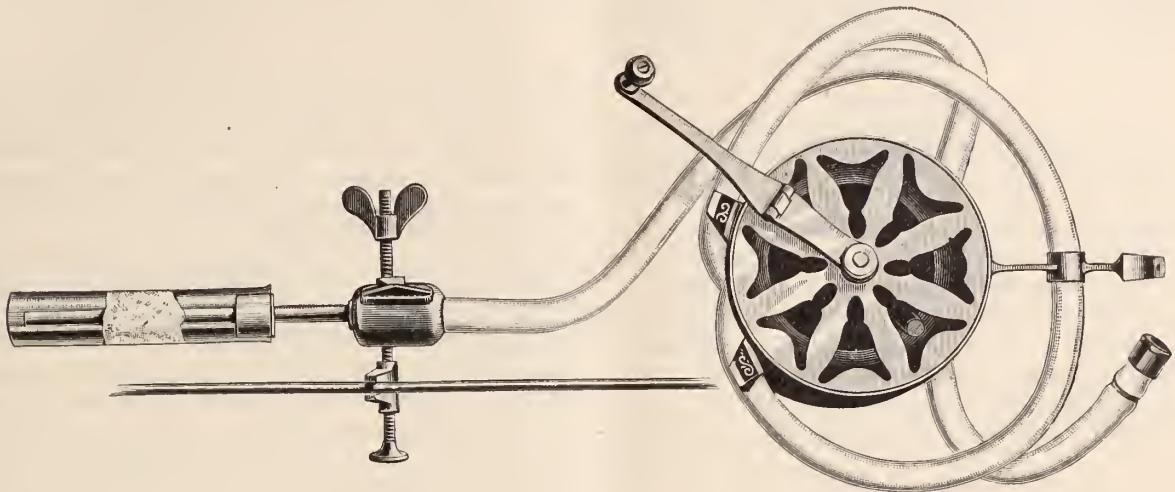

FIG. 1.

air up one nostril and down the other before examination, besides other faults, permits the entrance of mucus into the air filter, which it is impossible to protect from contact with the walls of the nasal chambers.

After the ten litres of air are drawn through in each case the sugar is dampened and partly dissolved with a few drops of carefully sterilized water to facilitate its removal from the glass tubing. By means of a sterilized stiff brass rod the wire gauze is pushed along the tubing, forcing the wet and partly dissolved sugar out into shallow glass dishes, where it is thoroughly dissolved and mixed with ten-percent. nutrient gelatin. The glass tubing is filled with gelatin and stopped at both ends with cotton. The gelatin in the dishes is allowed to solidify slowly so as to insure the complete dissolving of the sugar. It was found that very few, in many cases no, colonies developed in the glass tub-

of dishes were counted and compared. As I said before, too few examinations were made to arrive at hard and fast conclusions. I only experimented on my own nose, and have succeeded only recently in getting results free from errors of technique. Speaking in a general way, the nasal chambers in my own case seem capable of filtering out about three fourths to four fifths of the bacterial contents of the air passing at the rate of one litre a minute. The photographs of an examination made during the presence of a considerable quantity of mold in the air illustrate this fairly well. This particular experiment was photographed because the white molds show the difference in a more striking manner than bacterial colonies, but the same proportion seems to hold good with them, as, for instance, in an examination made on April 25th of this year.

Ten litres of laboratory air contained four molds and a hundred and twenty-five bacteria. Ten litres of laboratory air, after passing through the nose, contained one mold and twenty-four bacteria. Of course noses must differ in this respect as much as in other ways, and the rapidity of the current we know makes a difference in the number of both molds and bacteria deposited in Hesse's apparatus. Counting 500 c. c. as the tidal air with each inspiration, we have about nine litres a minute passing through the nasal chambers in normal respiration. In the experiments just mentioned the rate was only a little over one litre a minute. In

litres of laboratory air after  
se and the postnasal space.

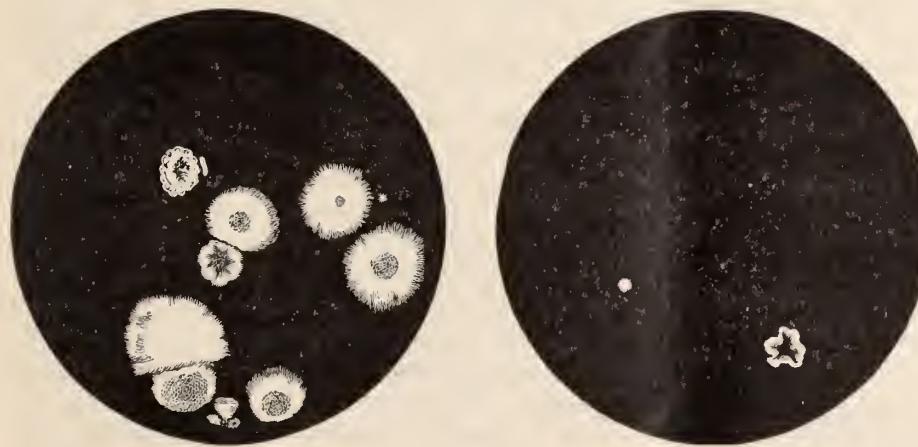

FIG. 2.

### Bacterial contents of ten litres of laboratory air.

Bacterial contents of ten litres of laboratory air after passing through the nose and the postnasal space.

ing, so completely did the sugar carry along its bacterial contents with it when pushed out. I have described the process hurriedly and omitted descriptions of the routine

spite, then, of the apparently well-adapted arrangement of the nasal chambers for a bacterial filter, even at this rate a really large number of bacterial forms are carried at least into

the larynx. It is to be hoped that further and more complete and reliable investigations will confirm or refute this somewhat premature assertion. Unless we are to throw aside the very numerous and careful observations made by bacteriologists in pulmonary diseases as useless, it is surely of the greatest importance that we should know something of the mode of ingress of microbes into the deeper pulmonary tracts.

est times. Good surgical treatment implies constitutional treatment as well as operative methods. My purpose in submitting this paper is not so much to show any particular method of operative interference as to indicate the great value of judiciously selected constitutional treatment in these particular diseases.

A glance at the minute anatomy of bone, and a consideration of the conditions under which the repair of damage takes place, shows that bone, like the softer tissues of the body, requires good food and pure air, essential factors in the production of good blood, for its normal sustenance. The relation of the digestive process to the maintenance of vigorous and nutritious bodily fluids is apparent to those most inexperienced in the management of disease. Any derangement or impairment of the digestive process, or ferments, produces a consequent impairment of blood supply delivered to the bones. The days and nights of pain incident to the usual course of caries or necrosis disorganize the digestive functions. The shock and fear, and chloroform narcosis incident to the operative procedures, frequently necessitated by these diseases, also undermine the digestive functions.

Children are the most frequent sufferers by these diseases. The impaired digestive functions in children yield more readily to properly selected treatment than is the case with adults. The conversion of starch into sugar by the digestive ferments is more frequently impaired in children suffering from caries and necrosis than is the conversion of albuminoids into assimilable substances. The use of artificial diastase is, therefore, indicated on the best of physiological grounds. Hip-joint disease, caries of the spine, chronic inflammation of the knee, and caries of the long bones are for some reason constantly accompanied by mal-assimilation and indigestion of the starches. When such cases proceed to a good, sound recovery it is through a thorough restoration of this particular digestive power, or a compensatory increase of the digestive power for hydrocarbons. In no case of hip-joint disease, were the operative methods ever so carefully or skillfully performed, has there been a repair of lesions until the digestive ferments have handled the starches perfectly. The same fact applies to the other varieties of bone diseases above mentioned.

My experience in the treatment of hip-joint and spinal cases, necrosis and caries of the various bones, embraces large numbers of cases, probably because my professional brethren have lacked the patience and perseverance and rigid attention to the digestive power essential to the cure of these long-time maladies. The Trommer extract of malt has been of great service in enabling me to bring numbers of these cases to a happy termination, and in a space of time of shorter duration than is accomplished by the use of cod-liver oil or hypophosphites.

From my case-book I quote the following cases:

CASE I.—W. S., aged eight years; parents, farmers; residence, Lenawee County, Mich. Double hip-joint disease; sinuses in the right gluteal fold over the right trochanter near the base of the left Scarpa's triangle, on the inner aspect of the left thigh; could drink milk, but ate no bread or potatoes; was ordered teaspoonful of Trommer's extract of malt every three

## THE CONSTITUTIONAL TREATMENT OF CARIES AND NECROSIS.

BY HAL C. WYMAN, M. S., M. D.,

PROFESSOR OF PRINCIPLES OF SURGERY AND OPERATIVE SURGERY IN THE  
MICHIGAN COLLEGE OF MEDICINE AND SURGERY, DETROIT, MICH.

THE surgical aspects of these distinct maladies have been the subject of discussion by surgical writers from the earli-

hours; was put on a diet of corn meal, bread, potatoes, milk, and eggs. Sinuses were laid open, drainage effected by maintaining free openings with oakum tent; plaster of Paris applied to the thighs and pelvis to limit mobility of hip joints. Sinuses closed at the end of five months; ankylosis of left hip; limited motion of right. Came under treatment in May, 1877; has had no return of the disease to date.

CASE II.—Miss F., aged sixteen years. Consulted me on account of a constant, dull, uneasy feeling in the epigastric region; emaciation and pallor; poor appetite; movements awkward; pain in riding; could walk easier than sit; examination of the spine revealed small fluctuating tumor about two inches to the left of the spinous processes, between the eighth and ninth ribs.

*Diagnosis.*—Caries of the dorsal vertebra, with abscess pointing between eighth and ninth ribs. Put upon the extract of malt, tablespoonful every four hours. Abscess was opened by incision and double drainage-tube inserted to the depth of four inches. Abscess cavity washed out daily with one-per-cent. solution of carbolic acid. Profuse discharge of pus for two weeks; plaster-of-Paris jacket applied; discharge of pus was succeeded by a thin serous fluid; pain disappeared from epigastrium; progressing favorably for two months. Passed into the hands of another practitioner; plaster of Paris removed; drainage-tube withdrawn; sinus closed. So-called blood medicines administered; pain returned in a couple of weeks; sinus re-opened; angular curvature developed suddenly. Came into my hands again. Marked angular curvature, gibbosity; abdomen distended and lower part compressed, narrowed in upper portion; severe epigastric pains; tongue white, pasty. Sleepless, feverish. Reapplied plaster of Paris; enlarged sinus and introduced drainage-tube; washed out cavities as before and readministered Trommer's extract of malt, tablespoonful doses every four hours for a year and a half. Drainage-tube came away spontaneously; sinus is healed; plaster was reapplied four times; patient at date has no return. Has married and is the mother of one child, healthy.

CASE III.—J. R., aged thirteen years; Monroe County, Mich.; large, raw-boned boy. Had been sick four months; left thigh flexed upon the abdomen; toe inverted; fluctuation in obliterated left gluteal fold; pain in the knee; sleepless; no appetite; temperature 101°. Abscess opened and drainage-tube inserted. Plaster of Paris applied to the leg, thigh, and pelvis; limb and thigh extended under chloroform, one inch added to the right sole; used crutch. Took extract of malt in tablespoonful doses every four hours, and six months after coming under treatment all sinuses closed; injury repaired by ankylosis.

CASE IV.—W. R., aged fourteen; residence, Fulton County, Ohio; German parentage; was robust farmer's lad until attacked two months before I saw him with phlegmonous erysipelas of the right leg and left thigh and knee; sinus had opened on the outer aspect of the right leg and behind the external malleolus. Probe passed along the whole length of the right fibula gave the rough feeling indicative of necrosis; left thigh and knee joint swollen; fluctuation in the left ham; fever, chills, hectic; left leg laid open by incision along the course of the fibula, and whole of that bone removed from the malleolus upward. Abscess in the left ham opened by free incision; treated by drainage by means of tent. Knee, left leg, and thigh put in plaster to immobilize left knee. Took Trommer's extract of malt, tablespoonful every three hours. Wound in right leg healed promptly; fever disappeared; abscess in left thigh healed, and knee joint healed by ankylosis in two months after treatment began.

CASE V.—German boy, aged nine years; residence, Lenawee County, Mich.; good general health; was lost in woods over night while searching for cattle; fall of snow same night. Boots were ragged; feet suffered terribly from frost. Came under my

treatment three weeks after the exposure; had been sick ever since; fever and chills; sinus had opened about the left heel; foot and ankle swollen and oedematous; probe showed the os calcis carious and necrosed. Incision across the heel below the insertion of the tendo Achillis; os calcis removed with forceps; wound washed daily with weak carbolic-acid solution. Took teaspoonful of extract of malt every three hours. Cured in four months, but foot not of much use.

These cases occurred so long ago that plenty of time has elapsed for return of the disease if the cures had not been perfect. They are sufficient to show the value of the treatment employed. Other cases have occurred since and have recovered. Many other cases are still under treatment and will recover.

I attribute the good results in the cases mentioned fully as much to the artificial digestion of starchy foods craved by these patients as to the operative methods employed, and believe that in many instances the cases would have progressed to the same happy ending had the rigid attention to the diet only been employed, but more time would have been necessary.

## Correspondence.

### LETTER FROM PARIS.

*M. Budin on Haemorrhoids during Pregnancy.—The Use of Chloroform in Obstetrics.—The Employment of Drainage in Large Surgical Wounds.—Caffeine as a Tonic.*

PARIS, May 30, 1889.

M. BUDIN has just published a handsome volume of his clinical lectures on obstetrics\* that met with such success when the author was in charge of the *Clinique d'accouchements*. The opening lecture details the new method of teaching obstetrics, which was devised and first put in force by Professor Budin. This system I referred to at the time, and I can now say that it has met with wonderful success. It is difficult to pick out the most interesting parts of a work that has so much important matter in it, but the lecture on haemorrhoids during pregnancy, and the one on the use of chloroform in obstetrics, present practical points that will be of interest to the general practitioner. As to the first, M. Budin showed a case of a woman who, up to that confinement, had had no varicose veins or haemorrhoids, but on this occasion a large haemorrhoidal tumor persisted after the expulsion of the foetus. The next day the patient was very ill with pain, that had prevented her sleeping all the night before, and, on examination, there was seen a mass of piles as large as a small orange. A pomade of vaseline and cocaine (one to twenty) was ordered to be applied, and a purgative (sulphate of sodium) was given, but the next day the patient was as bad as ever. Reductiou was then made under the influence of a few inhalations of chloroform; all pain seemed to leave the patient at once, and, the sphincter ceasing to contract, the tumor disappeared very rapidly under slight pressure. Afterward a cotton tampon, covered with vaseline and iodoform, was applied, and the case ended satisfactorily. The important fact brought out by this observation is that there is a complete analgesia in painful piles under extremely small doses of chloroform. The patient was conscious all the time, and felt no pain during the reduction. Haemorrhoids

\* "Leçons de clinique obstétricale," par M. Budin, professeur agrégé à la Faculté de médecine de Paris.

have been considered frequent during pregnancy by some authors, while others deny their presence; it is probable that this divergence of opinion arises from the class of patients under observation. M. Budin found only eighteen cases in some three hundred women at the Maternity, but in private practice the number is much greater, owing, no doubt, to the fact that the hygienic conditions are different. The better class of people follow a sedentary course of life during pregnancy, at least in the last months, and they also partake of a rich form of alimentation, so that there is a predisposition in their cases that does not exist in the laboring classes who are confined in the hospitals. The direct cause of haemorrhoids exists in the increase of volume of the uterus, which acts by compression on the rectal veins; besides this, there is a vascular tension in the organs of the pelvic region which is much increased during pregnancy, and the ano-rectal veins permit of easy dilatation through this extra fluxion.

Constipation then is also usual, and the consequent distension of the rectal ampulla irritates the mucous membrane and causes increased effort during defecation. As to the symptoms and complications, they are the same as in any haemorrhoidal cases, and the diagnosis of vegetations is not difficult, owing to the bright-red color of the latter. It is essential to remember that haemorrhage may occur from internal piles during pregnancy, and not to mistake it for some other and more serious bleeding. M. Budin gives Tarnier's method\* of turning the rectal mucous membrane inside out in such cases, and it is the most certain way of avoiding a mistake in diagnosis. It is practiced as follows: The index finger is passed into the vagina along the posterior wall, and when it has gone beyond the anal sphincter it is turned forward, like a hook, and continuous pressure is made from above downward on the rectal membrane until it is turned inside out and appears at the anus little by little; then, if there is an internal pile, a smaller or larger black tumor will be seen on the membrane. (It need hardly be said that the finger nail must be cut close before doing this operation.) As to treatment, M. Budin says that one should not fear to purge pregnant women and to advise moderate exercise and baths; but there is a difference of opinion as to the kind of evacuant to be used. Tarnier and others think well of castor-oil, but Fordyce Barker accuses it of causing irritation of the rectum and congestion of the pelvic organs. M. Budin finds that sulphate of sodium (in three- to six-drachm doses) acts very well. Leeches are not applied now to haemorrhoids, as it is feared that they may open the door to infection. All such patients should use lotions of water for cleanliness, as the use of paper after defecation may bring about haemorrhage by rubbing too hard and irritating the piles. This small hygienic point is well known to the natives of India, who go out into the fields and proceed after the directions of that great hygienist Moses, who instructed his people to go into the fields, dig a hole, and after covering it over, to wash the part. The Indian natives can be seen to this day carrying a small bowl of water with them on such occasions.

In regard to the use of chloroform in obstetrics, M. Budin gives numerous cases to prove that labor pain can be lessened by quite small doses of chloroform in most cases. It is given here in the manner called "*Queen's chloroforming*"; that is to say, just enough to dull sensibility. In a few cases, however, it is necessary to proceed to complete anaesthesia, which does not prevent labor going on to a successful issue. The principal indication for the use of chloroform in labor is found in extreme pain. Often it is only during the period of expulsion that it is needed, but when the pains are intense during dilatation it

may also be used. Rigidity of the os uteri is an important indication. There is an extraordinary degree of tolerance in parutient women for chloroform, so that the contra-indications are extremely few.

The question of suppression of drainage in large surgical wounds, and that of washing out the same, has been before the *Société de chirurgie* for several weeks, and at first thought the idea of giving up drainage seems a backward step. M. Nicaise said he had remarked that the washing out of large wounds favored exudation and retarded cicatrization, so that he had reduced the number of washings and contented himself with drying out the wound and putting in a drain which he could take out on the second day. He would not say as yet suppress the drains, but reduce the washing out and thus do away with the need of much draining. M. Kirmisson seemed to think that the use of drains had been abused, but that there should be defined and regular rules laid down for their use. Whenever the tissues could be brought in close contact by the dressings used there was no need of putting in a drain, but in vast wounds covering a great surface they were needed. M. Terrier thought that to drain or not to drain depended on two important points. The first was as to whether the tissues cut were healthy or not; if not, then drains must be used, and where there was considerable effusion to be feared, they should be used. M. Jules Bœckel (of Strassburg) said that he had first of all used a drain one day only, and then had given them up altogether, and at the present moment he *considered them as a surgical error*. He then gave details of thirty-three grave successful surgical operations in which he had not used drainage. These operations had been castrations, amputations of the limbs and of the cancerous breast, resection of the knee, etc. M. Bœckel related the details of some extensive operations for secondary cancer where he had had to remove the axillary ganglions and do an osteotomy of the clavicle, and yet the wounds had healed without drains and with his single dressing in a week. He depended on perfect antiseptic dressings and careful washing of instruments, with drying the wounds with iodoform gauze, and a small number of ligatures. The dressing was made to act by compression.

Dr. Henri Huchard has some good observations to present on the use of caffeine as a tonic or excitant in adynamic states. He considers it much superior to ether, which may be more exciting but is much less tonic in its action. The diuretic action of caffeine is now admitted by everybody, but its cardiac action is still contested. One point in the use of caffeine in adynamic states is that it can be given in considerable quantities without danger. In one case of extreme weakness (with from forty to fifty stools a day) as many as ninety-five hypodermatic injections of caffeine were given in a month. Dr. Huchard uses these injections with great freedom in typhoid fever at the Bichat Hospital, as well as in cases of serous pneumonia, and reports a number of cures in very grave cases. In experiments that M. Huchard made on animals, he found that the drug acted on the nervous system, and Semmola (of Naples) states that its principal action is on the medulla oblongata. In any case two important facts are evolved from Huchard's experiments: First, that caffeine has a remarkable efficacy in large hypodermatic injections in all adynamic cases. Secondly, it can be given in large doses without danger. M. Huchard employs the following formulas: Rx Caffeine, 2 grammes; benzoate of sodium, 3 grammes; and distilled water, 6 grammes. The solution must be made while hot. Each syringeful contains 20 centigrammes of caffeine. Sig.: Inject 6 to 10 syringefuls *per diem*. The second formula is: Caffeine, 4 grammes; salicylate of sodium, 3 grammes; distilled water, 5 grammes. Here the syringe contains 40 centigrammes of caffeine, and from four to five injections are given each day.

FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JULY 27, 1889.

THE FUNCTION OF THE RENAL GLOMERULI.

In his "Lectures on Important Symptoms," in treating of albuminuria, Professor Grainger Stewart considers the glomeruli of the kidney as mere filters, leaving out of consideration the possibility that their epithelium may be of a secretory nature. In a recent thesis on "The Functions of the Glomeruli of the Kidneys; a Contribution to the Study of Albuminuria," Mr. J. G. Adami, demonstrator of pathology in the University of Cambridge, discusses the various theories of renal activity at some length, especially with reference to the part played by the glomeruli.

The mechanical theory, based upon the researches of Ludwig and his school, broke down when Bowman, by injecting sulphindigotate of sodium, demonstrated the passage of substances through the cells of the tubuli contorti, and showed that these cells, instead of absorbing, excreted into the lumen of the tubules. Notwithstanding this, there are still able men that hold, with Professor Grainger Stewart, that the general blood pressure is the determining factor in the production of the fluid part of the urine. Adami shows, however ("Practitioner," April, 1889), that blood pressure plays a secondary rôle. This becomes evident, says Adami, when we study the cases in which, the general arterial pressure remaining constant, the outflow through the renal veins is obstructed. Ludwig pointed out, a quarter of a century ago, that narrowing or temporary closure of the renal veins was accompanied by a rapid slowing or stoppage of the flow of urine, notwithstanding the undiminished general arterial pressure, which is accompanied by increased pressure in the glomerular loops. Ludwig's explanation of this, that the dilated capillaries so pressed upon the tubules as to constrict them, close their lumen, and prevent any passage through them, was combated by Heidenhain, who propounded the theory that it was the rate of flow through the glomeruli, rather than the blood pressure, that governed the passage of water through the kidney. This theory, however, does not imply that the blood pressure is not a factor in the process, and the recent work of Paneth has confirmed and established Heidenhain's contention. And Munk cites experiments to show that the rate of blood flow, and not simply the blood pressure, determines the glomerular excretion, though he did not in his experiments entirely eliminate the factor of blood pressure.

It is now generally conceded by physiologists that it is the velocity of the flow through the glomeruli, and not solely the blood pressure in them, that governs the excretion of the fluid of the urine. This being admitted, the question now arises: What is the nature of this excretion? Is it simply a process of

filtration, or is it more of a process of secretion? These questions are of great importance in the interpretation of albuminuria. Both Heidenhain and Cohnheim have insisted upon the secretory view, but Senator, Runeberg, and Grainger Stewart hold to the theory that the glomeruli act simply by transudation. Of course the composition of a secretion entirely precludes the idea that it is a filtrate, nor can a secretion be explained by the laws of filtration; its quality is determined by the specific characteristics of the gland cells. Given a membrane that, while the blood pressure remains constant, at one time permits and at another time prevents the passage of fluid from the blood, such membrane must have specific properties, too complex to be accounted for by the laws of a simple form of physical action. Senator's theory is that the fluid portion of the urine is derived in part from the glomeruli by transudation, and in part from the epithelium; and he considers that the cells of the tubules, like other cells, in secreting any substance always excrete with it a certain amount of watery fluid. Grainger Stewart thinks that we may hold with certainty that the water is mainly eliminated by filtration through the Malpighian bodies; but the urea and other urinary solids are not discharged by filtration, but by a secretive process performed by the cells of the tubules; and that along with this secretion, as in the case of other glands, a certain amount of watery fluid passes.

But the supporters of the filtration theory have a great obstacle to contend with; they must explain how it is that a filtrate from the albumin-containing blood serum is normally free, or almost entirely free, from albumin. If the capillary loops of the glomeruli with their epithelial covering form but a passive filtering membrane, then the loops must obey the same law as, and correspond in general action to, other animal membranes. All other transudations contain albumin, and fresh animal membranes, when used as filters, always allow the passage of albumin. Why does not the normal glomerular membrane permit the passage of albumin always in the normal state? Grainger Stewart himself admits that, even after considerable concentration, albumin is not to be discovered in what he rightly terms normal urine. It may be said that the cells of the tubules reabsorb the albumin transuded through the glomeruli. But Senator has shown that the cells of the tubuli, so far from absorbing, may actually excrete albumin under certain conditions. Grainger Stewart inclines to the opinion that "the blood pressure in the capillary loops, and the walls of these vessels with their epithelial coverings, are so balanced as to permit of the transudation of fluid, and yet completely to prevent the passage of albumin . . . and at all events we may hold with certainty that water is mainly eliminated by filtration through these structures."

There is certainly a definite blood pressure in the glomerular loops. But a high pressure does not prevent the passage of albumin through simple animal membranes. With a pressure below that which in the dog and in man is accompanied by a total cessation of urinary excretion, albumin continues to transude through membranes outside the body. Where, then, asks

Adami, occurs the balance of which Grainger Stewart speaks? If we say that such a comparison between dead and living membranes is unjust, we must acknowledge that the living membrane has some factor that the dead one has not; that the glomerular walls have specific properties and actions unaccounted for by the laws of filtration and transudation; in other words, we are on the verge of asserting that the glomerular epithelium may exercise a selective function; which is the position in which Stewart finds himself.

There are other grave objections to the filtration hypothesis. Runeberg has shown that, at a mean pressure of 73 mm. of mercury, as much as 95 per cent. of the albumin in solution may pass through an animal membrane; even at a pressure of 7.3 mm. there is still a high percentage. At the ordinary blood pressure of 120 to 150 mm. of mercury there should be no great diminution in the amount of albumin filtered. What is the fact? The piezo-acid test shows that in the normal state there is less than 0.00015 per cent. of albumin passed! According to Hammersten, normal blood serum contains 4.516 parts of serum albumin; so that, even if normal urine contained 0.2 instead of less than 0.00015 per cent. of albumin, the theory of urinary filtration is still at fault, even if we admit that the greater portion of the urinary fluid is excreted through the tubules. Again, says Adami, we know that blood serum contains large amounts of two proteins—serum albumin and serum globulin. Both transude through fresh animal membranes, and, serum globulin being the more diffusible of the two, it should appear in the urine in cases of albuminuria. The two proteins should be present together in the urine, and in fairly constant proportions. But such is by no means the case. The theory that glomerular activity is of the nature of simple filtration or transudation fails absolutely. We must consider the glomeruli as possessing functions of a selective or secretory nature, permitting the passage of some substances and preventing the passage of others. In favor of this view there are the following facts: The glomeruli are not solely blood capillaries; each capillary loop is covered with a fine membrane with a single layer of epithelium the cells of which must be considered as having active vital properties, one of which is contractility, as shown by Hedinger. The histology of the tubular epithelium, of which the glomerular epithelium is but a part or a continuation, shows that it is of a selective and secretory nature. Experimental physiology shows the same thing. The investigations of Afanassiew and Hunter in regard to haemoglobinuria confirm this view. Adami does not allege for the glomerular epithelium any synthetic power; his argument is that it has a selective power, active and not passive, producing a secretion and not a transudation.

What, then, are the factors that determine the appearance of albuminuria? It is admitted that albumin, when it appears in the urine, passes through the glomeruli. Senator's experiments seem to prove that some of the albumin has its origin in the uriniferous tubules, "and it is not improbable that in parenchymatous nephritis and in venous engorgement of the kidney a certain, and it may be a large, proportion of the albumin

originates from the affected cells of the tubuli." There is no denying that infinitesimal amounts of albumin may be present in normal urine. The absence of ascertainable quantities is probably due to the healthy state of the tubular cells and to the normal functional activity of the glomerular epithelium, which prevents the passage of albumin and globulin, provided they are not in the blood in excessive quantities. Aside from this excess, the amount of albumin passed is mainly determined by the state of the glomerular epithelium, which in a condition of lowered vitality permits the egress of a fluid more of the nature of a transudation; the lower the vitality of the epithelium, the more is the fluid passed of the nature of a filtration, the epithelium having to a certain extent lost its selective and controlling power. In this way the proteins of the blood serum sink to a percentage below the normal. Reasoning on these lines, we can, says Adami, explain the graver forms of Bright's disease, and also many cases of transient albuminuria. The factors that, singly or in combination, temporarily lessen the rate of blood flow through the glomeruli, and thus cause imperfect nutrition of their delicate walls, or directly lead to imperfect nutrition and lowered vitality, will probably explain most cases of transient albuminuria, febrile, toxic, puerperal, and functional.

### MINOR PARAGRAPHS.

#### THE EXTERMINATION OF HYDROPHOBIA IN ENGLAND.

In "Nature" for July 4th we find an account of a meeting at the Mansion House, London, held July 1st, to discuss the prevention of hydrophobia. The increase of rabies, on the one hand, and, on the other, the efforts of certain societies to resist the introduction of the Pasteurian methods into England, have caused this rally of the friends of Pasteur. Two letters, among others, were read at the meeting, written by Professor Huxley and M. Pasteur. Huxley's letter characterizes very pungently the opposition of the anti-vivisectionists as coming from a class of people "who prefer that men should suffer rather than rabbits and dogs." His opinion of the value of M. Pasteur's work is positive. He says: "Medicine, surgery, and hygiene have all been powerfully affected by the labors of Pasteur, which have culminated in his method of treating hydrophobic victims." The letter of M. Pasteur, dated as late as June 27th, was read by Sir Henry Roseoe, M.P. It is interesting as giving his latest figures, amounting to nearly seven thousand patients treated. The number, to June 1st, was 6,950, and the deaths were 71. In short, the general mortality has been 1 per cent., but, if an exception is made of the cases in which hydrophobia had "burst out" before the curative process could be complete, the general mortality is reduced to 0.68 per cent. M. Pasteur assures the English people that they can "stamp out" rabies in their country if the proper measures, which are entirely feasible, are carried out, and he cites to them the fact that Norway, Sweden, and Australia are countries where the disease is not known.

#### THE ANTI-PARASITIC TREATMENT OF CHOLERA.

HERR LOEWENTHAL has been at work at the Cornil laboratory in Paris, studying the relations of salol to the bacilli of cholera. He is convinced that he has found the specific antiparasite for that disease, and he has so far convinced the French Govern-

ment that they have issued to him a remarkable commission to enable him to pursue, with dignity and independence, his inquiries at Tonquin, where the disease exists. His commission gives him high rank in the regular French service, without exacting any alienation of his allegiance to the country of his birth. The necessary funds have been appropriated by the Government to pay the expenses of these researches. Herr Loewenthal regards salol as perfectly harmless—that is, as much as five drachms may be taken in a day. In experimenting upon himself, he has taken as much as seventy-five grains night and morning. The morning dose, taken fasting, caused a passing vertigo only, while the evening dose produced no appreciable symptoms. He proposes to use thirty grains three times a day as a prophylactic in the case of those exposed. For a patient showing the first symptoms of cholera he would begin, according to an abstract in the "Medical News," with sixty grains for the first dose, and then follow with fifteen grains hourly.

#### FOREIGN STUDENTS AT VIENNA.

THE "Progrès médical" states that a society has been formed in Vienna to provide hospital accommodations for the students, medical and others, who fall ill. In May last, one sixth of the medical students at the University were foreigners, and one thirtieth were Americans; or, more exactly, of 3,185 of all nations, 530 were foreigners and 105 cisatlantic students. The "Vienna Weekly News," printed in English, for the benefit of the Americans and others conversant with that tongue, has opened an inquiry office, near the General Hospital, for the free use of English-speaking students seeking information as to lodgings, lectures, and other matters.

#### FAITHFUL SERVICES RECOGNIZED.

DR. JAMES F. HARTIGAN, of Washington, has been appointed to an important Austrian consulate, and it is reported that the office has been given to him, in preference to many others, on account of an impairment of his health incurred in governmental service. While the fever prevailed in Florida, he undertook some special medical duty in that State for one of the departments at Washington, in the course of which he became ill and has been disqualified for active practice ever since. It is pleasing to make mention of this, both as a preferment won by faithful medical work and as an unusual and honorable act on the part of the authorities.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 23, 1889:

DISEASES.	Week ending July 16.		Week ending July 23.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	23	0	24	6
Scarlet fever.....	50	9	41	11
Cerebro-spinal meningitis....	1	1	3	3
Measles.....	55	3	67	5
Diphtheria.....	76	26	98	23

**The White Mountains Medical Society** will hold its semi-annual meeting at Hanover, N. H., on the 1st and 2d of August, in conjunction with the Connecticut River Valley Medical Society and the White River Medical Society. Dr. G. W. McGregor will preside, and members of the faculty of Dartmouth Medical College will take part in the proceedings. The subjects announced are as follows: "The Radical Cure of

Hernia," by Dr. Conner; "Acute Glaucoma," by Dr. Webster; "Modern Surgical Methods of treating Obstructive Diseases of the Nose and Naso-pharynx," by Dr. Hooper; "The Symptoms and Treatment of Fibroids of the Uterus," by Dr. Mundé; "Antiseptic Obstetrics," by Dr. Parish; "The Mechanism of Insanity," by Dr. Cowles; and "Sulphonal," by Dr. Field. Clinics will be held by Dr. Conner, Dr. Webster, and Dr. Hooper.

**The College of Physicians and Surgeons.**—The new catalogue, which has just appeared, shows that the number of students in attendance last year was 701, a smaller number than usual. This decrease was due, very naturally, to the more rigid requirements of the new curriculum. Dr. James W. McLane is publicly announced as president of the college, but still retains the professorship of obstetrics. Dr. Richard J. Hall, professor of anatomy, has resigned and his place has been given to Dr. George S. Huntington, for some years demonstrator of anatomy. Dr. Charles T. Parker is made assistant demonstrator of anatomy. The incoming class already numbers 220, a hundred more than entered last year.

**Recent Deaths.**—Dr. Alvin Ava Austin, of the navy, has died at New London, Conn., after an illness of two weeks. He was a native of Missouri, studied medicine at the Jefferson College, Philadelphia, and graduated there in 1873. In 1874 he was commissioned assistant surgeon, and five years later was promoted one grade higher. He was ordered to the New London station in 1879, and of late had been on duty on the steamer Gedney in the Coast Survey. His home was in Philadelphia.

Dr. Harris H. Beecher, of Norwich, N. Y., died on July 14th, at the age of sixty-nine years. He was a native of Coventry, N. Y., and a graduate, in 1847, from the Castleton Medical College. He was a member and officer of the Chenango County society. He was assistant surgeon, and afterward historian, of the 104th Regiment. During his service in the war he received a disabling injury. He was a platform speaker of more than local repute, and was a member of the Assembly in 1874.

Dr. Edwin De Witt Nooney, of Stratford, Conn., died on the 18th inst. He was forty years of age. He was an alumnus of the College of Physicians and Surgeons, in the class of 1871. He was medical examiner for his district.

**The "Medical and Surgical College of the State of New Jersey."**—An officer of this institution, referring to our article entitled "The Transplantation of a Medical Fraud," published in the issue for July 6th, has written us a letter in which he states that his institution has no connection with the late "United States Medical College" of New York, and never had any; and that it was chartered by the New Jersey Legislature in 1870.

**The late Dr. Stephen Wickes.**—At a special meeting of the staff of the Orange Memorial Hospital, held on Tuesday, July 9, 1889, all the members being present, the following action was taken upon the death of Dr. Stephen Wickes:

*Whereas*, In His infinite wisdom, our Heavenly Father has taken to himself our beloved colleague, Dr. Stephen Wickes,

*Resolved*, That this staff has lost a faithful co-laborer. He was zealous and devoted to all the duties pertaining to his office as a medical attendant of this institution. He was an earnest Christian gentleman, whose character and disposition were molded by Christian grace. He was modest, retiring and considerate, charitable, and always ready to give of his time and strength to those in need. He was beloved by those to whom he ministered, and by those with whom he was associated in relieving the sufferings of the sick. Words do not truly express the veneration, respect, and esteem which were accorded to our

deceased friend and professional brother by all who knew him, within medical circles and by the general community. His literary labors have resulted in the production of much valuable matter, especially of a historical nature, that will serve as a memorial of a useful life. To his family we offer our heartfelt sympathy in their great sorrow, but they still will share with us a joy and comfort that Dr. Wickes was ripe in years, rich in honors, and sure of reward for a helpful and blameless life.

[Signed.]                    T. R. CHAMBERS,  
                                T. W. HARVEY, } Committee.  
                                GEORGE BAYLES,

**The American Rhinological Association** will hold its seventh annual meeting in Chicago, on the 28th, 29th, and 30th of August. A committee will report on the relation of nasal inflammations to affections of the mind.

**Change of Address.**—Dr. Horace T. Hanks, to No. 766 Madison Avenue.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 14 to July 20, 1889:*

BRECHEMIN, LOUIS, Captain and Assistant Surgeon. By Par. 1, S. O. 159, A. G. O., July 12, 1889, ordered to Illinois National Guard, near Springfield, Illinois, during remaining portion of encampment.

BALL, R. R., Lieutenant and Assistant Surgeon, is granted leave of absence for fifteen days. Par. 3, S. O. 87, Department of the Missouri, July 9, 1889.

BURTON, H. G., Captain and Assistant Surgeon. By direction of the Secretary of War, the extension of leave of absence on surgeon's certificate of disability granted in S. O. 22, January 26, 1889, from this office, is further extended two months on account of sickness. Par. 1, S. O. 162, A. G. O., July 16, 1889.

INES, F. J., Assistant Surgeon, now at Fort Lyon, California, will proceed to camp near Oklahoma City, Indian Territory, and report to the commanding officer for duty, relieving Captain W. C. Gorgas, Assistant Surgeon, who, when so relieved, is authorized to avail himself of the leave of absence granted him in Par. 2, S. O. 84, c. s., Department of the Missouri. Par. 1, S. O. 87, Department of the Missouri, July 9, 1889.

#### Letters to the Editor.

##### DR. TRACY'S MORTALITY STATISTICS.

NEW YORK, July 23, 1889.

To the Editor of the *New York Medical Journal*:

SIR: I have waited, before answering your somewhat off-hand criticism of my report on death-rates for 1888, until I should be able to send you a pamphlet copy of the report, which I inclose. In his airy condemnation of the tables as worthless, your critic shows that he has not read the text of the report, and does not know what the figures purport to represent. There are four ways in which they may be incorrect:

1. The census of the tenements may have been incorrectly taken. But the police officers inspect each tenement from top

to bottom twice a year. During the last inspection they also took the census. As each man was obliged to visit only five or six houses a day, to complete his district within the given time, the added duty was not onerous, and there is no reason to suppose that the figures obtained were not as accurate as those taken by the enumerators of the United States census. Moreover, in several cases, taken at random, other officers or clerks were sent to verify the census of houses, and the second report practically tallied with the first. When it did not there was found to be a good reason for it—a family had moved out or in, or some one had died or been born, or the like. In this way the population of 32,390 tenements was obtained, by street and number, comprising 1,093,701 persons. Can your critic suggest any way of getting a more accurate census?

2. The number of deaths given may not be correct. We have reason to believe that all the deaths in the city are reported at this office. No dead body, too large to be carried in a cigar-box, can be taken out of the city, or buried in any cemetery within it, without our knowledge. Each death was copied on a small card, giving the street and number, cause of death, age, date of death, and the number of the doctor's certificate. These cards are filed alphabetically and numerically, so that the deaths during the year in any house in the city can be ascertained within a few seconds. Deaths in institutions, when the previous residence of the patient was given on the certificate, were referred to such residence in the card catalogue. Can your critic suggest any more accurate method of determining the number of deaths in each house?

3. The total population of the city may be underestimated. I have made the estimate in the only way I know of that promises to give a result which is not wholly guesswork, but has a foundation to start from. The method is stated in the report. Can your critic suggest one which is likely to give a more accurate result? If he can, I should be glad to adopt it.

4. The figures from which the tables are made may have been added incorrectly. I used in all computations a mechanical adder of unvarying accuracy, and the results all correspond.

The work of compilation was enormous. Every house was taken singly, the deaths and population combined carefully by myself alone, in lack of sufficient clerical assistance, and it took me nearly six months to do it. Both the census, house by house, and the deaths, each one certified, are in such shape that any skeptic who chooses to do so can verify them for himself in the case of any particular house or houses. Under these circumstances I must plead, in my own justification, that any critic, instead of dismissing the tables with a wave of the hand, ought to show what precautions have been neglected in their preparation.

The figures quoted by your critic are not contained in the body of the report, but in a sort of addendum, thrown in with a deprecatory remark, as slightly corroborative of the report. Perhaps it had better have been left out, but not for the reason your critic suggests, for that is based upon an entire misunderstanding of the figures. He says:

	1869.	1888.
Total population .....	894,419	1,526,081
Tenement " .....	468,492	1,093,701
Other " .....	425,927	432,380

showing that while the tenement population has increased more than 600,000 in the twenty years, the population of the dwellings has increased only 6,500, which is preposterous. And so it is.

If he had read a few lines below, he would have seen that in 1869 the tenement-house was one containing four or more families, and in 1888 one with three or more—*i. e.*, the tene-

ment-house population in 1888 includes all persons living in houses occupied by three families, which were included in the other part of the population in 1869. The exact population of these houses I can not give just now, but it probably constitutes the greater part of the class included in my tables as living in houses containing less than twenty tenants. These amounted to 121,815, a certain proportion of which, say 100,000, is to be deducted from one class and added to the other in order to make the comparison your critic desires to make. This would give, instead of his figures, a tenement population in 1888 of 993,701, and a dwelling population of 532,380, or, as compared with 1869, an increase of 535,209 in the tenements and of 106,453 in other dwellings, which is probably not far from the true proportion.

ROGER S. TRACY, M. D.

\* \* Whether or not our remarks on Dr. Tracy's figures were "offhand" and "airy," our readers can determine for themselves by reference to the article, which was published in our issue for June 29th, on page 718. The article opened with the intimation that it dealt with Dr. Tracy's statistics "as given in the newspapers." So long as the results of scientific investigations are given to the newspapers in advance of their publication in a complete form, the inadequate versions given in the newspapers will necessarily be taken as the basis of criticism.

#### A GUNSHOT WOUND DISGUISED BY A STAB.

BRADFORD, PA., July 12, 1889.

To the Editor of the New York Medical Journal:

SIR: An interesting case of murder has just occurred here. I wish to call your attention to it, to see if it has a parallel. A dissolute woman shot her lover in a drunken quarrel. The ball (.32 caliber) entered the left thigh at the middle of Scarpa's triangle; the man was sitting in a chair about ten feet from her at the time. She was alone with him in the room for some little time after, and, evidently to cover the shot wound, stabbed him to the bone. The external wound presented nothing different in appearance from a knife thrust, and the first autopsy revealed nothing more. During the progress of the coroner's investigation she changed her first story—that he had stabbed himself—stating that she had shot him in self defense, and afterward "gone after" the ball with a case-knife, to get it out and save him. A second examination resulted in finding the ball.

JAMES JOHNSTON, M. D.

#### Proceedings of Societies.

##### MASSACHUSETTS MEDICAL SOCIETY.

*One Hundred and Eighth Annual Meeting, held at Boston, Tuesday, Wednesday, and Thursday, June 11, 12, and 13, 1889.*

The President, Dr. DAVID W. CHEEVER, of Boston, in the Chair.

**Aseptic and Antiseptic Surgery.**—Dr. H. L. BURRILL, of Boston, read a paper on this subject, in the Section in Surgery, in which, remarking upon the great value which the new science of bacteriology was destined to have with reference to the department of practical surgery, he proceeded to describe in detail a number of experiments conducted by himself and Grenville R. Tucker, which were intended to show by what methods and by the use of what chemical agents the various instruments and the separate steps in operative surgery might be rendered practically aseptic.

1. As to the preparation of the room for an operation, he said that all movable objects should be removed; then the room should be carefully swept and dusted, and the walls sponged over with a sublimate solution (1 to 1,000). In emergency cases nothing should be disturbed.

2. As to the toilet of the surgeon and his assistants, their hands should be washed according to the usual methods—viz., soap, nail-brush, etc., then immersed in ether, then in corrosive-sublimate solution (1 to 1,000).

3. As to the preparation of the operative field, it should be shaved if necessary, scrubbed with soap and water, and then washed with ether and corrosive sublimate (1 to 1,000).

4. As to the sterilization of instruments, Dr. Burrill concluded that of all methods, that of baking the instruments in an oven at a temperature of from 140° to 160° C. was the best. A higher temperature injured them. Needles should be subjected to a similar process.

5. As to the disinfection of sponges, steaming caused great shrinking; the most satisfactory method, attaining at the same time to well-nigh perfect sterilization, consisted in washing sponges in running water again and again, then placing them in a solution of permanganate of potassium for twelve hours, then washing them in oxalic acid, then washing, then placing in carbolic acid (1 to 40) in jars, and storing for future use.

6. As to ligatures, they should be taken from original bottles, wound upon glass spools, and placed in a solution of corrosive sublimate (1 to 1,000) in a bottle specially designed by Mr. Tucker.

7. As to irrigation, corrosive sublimate (1 to 4,000) was most satisfactory.

8. As to the dressings, to render them aseptic they should be taken in the shape of bleached gauze, and subjected to a temperature of 150° C., then saturated with a ten-per-cent. solution of glycerin, then dried. Thus treated, they were possessed of marked absorbent properties, excelling in this respect all other dressings.

In conclusion, the author urged the importance of putting these methods into practice, and, though he admitted the difficulty of absolute sterilization, yet it was possible to approach very closely thereto. Every surgeon, he thought, should operate with thoroughly cleansed hands, with thoroughly cleansed instruments, upon a thoroughly cleansed patient.

In the discussion, Dr. J. C. WARREN, of Boston, remarked upon the ill effects oftentimes arising from a too free use of the so-called germicides in efforts to procure asepsis. The safety of drugs in this respect was inversely proportional to their power as germicides. Boric acid, for instance, was perfectly safe, yet had no antiseptic action whatever, as it was used in ordinary wounds. He could not advise too strongly against a too lavish use of antiseptics in the dressing of wounds. He cited a case of carbolic-acid poisoning in a patient suffering from slight burns of the hands and face, which had been treated with carbonized vaseline (1 to 40). Since having a patient suffer from high temperature, insomnia, and then delirium, because of a too generous use of iodoform in powder after an operation for proctocele, he had ceased using it, preferring the gauze instead. He did not mean to convey the idea that he looked with disfavor upon antisepsis. He would always use germicides with a view of equalizing the equation of personal cleanliness, and of counteracting the general tendency to dirt in patients. Something more was needed than simple soap and water.

The speaker referred to the series of experiments by Watson Cheyne, which tended to prove that different portions of the body were possessed of different powers of resistance to the influence of infection by bacteria and micrococci: for example, the peritoneal cavity was remarkably tolerant of the action of

bacteria or septic materials, and did this not explain the success attending surgeons in their operations in this region, where no antiseptic precautions whatever were taken? Other places more cellular in structure were less tolerant, and disregard in taking antiseptic precautions would show correspondingly bad results in operations.

Dr. A. T. CABOT, of Boston, remarked that the chief use to be made of antiseptics was in the way of preparation—preparation of the hands, sponges, instruments, and surface to be operated on. This being done, we could proceed much as surgeons used to—with care that the instruments did not come in contact with objects not previously disinfected. He said that the two agents most promotive of putrefaction, and thus of poor results in operations, were (1) moisture and (2) heat. The former could be largely done away with by proper attention in applying the dressings. All blood should be scrupulously sponged out before closing the wound; a drainage-tube should be properly introduced, and then firm pressure made and kept up while the outside bandages were being arranged, and in this manner prevent the filling up of the wound with blood and serum. It was often desirable to sew the deeper parts of a wound together, so that healing by first intention might result. As to the use of iodoform, boric-acid powder, etc., he believed that the explanation of their favorable action on wounds and suppurating surfaces was to be found in their drying qualities. Dressings should always be dry and have great absorbent power. When impregnated with these powders, they possessed these qualities to a marked degree, and so kept the wound dry and promoted rapid healing. If he were compelled to abandon either antiseptic washes or dry dressings, he would unhesitatingly give up the former.

**Antipyretics.**—In the Section in Medicine, Dr. E. N. WINTERTIER, of Boston, read a paper on this subject, which began with a definition of normal temperature and allusion to the methods by which it was maintained. It was conceded that heat production and heat dispersion, occurring under the controlling influence of the thermotaxic mechanism, determined a condition which in health prevailed, and was called *normal temperature*. The subjects of the various papers which had of late appeared on the topic of fever were next brought up, and it was maintained that it was needful to set forth the prevailing views concerning the nature and origin of fever before an intelligent discussion could be held on the subject of the treatment of fever. This the reader proceeded to do, and cited various authorities to prove that bacteriology, as well as experimental pathology and physiology, were all agreed as to the nervous theory or doctrine deserving all the prominence that it had obtained. He defined fever as a symptom complex in which disordered heat occupied the dominant position and was necessarily the essential feature, and associated therewith, so intimately as to be a part of the process, were the derangements in the functions of the circulatory, respiratory, muscular, digestive, glandular, and other structures.

Papers by Dr. McAllister, Dr. Maelegan, Dr. Anstis Flint, Professor Welch, Professor H. C. Wood, and prominent physicians of the German school, were summarized, and a synopsis was given to substantiate the prevailing beliefs as to the nervous origin of fever.

Antipyresis was defined to include all measures taken to reduce temperature and to resist the noxious influence of the various infections and toxic fever-producing agents. Antipyretics were divided into antifebrile and antithermic remedies.

**Antifebriles** included the false antipyretics so called which acted on the vaso-motor system, and all measures which were conducive to the abstraction of heat and at the same time to the imparting of tone to the nervous system or to the ener-

gizing nerve centers. Under the head of antithermies were classified the modern synthetical compounds which belonged to the aromatics. The remaining portion of the paper was devoted to the discussion of the qualities and properties of those antithermies whose physiological, therapeutic, and toxicological attributes had been, by careful experiment both at the bedside and in the laboratory, proved to be of value in controlling high temperatures. They included antipyrine, acetanilide, phenacetine, and methacetine or pyrodine. The most valuable feature of the whole paper was the phenomenal showing by the author of the powerful influence in the control of infectious diseases of the reduction of temperature in the energizing nerve centers through the means of cold baths as antifebrile agents. A careful review of the various papers that had been written on the subject, particularly of the results obtained by Brand, of Stettin, and his followers, both German and French, showed that results of treatment by all previous and present methods for the control of infectious disease (chiefly typhoid) and the reduction of the mortality rate were insignificant as compared with the results obtained by cold baths and antifebrile remedies. Statistics furnished by Ziemssen, by Brand himself, by Glenard, and the summary recently published by Baruch, were collated and reduced to tables to likewise show that no other method had ever shown any results approaching this in the reduction of the mortality rate. The paper was brought to a close in giving utterance to the wish that this method should find more frequent use, and that we should no longer ignore its claims to our approval. The paper was discussed by Dr. F. C. SHATTUCK and Dr. F. H. WILLIAMS, of Boston.

**On Pain in the Small of the Back and Hips.**—Dr. J. A. JEFFRIES, of Boston, read a paper on this subject before the general session of the society.

**Modern Methods in Teaching Clinical Obstetrics.**—Dr. EDWARD REYNOLDS, of Boston, read a paper on this subject in which he spoke of the larger amount of material now at the command of the department of obstetrics at the Harvard Medical School, and said that systematization now enabled them to make the fullest use of the same for clinical teaching, and thus the student was now enabled to enter practice better equipped than ever before for his work. He proceeded to give in detail the steps in the management of patients from the time of their first placing themselves in charge till their subsequent discharge, and mentioned the duties which thereby devolved upon the students detailed to manage the cases. In conclusion, he gave a summary of the cases of persons treated for the past year as out-patients at their homes, and surrounded as they were by the most unfavorable sanitary conditions, and showed how the mortality rate had been less than one tenth of one per cent.

**The Treatment of Malignant Disease by Escharotics.**—Dr. J. C. MUNRO read a paper with this title in which he emphasized the fact that only in a small number of cases was treatment by escharotics advisable, and then only when treatment with the knife or sharp spoon was impossible. Next to the actual cautery, he considered nitric acid to be the strongest of caustics, then sulphuric, hydrochloric, glacial acetic, chromic, and carbolic acids in the order named. The two most convenient forms of escharotics were chloride of zinc and arsenic in the form of pastes; the latter to be preferred, since it was far less painful. The best paste was one consisting of acacia, one part; arsenic, two parts. This should be applied over the diseased area for about three days—*i.e.*, till a line of demarcation formed—then a poultice should be applied. The author then gave a short review of methods of treatment by caustics, by famous men of more or less questionable repute, from the earliest recorded times down to our own day. He brought his paper to a close by earnestly advocating an intelligent

and skillful use of escharotics, since they were oftentimes eminently indicated, and their use was attended by an extremely small risk to life. He knew that a prejudice existed against their use, partly due to their being employed by quacks, but also to a lack of familiarity in employing them; but should we not seek to rescue patients who, from fear of the knife, fell into the hands of quacks? Should we not, to this end, strive to make their treatment our own?

**The Annual Address** was delivered by Dr. HENRY P. WALCOTT, who spoke of the little attention which was paid in Massachusetts to matters relative to the practice of medicine, so far, at least, as the prevention of disease was concerned. He called attention to the necessity of a pure water supply and urged the thorough policing of the whole water-shed. He referred to the possible contamination of the milk supply, also to the need of further investigation as to how far it was possible that milk could serve as a vehicle of contagion from the cow to man through the agency of the tubercle bacillus discovered by Koch. He further touched upon the methods of disposal of sewage, and the possibility of sterilization of the products and their use upon lands. In the province of prevention of infectious diseases, he asked whether, since the discoveries by Pasteur, there was not here a very attractive field for original research, and was it not with boards of health alone that such investigations were possible? He concluded by referring to the immense progress made in the last twenty years as to our knowledge of diseases and the means of their prevention. There was still much need of expert work in many departments for the protection of health, and physicians were alone the agents to be employed. We should educate the people in sanitary matters in many directions. We had arrived at a stage in our progress where our knowledge of certain conditions essential to the state of health should become the property of all, and we should heartily join our forces with those of the city and State to further the dissemination of such knowledge.

#### NEW YORK ACADEMY OF MEDICINE.

*Meeting of June 6, 1889.*

The President, Dr. ALFRED L. LOOMIS, in the Chair.

**On the Dangers of the Spread of Leprosy in the United States.**—Dr. P. A. MORROW read a paper on this subject (see page 85).

Dr. C. W. ALLEN remarked that, since listening to this paper and looking at the illustrations, he was more convinced than ever of the desirability of such legislation as should tend to prevent the further spread of this disease. The whole number of cases in this country two years ago had been estimated to be one hundred and fifty. He thought this number now far too small. Dr. Morrow had, in his paper, reported forty-two cases in New Orleans alone. So long as a single leper existed in the United States, so long did the speaker consider the possibility of dissemination of this disease an imminent one.

Dr. L. D. BULKLEY considered this the most important question that had ever come before the Academy. It was possible that the conditions of civilization might so change as to lessen the liability to the disease, but he was certain that wherever the disease had been allowed freedom it had always spread. Formerly he had not feared the spreading of the disease, but latterly he had changed his views, till now he was keenly alive to such a danger. He thought the health authorities should be urged to make careful investigations and report upon the true and exact state of the disease in this country.

Dr. G. H. FOX doubted seriously whether leprosy had really increased in the United States. He admitted that the number

of cases had increased, but these were mostly imported ones, coming from the Sandwich Islands and the West Indies. He believed that liability to increase through contagion was very slight, for, although many lepers lived without restraint in crowded cities, yet there had never been an authentic case of contagion. There were surely other much more dangerous contagious diseases still flourishing among us without restraint, which ought to be first dealt with.

Dr. H. G. PIFFARD reminded the meeting that this very question had been discussed ten years previously, and that at that time a committee had been appointed by the Academy to investigate as to the true status of the disease. At that time they had found between forty and fifty lepers in the United States, chiefly in Louisiana, Wisconsin, Minnesota, and South Carolina, yet now in these same States their numbers had largely increased. He believed that the strictest segregation was necessary, for, wherever this method had been enforced, there had been a marked diminution; as a noted instance of this, Norway was cited. The general Government ought to prevent the entrance of lepers into this country by rigid enforcement of the quarantine laws; yet, once in, such lepers should be compelled by the separate State governments to enter lazarettos.

Dr. F. R. STURGIS did not think the danger an imminent one, and yet he was in favor of steps being taken for calling the attention of the proper authorities to it. This same question had occupied the attention of the Dermatological Society several years ago, and certainly the weight of evidence had then been in favor of contagion. There had always been a lack of evidence to prove this, but the case cited by Dr. Morrow was more valuable in substantiation thereof than the whole number of negative cases cited in support of the theory of non-contagion. He believed the early stage of the disease to be the more contagious. As to the presence of the bacillus as a cause of the disease, he was still a little skeptical. Perhaps, as in syphilis, the presence of this bacillus was adventitious, although many had maintained that it was the cause of that disease. Whatever the origin of leprosy might be, he was convinced of the importance of bringing to the notice of the national authorities the necessity of actively recognizing the possible danger of its increasing. In regard to the suggestion by a previous speaker that syphilis was equally dangerous to the public health, he did not think so, since syphilis was curable, while leprosy, though it may be alleviated by treatment, ended by killing its victim.

Dr. R. W. TAYLOR remarked that the facts presented by Dr. MORROW showed that there was a possible danger of leprosy becoming endemic in this country, and thus destructive to life. In the last fifteen years he had seen on the average from two to three cases a year at the Islands, and, although the patients slept and lived with others unrestrainedly, yet there had never been a known case of contagion. He was not inclined to disregard the danger, nor would he, on the other hand, exaggerate it, feeling convinced that the disease would not prove so terrible as some of the previous speakers thought. Legislation would surely and at the proper time correct the evil. His motto was that "Sufficient unto the day was the leprosy thereof."

Dr. MORROW closed the discussion by asserting that leprosy in the Sandwich Islands had developed under the existing conditions of civilization. The Hawaiian partook largely of animal food and lived under infinitely better conditions than the larger majority of the poorer classes in this country, and yet, under such improved sanitary conditions, the disease had advanced and attained to such fearful proportions. He had not read his paper with a view of inducing legislation on the subject, but only with the purpose of bringing clearly before the medical profession the true condition and status of the disease in Mexico and the Sandwich Islands. He thought, however, that if only

one hundred cases of any other infectious disease existed in the United States and could be stamped out, it would surely be done, and yet this was practically the position of leprosy and no action was taken to do so.

## Reports on the Progress of Medicine.

### OPHTHALMOLOGY.

BY CHARLES STEDMAN BULL, M. D.

**The Nature of Light-percipient Organs and of Light Perception and Color Perception.**—Gunn ("Roy. Lon. Ophth. Hosp. Rep." xii, 2) draws the following conclusions from the main facts regarding light-percipient organs: 1. All light-percipient cells are modifications of epithelial cells, or developed from the same embryonic layer which forms them. 2. The ends of these cells corresponding to the cuticle have generally cuticular structures formed in the shape of rods. 3. The opposite ends of these cells are either directly continued as nerve-fibers, or are connected with ganglion cells, and ultimately with nerve-fibers. 4. Pigment is practically always present, either in the light-percipient cells or in close connection with them. Exceptions exist where a tapetum is present and in the rare albino individuals having eyes of high types; but then non-pigmented cells always exist, which are evidently capable of performing similar functions to those of the pigmented cells, though in a minor degree. 5. All forms of vegetable and animal protoplasm sensitive to light are acted on by the shorter waves corresponding to the violet end of the spectrum, and the same holds good in a marked degree in the case of all those light-percipient cells as yet known to act to light. 6. The property of *phototaxis* is universally influential in the manner in which these cells arrange themselves and in the direction in which they contract on exposure. When the cell is free, this effect exhibits itself in free photoactive motion, while in the case of attached retinal cells it shows itself in contraction toward the incident light. 7. The pigment cells have the property of secreting chemical fluids according to their exposure to light and shade, and the pigment contained in them is doubtless of service as being light-absorbent, and thus aiding a rapid transformation of light-energy into protoplasmic action. 8. The result of the action of the secretion of the pigment cells on the segments of the light-percipient cells may be demonstrated by the electrical current produced. 9. The strength of this current depends upon two factors—viz., (a) The activity developed in the pigment cell under the action of light, and (b) the depth to which the cone is imbedded in it. 10. In the case of vertebrates this resultant current is greatest on exposure to yellow light. 11. Differences in the action thus produced, and consequently in the nerve-current transmitted to the visual center, are associated in our minds with sensations of differences in color. 12. In regard to the stationary rods, the action induced will probably depend upon the amount of destruction of retinal purple, and the consequent demand upon the pigment cell. As this action is known to depend more on intensity of wave-height than on wave-length, it is improbable that the rods have any higher function than that of transmitting impressions which will be appreciated in our conscious centers as variations in light intensity. 13. The function of the retinal purple is probably mainly to protect the pigment epithelium from too great exposure, and thus to modify its secretion and its action on the end organs imbedded in it. If the peripheral area of the retina were not defended in this manner, strong lateral illumination would have an unnecessarily great and confusing effect. The retinal purple is constantly being regenerated in the living retina during exposure to diffused light.

**Concomitant Convergent Strabismus.**—Lang and Barrett (*ibid.*) draw the following conclusions from their investigations upon this subject: All evidence tends to show that in cases of concomitant convergent strabismus, treatment is of value chiefly for cosmetic purposes. There is no definite evidence to show that valuable improvement in the vision of the amblyopic eye ever takes place under any circumstances.

Good vision in the squinting eye is retained usually in cases of strabismus in which the disease appears later in life than usual—*i. e.*, after five years of age. Many of the cases which begin late in life are cases of alternating strabismus in which excellent vision exists in each eye. In a fair number of these cases of late origin the extinction of vision by nebulae seems to cause the strabismus to appear. In the great majority of cases of concomitant strabismus (excluding alternating cases) the amblyopia is irremediable. Correction with glasses, prolonged monocular use of the amblyopic eye, cure of the squint, and even the re-establishment of binocular vision, all fail to produce any valuable improvement in vision. It is only at a very early period of life that the amblyopia is capable of being produced; we should regard the amblyopia as being due not to a deterioration of vision but to a failure of development. It is probable that in these amblyopic cases there is failure to educate the visual sense at the only time in life when the education is possible—viz., when the sense in the other eye is being acquired. A minority of cases of amblyopia are probably congenital in origin, and the amblyopia in these cases probably determines the development of the strabismus. It seems that the existence of hypermetropia is almost essential for the development of squint; and astigmatism or irregularities of refraction frequently exist in the squinting eye. These latter conditions are found so early in life that the explanation of their presence on the ground of arrested development from disuse must be rejected, and we must believe that in many cases they are causally related to the strabismus. After the enumeration of every possible cause, however, there remains something which can not be explained—a "further something" which determines the presence of strabismus in one case, and the absence of which negatives the presence of the strabismus in an exactly similar case in all other respects. That this something is transmissible seems probable from the records of our cases.

**The Prognosis and Treatment of Chronic Glaucoma.**—Nettleship (*ibid.*) considers that one obstacle to the formation of a trustworthy decision on any of the clinical features of glaucoma is found in the long duration of some cases even when left entirely untreated; another in the doubt which occasionally surrounds the diagnosis of the disease in the earlier stages; another in the optical inconvenience which a large iridectomy often occasions; another in the common belief that if iridectomy be done when the field is already contracted, the operation is apt to be quickly followed by a further loss of visual area. In most cases of chronic glaucoma the changes and the symptoms progress steadily to total blindness within a period varying from some months to a couple of years. In a great many cases the second eye suffers before very long; and when the stage of blindness has been reached, the eyes usually remain quiet. Several of the factors in the glaucomatous process may vary considerably in relation to each other. The degree of tension in the quietest forms is sometimes never perceptibly increased. The pupil and anterior chamber may be almost, if not quite, natural. The depth of the excavation in the optic nerve bears no constant relation either to the atrophic pallor of the disc or to the degree of tension of the eye. We sometimes meet with appearances in the disc which are very suggestive of glaucoma though without any symptoms or results of the disease. This shows the importance of any facts which tend to prove that chronic glaucoma begins rather in the optic nerve than in the ciliary region. We should be very cautious in inferring that a person whose eyes show changes resembling those of glaucoma is really safe, however free he may be from the symptoms or other signs of the disease. Glaucoma is sometimes markedly hereditary. The occasional extreme chronicity of glaucoma precludes us from saying with certainty whether the disease ever really stops short of blindness. Nettleship regards it as fair to infer that where one eye has been operated on and the other not, a permanent or prolonged arrest of downward progress in the operated eye is attributable to the operation. As regards the question of symmetry, it is probably safe to infer that in something like two thirds of the cases the disease is sooner or later symmetrical in the two eyes. It is not probable that eserine is effective in stopping the progress of chronic glaucoma, except in rare instances, though it may help to keep the disease at bay for some time. As regards the stage of the disease, an operation is much more likely to succeed if performed early in the disease than late. The state of the field

affords no constant guide. Acuteness of vision has no necessary relation to success or failure. The degree of cupping and pallor of the disc afford no constant guide to the future. The state of the pupil seems to furnish the best prognostic guide. Health and age seem to exert a decided influence on success. Senile cachexia in its various forms is distinctly unfavorable to operation. Absence of senility and an active pupil are favorable points. Nettleship regards it as our clear duty to operate in chronic progressive glaucoma, and the earlier the better, and that even in advanced cases an operation should be performed unless there are special reasons rendering it undesirable. Many of the cases which fail unexpectedly do so owing to some unfavorable process going on at or near the wound. Some of these come under the heading of "malignant glaucoma." Displacement of the lens, caused by the suddenly reduced tension at the operation, probably accounts for some of these. But it would seem that when the suspensory ligament is unsound, the intra-ocular blood-vessels are often unsound also, and the eye may subsequently be lost by hemorrhage. In other cases a chronic inflammation is set up in the wound, leading to slowly progressive haziness of the cornea, or to permanent thickening and irritability of the scar. Nettleship prefers iridectomy to sclerotomy in chronic glaucoma.

**The Harmonious Non-symmetrical Action of the Oblique Muscles explains Binocular Astigmatism.**—Savage ("Amer. Jour. of Ophth., Sept., 1888) believes that the cause of "binocular astigmatism" is the harmonious non-symmetrical action of the oblique muscles—that is, the superior oblique of one eye acts with the inferior oblique of the other in such a way as to rotate the eyeballs so as to always keep the naturally vertical meridians parallel, thus preventing double vision. This habit of rotation is formed early, and continues throughout the life of the individual, unless a pair of correcting lenses are given. At first, even with the glasses, the old habit of rotation may continue, and, if so, some of the phenomena of binocular astigmatism will appear.

**Disturbance in the Nutrition of the Cornea of both Eyes in consequence of Gastric Fever.**—Despagnet ("Rec. d'ophthal.", Sept., 1888) reports a case of this kind occurring in a man aged forty-three. For two years he had suffered from a general malaise, vertigo, and indigestion, and, about three weeks before Despagnet saw him, he had been seized with a violent headache, which was followed in a few days by fever with gastric complications. When Despagnet saw him there was marked circumcorneal injection and slight obscuration of vision, due to a central infiltration of the cornea. The patient's condition was always better in the afternoon. The ocular complication became better as the patient's gastric troubles were ameliorated.

**Suture of the Cornea.**—Gillet de Grandmont (*ibid.*) reports the case of a child, aged three, who received an irregularly triangular wound of the cornea from a sharp stone. Twenty-four hours later there was a perceptible diminution in volume of the eye, and the vitreous presented through the wound in the cornea. The child was etherized and the entire *cult-de-sac* carefully washed out with an antiseptic solution. The prolapsed vitreous was cut off, the lips of the wound brought into coaptation, and held in place by the introduction of three very fine silk sutures, which had been sterilized and left untied. The operation succeeded perfectly, and two years later the eye, though one third smaller than the other, was not misshapen. The cornea showed a central leucoma, but was not staphylomatous, and there was a small anterior chamber.

**Naphthol in the Treatment of Purulent Ophthalmia.**—Valude (*ibid.*) regards antiseptic applications as of great importance in the treatment of purulent ophthalmia, and advises strongly the use of naphthol for this purpose. He employs the variety known as *naphthol a*, in a solution composed of distilled water, 1,000 grammes; naphthol *a*, 0.50 gramme; and alcohol, 25 grammes. These applications of naphthol in solution are especially valuable in causing a disappearance of the swelling of the lids, and may be used as often during the day as may seem desirable.

**Infectious Keratitis and its Treatment with Creolin.**—Galezowski (*ibid.*) strongly recommends creolin in the treatment of this disease on account of its superior parasiticidal qualities. He employs a solution of ten centigrammes of creolin dissolved in ten grammes of water, and touches the ulcers once or twice a day with this solution. He also employs a spray of half this strength directly upon the naked cornea, for one or two minutes, five or six times a day.

**The Notation or Designation of Astigmatism.**—Suarez de Mendoza (*ibid.*) thinks that by modifying the disc of Javal's apparatus the symmetrical designation will give satisfaction both to those who only make a subjective examination and to those who employ the ophthalmometer. The symmetrical designation with regard to the axis of the body should be preferred to the designation with reference to the median plane of the eye, as it is easier to express and fully as easy to understand. In the dissymmetrical designation proposed by the Committee of the Ophthalmological Society the numbering of the test-lens must start from the same point as that of the other apparatus, in order to refer all the angles to the same line. In both systems Mendoza proposes to describe myopia by M, and hypermetropia by H.; myopic astigmatism by Am, and hypermetropic astigmatism by Ah. He also proposes to retain the sign ± of Javal for describing the result of the ophthalmometrical examination, or indicating which meridian is of the highest refraction without being always the defective meridian. He also proposes to retain the signs + and — in prescribing glasses which are to be filled by the opticians, writing first the number which indicates the degree of the angle, next that of the cylinder, and finally that of the glass.

**Metastatic Carcinoma of the Choroid.**—Schapringer ("Amer. Jour. Ophthal.", Oct., 1888) reports a case of this kind occurring in a woman aged fifty-one. In October, 1885, the right breast and axillary glands were amputated for scirrhus; the wound healed by first intention, and there was no subsequent return of the disease *in loco*. In August, 1887, she accidentally discovered that the sight of the left eye was almost gone, though she could still see objects situated at the side. Her health also began to fail and she became cachectic. In October there was a large quantity of fluid in the pleural cavity. The left pupil was dilated and immovable. The central and upper part of field was gone. The media were clear and the outlines of the disc were well defined. In the region of the yellow spot and outward there was a reddish-white discoloration about four times the size of the disc, the refraction of which was +D. 3.50, the rest of the fundus being emmetropic. This was traversed by a few thin blood-vessels. Below this there was a serous detachment of the retina. The patient died two months later. The autopsy showed a large number of round cancer nodules in both lungs and the liver. An examination of the eye showed numerous epithelial cells in the choroid, similar to those found in the scirrhus tumor of the breast.

**Is Astigmatism a Factor in the Causation of Glaucoma?**—Theobald (*ibid.*, Oct. 1888) thinks that in astigmatism the direction of the meridians of greatest and least refraction determines, to a marked degree, the amount of the asthenopia and other ill consequences which usually attend this form of asthenopia. An astigmatism in which the meridian of least refraction is vertical, or nearly so, will, as a rule, give rise to much more trouble than will one of equal or even greater degree in which the meridian of least refraction is horizontal or nearly so. The eye seems to be capable of rendering this form of error latent through the action of the ciliary muscle upon the lens. By far the greater number of pronounced cases of chorio-retinitis from accommodative strain which Theobald has met with have been associated with this variety of astigmatism. In most cases there are two factors which aid in bringing about the glaucomatous condition: first, a defect or inadequacy in the drainage apparatus of the eye; and, second, an excessive formation of fluid in the posterior chamber of the eye. Among the conditions which have been suggested as capable of producing such an undue formation of fluid in the vitreous chamber, hyperemia of the ciliary body and choroid occupies a prominent position. Astigmatism is particularly qualified to produce such a hyperemia, and thus acts as a factor in the causation of glaucoma. There was well-marked cystoid degeneration at the ora serrata, but the several layers of the retina were well preserved, except at the region of the macula lutea. Here the retina was infiltrated with small cells. The choroid on the temporal side of the optic disc was markedly thickened and entirely transformed into carcinomatous tissue. The new growth replacing the choroid is composed of a firm groundwork of fibrillar connective tissue, containing numerous nests of large epithelial cells.

**The Pathology of Albuminuric Retinitis.**—Weeks's ("Arch. of Ophth.", xvii, 3) observations are based upon the histological examination of six eyeballs removed from as many patients who had suffered

from or had died with disease of the kidneys. He concludes that two classes of retinal disease are included under the present name of albuminuric retinitis. One depends almost entirely on the condition of the blood brought about by an acute disease of the kidneys, the renal symptoms preceding the change in the retina; the other on a general (systemic) diseased condition of the arteries, capillaries, and, to a less extent, the veins, in which the ocular changes and symptoms may and not infrequently do precede the kidney symptoms. To the first class belongs the retinitis of pregnancy, scarlatina, diphtheria, etc., and all forms of acute diffuse nephritis. In these cases the oedema and white plaques are the first evidence; haemorrhages, more or less numerous, often follow. To the second class belong the cases in which the first retinal change is a haemorrhage or a few small haemorrhages, usually in the vicinity of the macula. The oedema and white plaques appear later. Contemporary with, preceding, or following the haemorrhages in the retina, we may find evidences of capillary haemorrhages in other parts of the system. The first variety may be termed an irritation nephritis, due to the effect of a morbid element on the kidney tissue, in which the kidney usually becomes enlarged and the circulation interfered with by pressure on the vessels from the swollen tissue. The latter variety is rather a strangulation nephritis, in which the blood-supply is cut off by arterial stenosis, the kidney being always found contracted, and in which the morbid element contained in the blood causes a thickening and degeneration of the walls of the vessels with a diminution of their caliber. Both conditions may exist at the same time in varying degree. A large percentage of the cases of retinitis accompanying albuminuria undoubtedly belong to the latter category.

**A High Degree of Astigmatism after Cataract Extraction improved by Operation.**—Schiötz (*ibid.*) reports an interesting case occurring in a man aged thirty-three with zonular cataract in both eyes. An iridectomy was made upward on the left eye and the lens was extracted. A portion of the lens matter remained in the anterior chamber. During the healing process a piece of the lens mass was pressed against the inner side of the wound so as to push the corneal flap forward, and this was probably the principal cause of a considerable alteration in the corneal curvature that remained. The eye showed a corneal astigmatism of one dioptre, the vertical meridian being that of maximum refraction. The radius of curvature in the meridian of weakest refraction was 8·26 mm., and in that of maximum refraction was 8·16 mm. About four months after the extraction there was found a corneal astigmatism of 19·50 dioptres. Fifteen months after the operation, the astigmatism having remained about the same, an incision was made upward with a Graefe knife through the base of the most bulging part, and a small flap cut away with scissors. After the wound had healed the eye was again examined, but no change was noticed in the astigmatism. Three weeks later an attempt was made to cut a small flap from the upper lip of the wound, and this operation reduced the astigmatism by 3·75 dioptres. Three weeks later a third operation was done with a Graefe knife, the incision being made upward and inward in such manner that the incision made an obtuse angle with the original corneal section at the time of the extraction. The ultimate result was a reduction of the astigmatism from 19·50 to 7 dioptres. The partial excision of the cicatrix proper exerted only a proportionally trifling effect on the curvature of the cornea; on the other hand, the division of the normal parts adjoining the cicatrix proved very efficacious.

**Sixfold Paralysis of the Left Cerebral Nerves.**—Grossmann (*ibid.*) reports an interesting case occurring in a woman, aged forty-four, who had always been delicate, and had suffered from diplopia, vertigo, deafness, and tinnitus in the left ear for some time. An examination showed paralysis of the left abducens, slight myopia, left lagophthalmus, deafness of the internal ear on the left side; anaesthesia of left side of forehead and cornea, face and lips; stuttering and slowness of speech. Loss of smell in left nostril and of taste on left side of tongue; tip of tongue directed to the left. There was difficulty of deglutition, weakness in the left extremities, and inability to stand on the feet. The sound-perceiving apparatus appeared diseased, because the drum membrane was normal and the deafness was not relieved by catheterization. The trigeminus was paralyzed in both motor and sensory branches. The left-sided anosmia was partly due to trigeminal anaesthesia and partly to facial paralysis, but the olfactory nerve may

also have been paralyzed. The dysphagia indicated glosso-pharyngeal paralysis, although the same disease in the hypoglossus may have contributed to the difficulty. The poor articulation indicated hypoglossal paresis. The lack of taste arose partly from anaesthesia of the lingual branch of the trigeminus, and partly from disease of the glosso-pharyngeus. There must have been a lesion at the base of the brain to excite so extensive a paralysis of the fifth, sixth, seventh, eighth, ninth, and twelfth pairs, or at the pons. The only support for such a disease in this case was cerebral motor-nerve paralysis. Yet the absence of alternating paralysis of the extremities rendered this diagnosis doubtful. Other symptoms, favoring the seat of the lesion in the pons were paralysis of the facial and abducens, the excessive trigeminal anaesthesia with anaesthesia of the left extremities, and finally the dysphagia and paralysis of the hypoglossus, as manifested in the disturbance of articulation and defective motion of the tongue. The history seemed to indicate syphilitic gummatous periostitis at the base of the brain, terminating in pressure on the basal surface of the pons. Grossmann administered one gramme of potassium iodide daily, and in ten days the dysphagia began to yield, and in ten more it had disappeared. The tongue also moved more rapidly, and the eye could be voluntarily rotated beyond the median line. The effect of the administration of the iodide seemed to justify the belief that the lesion in the pons depended on bone disease at the base of the skull. In the course of the treatment a sequestrum of bone was exfoliated from the root of the left pterygoid process. This was apparently due to osteitis syphilitica, and proved that a gumma can originate from the embryonal connective tissue in the medullary space as well as under the periosteum. The patient died from a sudden and profuse epistaxis, and, from the manner in which the blood gushed from the nostrils, some large artery, either the carotid or basilar, must have burst from erosion. Although the paralysis decreased and the general health improved, the bone disease continued to progress.

**Dyslexia or Dysanagrosis with Autopsy.**—Nieden (*ibid.*) reports a very interesting case of this kind occurring in a man, aged thirty-nine, who, for some weeks after a sudden convulsive attack, had suffered from a great loss of strength. The attack lasted about twenty minutes, and was followed by severe pain in the head and nape of the neck on the left side, which was increased by pressure upon a corresponding portion of the vertebral column. Eight days later there was a similar attack, which chiefly involved the upper extremities and lasted half an hour. The patient claimed that he could not read; there was no blurring or swimming of the letters, but an unconquerable inclination to turn away the head. Vision was normal with his hypermetropia corrected. In testing the near vision the patient read correctly the first four lines of No. 1, and then suddenly turned away the book, declaring that he could read no further, and, if persuaded to try again, the mental exertion was followed by a sort of fainting attack, and he complained that he perceived a peculiar foul odor. The visual fields and color sense were normal. Fourteen years before, the patient had had a similar convulsive attack. About a month after the second attack an acute gastro-enteritis set in without any assignable cause. The patient complained of general headache and drowsiness, and gradually sank into a soporific condition. The pupil of the left eye became dilated, but reacted normally. Two weeks later there was retention of urine, and three days after this, paresis of the facial muscles and extremities of the right side was noticed, which on the next morning had disappeared. The patient slept almost continuously, and died comatose three days later. The autopsy showed a discoloration of the parts in and around the corpus striatum. A section through this region showed three apoplectic foci, each in a different stage of transformation. The largest focus, the size of a walnut, situated in the anterior portion of the corpus striatum, was surrounded by a delicate sheath of connective tissue. All the white substance anterior to the inferior frontal convolution was involved in a state of yellow softening. The second focus, situated above and behind the first, was smaller, and its consistence and color indicated a more recent origin. It was also surrounded by a well-marked capsule. The third focus, about the size of a pea, was the most recent. It occupied the center of the lenticular nucleus and consisted of two fresh blood-clots. The central portion of the nucleus was destroyed, and the surrounding tissues were oedematous. There was at

no time in the course of the disease any amnesia or ataxic aphasia, agraphia, or a loss of the ability to understand spoken language.

**The Magnet Operation.**—Neese (*ibid.*), from his observations, thinks that the magnet is especially adapted for the removal of foreign bodies from the lens, from the fact that the loose and swollen tissue of the latter offers very little mechanical resistance to the action of the magnet, while it is easier to find the fragment in the cloudy mass, and there is less danger of penetration into the vitreous. Extraction of foreign bodies in the anterior segment of the eye is usually successful, and with fairly good results as regards sight. The electro-magnet in a certain number of cases is not necessarily indispensable; in others it is positively contra-indicated; in a third class it does not fulfill the end in view. For the successful extraction of foreign bodies situated in the posterior portion of the globe, viz., (1) the foreign body must be freely movable; (2) the distance to it must be short. When surrounded by exudative masses, firmly imbedded in the membranes of the eyeball, or inclosed in a capsule of connective tissue, the foreign body is immovable and therefore inaccessible to the magnet. The advantages of early operation are therefore quite obvious.

**The Pathological Anatomy and Pathology of Optic Neuritis.**—Picqué (*ibid.*, Sept.–Oct., 1888) insists upon the necessity of establishing the line of demarcation between the retina and the intra-ocular expansion of the layer of optic nerve-fibers in the eye. The independent circulation of the retina and of the ocular expansion of the optic nerve, the functional integrity of the retina coinciding with the most advanced alterations in the optic nerve, sufficiently justify this claim. For example, retinitis albuminurica presents in its principal alterations the type of the neuritis of the intra-ocular expansion of the optic nerve; apoplectiform retinitis, at least in one of its most important varieties, becomes a complication and a symptom of atheromatous changes in the vascular system of the optic nerve. From the point of view of the relations of stasis to papillitis, it may be said that it is impossible to establish a precise limit between papillitis and papillary stasis, so that we are authorized in considering the stasis, not as the first stage of a condition which may or may not lead to papillitis, but as a very frequent variety of papillitis. In the present state of our knowledge we can no longer preserve the distinction between papillary stasis and papillitis, a distinction based on the deduction of an erroneous clinical fact and on a pathogenetic theory which subsequently we shall prove to be false. The oedema here present must be regarded as of inflammatory origin, the result and not the cause of the papillitis. The walls of the arteries are thickened and the vessels are varicose and diminished in caliber, and this diminution is especially marked in the small vessels and capillaries. It is a variety of endarteritis obliterans resembling the syphilitic endarteritis of Lancereaux and Heubner.

**The Value of the Cautery in the Treatment of Ulceration of the Cornea.**—Renton ("Ophth. Rev.", Oct., 1888) recommends strongly the galvano-cautery in the treatment of ulceration of the cornea. The cautery is to be applied lightly, and, where necessary, the corneal layers are penetrated into the anterior chamber. Renton considers traumatic ulcers at all stages and idiopathic ulcers of all kinds as suitable cases for the cautery. These may often be benefited, especially when recurring in strumous children and weakly women, rheumatic and gouty subjects, or those suffering from granular ophthalmia; the granulations may also be cauterized with great advantage.

**Conical Cornea treated with the Actual Cautery.**—Williams (*ibid.*) advocates the treatment of conical cornea by cauterization. One application to the apex of the cone immediately reduces the conicity and leaves a deep pit. This heals as an ulcer, and leaves a small, firm scar, rendering further ectasia practically impossible. He advises against the opening of the anterior chamber. He recommends this plan of treatment on the following grounds: 1. Its extreme simplicity. 2. Its freedom from danger and ease of performance. 3. Its good results, both visually and as regards the arrest of the morbid process.

**The Treatment of Symblepharon by Transplantation of Mucous Membrane from the Lip.**—Meighan (*ibid.*) prefers to transplant the mucosa of the patient's lip rather than the conjunctiva of the rabbit. After having repaired the original defect as well as possible by the surrounding conjunctiva, the remaining defect is to be mapped out on the inside of the patient's lower lip, and the mucous membrane is then to

be dissected off, making ample allowance for subsequent shrinking. The mucosa must be carefully cleaned of the labial glands and of any fat, washed with a 0·2-per-cent. solution of corrosive sublimate, and stitched in its new position with a sufficient number of sutures. The eye is then to remain bandaged for twenty-four hours.

**Hyalis Punctata.**—Benson (*ibid.*) proposes to designate by this name a condition observed on or in the neighborhood of the anterior portion of the hyaloid membrane, exactly similar in appearance to that observed so commonly on the posterior surface of the cornea in cases of serous iritis. There appear a number of punctate opacities in the position of the posterior capsule of the lens, exactly similar in arrangement and appearance to those on the cornea. These can only be seen when a strong lens (+ D. 26) is used in the ophthalmoscope. They extend over a considerable area and seem to lie on a plane at right angles to the corneal axis. They do not extend to any depth in the vitreous, but lie on or close to the posterior capsule. These spots are not to be mistaken for the dust-like opacities seen in specific disease. There is usually evidence of old choroiditis.

**The Relation of the Orbital Opening to Myopia.**—Weiss ("Kl. Mon. f. Aug.", Sept., 1888) formulates his views as follows: It is theoretically doubtless correct that when the entrance to the orbit is low, the anterior insertion of the inferior oblique and the trochlea are nearer each other, and that consequently both muscles surround the globe to a greater extent. The form and size of the orbital opening are therefore of some consequence in relation to the insertions of the muscles, and the latter is also of importance in relation to the course of the ocular muscles and their consequent pressure on the globe. It can not be denied that these may be important factors in the causation of myopia, in so far as a certain portion of the pressure exerted on the eyeball by the muscles depends upon them. The orbital index is actually smaller in myopes than in emmetropes or hypermetropes. Weiss advises a very careful examination of the shape of the skull and opening of the orbits on both sides in all cases of anisometropia, as a possible means of elucidating this question. Usually in these cases the two sides of the skull and face will be found asymmetrical.

**The Pupillary Reaction.**—Heddaeus (*ibid.*, Oct., 1888) calls attention to Magnus's scheme for recognizing the disturbances of the movements of the pupil caused by diseases in various parts of the reflex tract which presides over the pupillary reaction to light. He proposes a modification of this scheme by designating by the single expression "reflex sensibility" the power of the eye or retina to carry or conduct a light-wave or irritation to the centers of the oculomotorius. The course for the light-reflex consists of a centripetal part (the centripetal pupillary fibers) and a centrifugal part (the pupillary branch of the third nerve), and of the nucleus which represents the union of the two (pupillary nucleus of the third nerve). Anomalies in the centripetal portion cause disturbances of the reflex sensibility (retina); anomalies of the centrifugal portion cause disturbances in the motility of the pupil; anomalies in the nucleus cause disturbances in both as follows: I.—Destruction of the right optic nerve causes reflex dullness or blindness of the right eye. 2. Destruction of the right optic tract (or of the tubercula quadrigemina, or of the fibers of Meynert on the right side) causes reflex blindness of both right halves of the retinae. 3. Median sagittal section of the chiasm causes reflex blindness of the nasal half of both retinae. II—Destruction of the right pupillary branch of the third nerve causes mydriasis and immobility of the right pupil. III—Destruction of the right pupillary nucleus causes mydriasis and immobility of the right pupil.

**Stereoscopy by Difference of Colors for the Normal and the Color-blind Eye.**—Grossmann ("Ophth. Rev.", Nov., 1888) refers to the investigations of Einthoven upon this subject, who considered that the real reason why some colors seem to stand out more prominently than others consisted in the eccentricity of the eye and the symmetrical arrangement in the fellow-eye, whereby the red rays are united on a more temporal part of the retina than the blue rays. He considered also that the position of the pupil was of great influence, but that there was very little accessory help on the part of the accommodation. Grossmann considered that the phenomenon, at least in his own case, is attributable principally to accommodation. In testing, he arranges the two colors, red and blue, in a simple way, so that they form a perspective

drawing, and the stereoscopic effect is thereby greatly facilitated. If this figure be shown to some color-blind (red-green blind) individuals, they also perceive the red nearer than the blue, which proves that with them also the act is principally one of accommodation.

**Partial Hyperostosis of the Frontal Bone.**—Silcock (*ibid.*) reports a case of the above nature in a woman aged twenty. When first seen she presented a swelling over the left eyebrow, round in outline, with smooth surface, and hard and bony to the touch. The left eyeball was displaced forward, downward, and outward. The swelling had existed for two years, and was said to be increasing in size. There was a history of a blow on the eyebrow. Five years later the swelling had become considerably larger. At this time much of the frontal bone was removed with trephine and bone forceps, but it was found impossible to extirpate the growth. Microscopically there was seen a richly cellular and ill-developed connective-tissue growth undergoing ossification.

## Miscellany.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the abstract of sanitary reports received by him during the week ending July 19th:

CITIES.	Week ending—	Estimated population.	Total deaths from all causes.	DEATHS FROM—									
				Cholera.	Yellow fever.	Small-pox.	Varioloid.	Varicella.	Typhus fever.	Pueric fever.	Scarlet fever.	Diphtheria.	
New York, N. Y.	July 13.	1,573,097	1,187	...	...	...	...	...	4	10	28	4	12

**Scientific Uses of the Eiffel Tower.**—M. Janssen, of the Institute of France, is of opinion that the Eiffel Tower will have many scientific uses. One of the greatest difficulties of meteorological observations is the disturbing influences of the station of observation itself. How, for example, can a true deviation of the wind be observed if a purely local obstacle causes it to deviate? And how can a true temperature of the air be determined by a thermometer influenced by radiation from surrounding objects? Thus, the meteorological elements of great centers of habitation have to be taken outside those centers and at a certain height above the soil. The tower, since it rises to a great height, and from the nature of its construction does not modify in any way the meteorological elements to be observed, will get over this difficulty. A height of three hundred yards is in itself not a negligible quantity from the point of view of rainfall, temperature, and pressure, but these cir-

cumstances give all the more interest to the institution of comparative experiments on variations due to altitude; the electrical interchanges between the soil and the atmosphere can also be studied to advantage. Special arrangements can be made for avoiding accidents, and results of great interest should be obtained. M. Janssen recommends also the institution of a service of meteorological photography. A good series of photographs would give forms, movements, modifications which the clouds and atmospheric conditions undergo from sunrise to sunset. Thus a history of the skies would be written on a radius not hitherto dealt with. In physical astronomy various other observations might be taken, especially in relation to the study of the telluric spectrum. M. Eiffel announces that three laboratories have already been arranged on the tower. One will be devoted to astronomy, and the second will contain registering apparatus from the central bureau of meteorology, and will be devoted to physics and meteorology. MM. Mascart and Cornu expect to draw great advantages from its use in the study of the atmosphere. The third is reserved for biology and micrographic study of the air, to be organized by M. Henocque. M. Cailletet is arranging a great mercurial manometer, with which he expects to obtain pressure as high as four hundred atmospheres.—*British Medical Journal*.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

## Original Communications.

### SOME NEW TESTS FOR INSUFFICIENCIES OF THE OCULAR MUSCLES, TOGETHER WITH A SYSTEM OF ABBREVIATIONS SUITABLE FOR NOTE-TAKING.

By ALEXANDER DUANE, M. D.,  
NEW BRIGHTON, N. Y.

The important part played in the causation of all sorts of nervous diseases by anomalies of the oculo-motor apparatus is becoming daily more and more apparent. Since the epoch-making labors of Dr. George T. Stevens, the proposition that disorders of the muscular mechanism of the eye are a more potent and constant cause of functional nervous affections than any other source of reflex irritation may be considered as established on a firm foundation. Epilepsy, chorea, hysteria, neuralgia, and those aggregations of symptoms which have been vaguely lumped together under the names of neurasthenia, spinal irritation, etc.—in a word, the great concourse of nervous diseases which arise without the production of lesions of the nervous substance—are to a great extent dependent upon eye-strain, and, of the varieties of eye-strain, those which spring from anomalies of the muscular apparatus are the most distressing and the most severe. Nor is this wonderful when the matter is closely considered. Indeed, the wonder is rather that, in view of the obvious facts of the case, anomalies of this sort should hitherto have received such scant attention. It is true that there are many other sources of reflex irritation, all more or less distressing and all capable of producing serious nervous symptoms. The nasal, the oral, and the genital apparatus may each be the seat of some affection capable of giving rise by its presence to asthma, epilepsy, neuralgia, etc. The unfortunate who suffers from hypermetropia or astigmatism is still more liable to reflex troubles, for he is compelled during every minute of his waking existence to exert great and most tormenting strain so as to see with a distinctness sufficient for his daily needs. But he who has a faulty direction of the visual axes or a relative weakness of any of the ocular muscles is in a still worse case. A man, for example, who has a hyperphoria of two or three degrees must, during every minute that he uses his eyes, exert an enormous force, not merely to see distinctly, but even to see at all. Let any one who wishes to realize what a strain this means take a two-degree prism, place it base down before one of his eyes, and then try to read. The sense of confusion will soon become so maddening that few will venture to prolong the experiment beyond ten minutes. And yet this strain is not as great as many of us have to undergo during the whole time that our eyes are open. No one who has not himself suffered from this burden can realize how intolerable it is, how it dissipates the vital forces, how it renders inert and inactive a man of otherwise sound constitution and good mental capacity.

From the frequency of these sources of irritation and the great part they play in the causation of nervous troubles, their consideration is no longer confined to the ophthalmic

or to the neurological specialist, but interests all members of the profession alike. It is true that for their accurate determination and their cure the most painstaking and delicate manipulation is required, such as requires the aid of a special apparatus and a special professional training which the oculist alone can supply. But their recognition does not always or often imply the need of apparatus or of particular skill, and the tests which establish the existence of heterophoria are no more mysterious or complex than the tests of the reflexes in determining the presence of locomotor ataxia.

The object of the present article is to exhibit briefly the methods and limitations of certain simple tests which do not require instruments, and which therefore can be employed by those who do not possess or who have not the skill to use an oculist's armamentarium. The usefulness of such tests is not, however, confined to this application of them. In all cases they will be found serviceable as adjuncts to the instrumental tests, serving to check and confirm the latter, and in some cases are available where other tests fail or are uncertain.

It may be well, before entering into a description of these tests, to set clearly before our minds what we intend to determine by their aid. The problem for solution—that of the condition of the oculo-motor apparatus—is one both of statics and of dynamics; in other words, what we wish to ascertain is, first, the normal balance and the individual tendencies of the different muscles when the eye is in a state of repose, and the muscles themselves are placed as far as possible in a condition of equilibrium; and, second, the relative power of the individual muscles when set in action, and the resulting capacity of the eye for motion in different directions. Defects in the former regard—that is, in the static condition of the eye—constitute the various forms of strabismus and of heterophoria. Without going into a description of the latter condition, which has already been amply considered in the works of Dr. Stevens, we may say in brief that one or more of the following conditions may exist: Esophoria, or a tendency of the visual axes inward; exophoria, or a tendency of the visual axes outward; and hyperphoria, or a tendency to vertical divergence of the axes. The determination of the direction and the amount of these deviations requires the eye to be placed in a state of complete repose, and, as this condition of absolute equilibrium can never be perfectly attained, repeated and carefully conducted examinations must be made in order to approximate as nearly as can be to the ideal state and to eliminate accidental errors. Defects in the dynamic condition of the eye are constituted by such insufficiencies or such excessive actions of the ocular muscles as cause one or both eyes to perform either too greatly or to too slight a degree the movements of abduction, adduction, and sursumduction. These defects usually coexist with heterophoria, but do not necessarily do so, and their determination requires equally careful and repeated testings. In this case, moreover, the examination can also be made to do service as an exercise for the weaker muscles.

The whole problem, however, whether viewed from the

side of static or dynamics, resolves itself into this query: How far and in what sense do the visual axes deviate or tend to deviate from parallelism both in a state of repose and during the various associated movements of the eyes? With the proposition stated in these terms, it is easy to see that the perfectly acting eye, whether at rest or in motion, will be so directed that its visual axis \* is parallel with that of its fellow, while the heterophoric eye will in some position exhibit a deviation of the axis, to overcome which demands an extra muscular effort and a consequent overstrain of nervous energy.

By keeping this preliminary proposition in mind, the consideration of the tests themselves becomes greatly simplified. Like the problem which they are designed to solve, the tests themselves may be either static or dynamic. Of the former kind, which are concerned with the tendency to deviation exhibited by the eyes when in a state of rest, the most obvious—i. e., that afforded by the mere inspection of the eye—is rarely of any service, because the manifest variations constituting heterophoria are often so slight as to be unrecognizable by this means, and also because, when a variation is appreciable, it is often impossible to tell its direction from inspection alone. This is especially the case in hyperphoria, in which the tilting of one eye above the other is often masked by simulated turning in or out (apparent esophoria or exophoria). Corresponding to this rough objective test is the more delicate subjective one furnished by the patient's perception of diplopia when the eyes are in a position of equilibrium—i. e., when the head is in the normal erect position and the visual axes are directed straight forward at an object twenty feet or more distant.<sup>4</sup> This diplopia is, of course, usually recognized only when the red glass is employed to differentiate the images; and it is quite important to distinguish the cases in which diplopia occurs spontaneously (or can be produced spontaneously by the patient's will); and those in which it is apparent only upon using the red glass. The diplopia may be lateral (being then either homonymous or crossed) or vertical, and in the latter case may be designated as right or left according as the right or left image is below (indicating that the right or left eye is the higher). If prisms are

available, the amount of diplopia can be measured by the degree of the prism which, placed before either eye, causes fusion of the images.

The second set of tests for determining the static condition of the ocular muscles is afforded by the use of the screen. This procedure—mentioned by Landolt ("Examination of the Eyes"), but only in connection with the accommodation movements of the eye, i. e., with the visual axes converging, and employed by Stevens and others when the visual axes are in parallelism—is conducted by placing a screen (such as a card or the hand) before one eye and, while the other eye remains fixed upon one object, observing the direction which the covered eye tends to assume. By shifting the screen from one eye to the other, the eyes being steadily directed toward one object, the eye which is uncovered will, in order to see the object, move in a direction contrary to that which it had assumed behind the screen. For example, with both eyes looking straight forward at a candle twenty feet distant, and with the card placed alternately before either eye, the left eye on being uncovered moves down. The inference is that behind the screen it was standing higher than its fellow—i. e., there is a condition of left hyperphoria.

The screen test as thus performed is a very useful adjunct to the prismatic tests for heterophoria, and if the latter exceeds in amount a couple of degrees, the movement of the eye on shifting the screen is usually quite perceptible. On the other hand, when the manifest heterophoria is less than two degrees, it is difficult to detect any deviation behind the screen. When, therefore, this deviation exists, it is a strong confirmatory evidence of heterophoria; but its absence is not conclusive as to the non-existence of the latter condition, and in some cases—e. g., in such a one as that mentioned in a preceding foot-note—even its presence is not absolute proof either of the presence or of the character of the pathological condition. It can not, therefore, be implicitly relied upon unless checked and confirmed by other methods of examination, and yet it is of great value and should always be called into requisition in testing for muscular insufficiencies.

A modification of the screen test—which, as giving subjective instead of objective indications of the presence of deviation, bears the same relation to the ordinary screen test that the detection of diplopia by the red glass does to the estimation of heterophoria by the mere inspection of the eyes—is the *parallax* test. This, as far as I know, has not yet been employed in ocular examination: I am therefore inclined to regard it as original with myself. It consists in shifting the screen from one eye to the other and making the patient observe if the image moves, and, if so, in what direction. If the patient is in the standard position—head and shoulders erect and eyes looking straight forward at an object twenty feet or more distant—there should, if orthophoria exists, be no movement of the image when the screen is shifted. If, accordingly, under these conditions and after repeated trials, the object observed appears to the patient to always occupy the same position, it may be assumed that, as far as this test goes, there is no tendency to deviation from parallelism of the visual axis.

\* The visual axis in some very rare cases seems to be widely different from the optical axis. Thus, in one case in which there was well-marked deviation of the eyes out, both behind the screen and also when any attempt was made at fixation, there were homonymous diplopia and an esophoria of twelve degrees or more. Such a condition can scarcely be explained on any other hypothesis than that the region of most distinct vision was not situated at the normal position of the media, but at a point considerably external to the latter, so that even when the eyes deviated outward the visual axes were still convergent.

<sup>4</sup> Or more. In testing for muscular anomalies, twenty feet do not constitute infinite distance. This is seen especially in testing the abduction, which at a distance of twenty feet will often be found to be quite a little greater than at fifty feet and less than at ten feet.

: It may be here remarked that in testing the static condition of the eyes, voluntarily produced diplopia does not afford such trustworthy indications as diplopia spontaneously existing. The very act of separating the images by voluntary effort implies a muscular strain which distorts the relations of the eyes, and which may alter the direction of their axes in a vertical as well as in a horizontal plane. I have once or twice inserted this in practice.

If, on the contrary, the image appears to shift its position with the alternate withdrawal and replacement of the screen, there exists what may be appropriately denominated a parallax, and it may be taken for granted that heterophoria exists. The parallax is in reality only a form of diplopia, being produced, as diplopia is, by lack of parallelism of the visual axes; and, like diplopia, it may be homonymous, heteronymous, or vertical. In other words, if, when the left eye is uncovered and the right concealed, the patient sees the test object—*e. g.*, a candle—moved to the left, the parallax is homonymous and the visual axes tend to cross; if the candle-image moves to the right, the parallax is heteronymous (or crossed) and the visual axes diverge; if it moves down, there is vertical parallax (left parallax), indicative of left hyperphoria; if it moves up, there is right (vertical) parallax, indicative of right hyperphoria. Of course, we may have both lateral and vertical parallax combined, in which case both a lateral and a vertical movement of the image will be observed.

The test so performed is exceedingly simple, and yet, from a somewhat extensive trial of it, I am led to believe that it is a very delicate one. The degree of shifting of the images is a measure, approximately at least, of the amount of heterophoria, and, if it is desired to measure the latter precisely, this can be done by placing prisms before the eyes until the images no longer change their position with the movements of the screen. The strength and axial direction of the prisms will obviously indicate the amount and character of the correction to be employed for the heterophoria. Thus, suppose that the image moves down when the right eye is uncovered, a prism of one degree is placed, base down, before the right eye, thus elevating the image. The shifting of the screen still shows a parallax, but now in the opposite sense—that is, the left image moves down. The prism is now revolved until its apex points to  $30^\circ$ , at which point no vertical movement is observed on displacement of the screen. The test therefore indicates a right hyperphoria of about  $\frac{1}{2}^\circ$ , or, as I prefer to put it, there is a right parallax of  $\frac{1}{2}^\circ$ . Differences in the level of the eyes of one tenth to one fifth of a degree can usually be detected by the parallax test, and it is thus quite as delicate as the ordinary test for hyperphoria (*i. e.*, the production of artificial diplopia by the use of strong prisms with their bases directed in, and the estimation by the patient of the difference of level existing between the two images), and it has the advantage that one source of error—namely, the failure to perfectly adjust the diverging prisms—is eliminated. Moreover, in all tests performed upon the eyes, the nearer we approximate to the natural state the better; and I think there can be no question but that the use of prisms to produce diplopia introduces an artificial condition, and so tends to disturb the natural relations of the eye and to produce more or less involuntary muscular effort, when what we desire is the completest muscular relaxation possible. Hence I have lately been in the habit of regularly employing, first, the screen and parallax tests, which introduce conditions least removed from the natural; then using prisms to make the ordinary examination for hyperphoria and for lateral insufficiency; and, last of all, testing the

dynamic capacity of the eye by finding the abduction, adduction, etc. This last examination, by calling into play the different recti, tends to temporarily destroy the balance of these muscles, and should therefore be always deferred till the static tests, which presuppose the recti to be as far as possible in equilibrium, have been performed.

Another example of the usefulness of the parallax test in examining for hyperphoria is found in those cases in which we have had the patient wear a trial prism in order to detect the amount of this condition. If, for example, we have suspected right hyperphoria, and, in order to test the matter, have had the patient wear a prism of  $1^\circ$ , base down, before the right eye for a day or so, and, on coming back, he has shown, with his prismatic glasses on, no parallax or ever so slight a tendency to left parallax, we infer that the glass is overcorrecting, and that our suspicions were probably erroneous. For, after wearing such a glass, a patient who really has right hyperphoria of any appreciable amount would show more than  $1^\circ$  of it, and hence would, with his glasses on, exhibit a right parallax. I have found this application of the parallax test very useful, and by its aid have succeeded in measuring very precisely even minute degrees of hyperphoria.

In examining for lateral insufficiency, the parallax test is equally useful and equally delicate, an exophoria or an esophoria of one degree or more being usually evidenced by a distinct movement of the images from side to side. The amount of lateral deviation may be quite accurately measured by the degree of excursion of the images, or, if desired, by the strength of the prism which, placed base in or out, abrogates the parallax.

The parallax test is further of service when we wish to ascertain whether a glass, designed for the correction of refractive errors only, exerts a prismatic effect. For instance, suppose that a patient with hypermetropia shows, when his refractive error is corrected by properly centered lenses set in a trial-frame, no parallax, but that, when he puts on spectacles made for him by the optician, a distinct parallax is obtained, it is evident that the spectacle-glasses are either improperly adjusted or, from some defect in construction, contain a prismatic element. They should now be adjusted upon the face till the parallax disappears or becomes as small as possible, when the error due to the former cause will have been eliminated. Then any error due to improper construction can be measured by noting the strength and direction of the prism which, placed before the glasses, causes the residual parallax to disappear.

The results of the parallax and of the screen tests should always be congruous; and even in such a rare case as that before mentioned—in which, with deviation of the eye outward, there were homonymous diplopia and an esophoria of  $12^\circ$  or more—the parallax was necessarily heteronymous.

All the tests which have been hitherto described are arranged for determining the static condition of the eyes. The dynamic tests, or those which aim to determine the power of the different muscles, are various. Besides the estimation of the abduction, adduction, and sursumduction, by placing prisms before the eyes with the bases in, out, up,

and down, the diplopia produced by which the patient is required to overcome, there is one rough test that I have lately employed with, I think, considerable advantage in estimating the excursion of the eyes inward and outward. It is analogous to the expedient ordinarily employed in examining for weakness of either of the lateral recti—an expedient which consists in moving before the patient's eyes a small object as a pen-point or the finger and watching the behavior of the eyeballs as they follow the latter from side to side. In the modified test, which, for want of a better name, I call the *excursion test*, the object looked upon is stationary and twenty feet or more distant, and the patient's head is slowly turned from side to side while his eyes remain fixed upon the object. The test is both objective and subjective, the physician observing any tendency to deviation which the eyes may exhibit during their excursion, and at the same time requiring the patient to notice any diplopia or other subjective evidence of heterophoria. For the latter purpose, the use of the red glass placed before either eye is almost always necessary. Starting with the standard position, which, borrowing military phraseology, may be designated as "eyes front," the head is successively moved to the right (giving the position of "eyes left") and to the left (giving the position of "eyes right"), and in each position the presence and direction of any obvious deviation of the eye, of diplopia, and of parallax are noted. A case from actual practice will illustrate the applicability of the method. In a patient, previously operated upon by partial tenotomy of both internal and external recti, there were in the "eyes-front" position an esophoria of  $1^{\circ}$  combined with an abducting power of only  $3^{\circ}$  and an adducting power of  $50^{\circ}$ , a tendency to spontaneous homonymous diplopia, and a homonymous parallax. In the "eyes-right" position the homonymous diplopia and parallax were still more marked, increasing progressively till the former could not be overcome by voluntary effort. In the "eyes-left" position the conditions were reversed, the homonymous diplopia and parallax diminishing to zero and then becoming heteronymous. In other words, as the eyes moved in association to the right, there was a progressively increasing tendency to convergence, and, as they moved to the left, an increasing tendency to divergence of the visual axes. Moreover, the position of equilibrium for the eyes was not in the position of "eyes front," but in a slightly "eyes-left" direction. To explain these phenomena, any one of the following hypotheses may be advanced:

1. The movements of the left eye are excessive both in abduction and adduction, without impairment of the functions of the muscles of the right eye. This hypothesis is scarcely tenable, especially in view of the restricted adduction (only  $3^{\circ}$  instead of the normal  $8^{\circ}$ ).

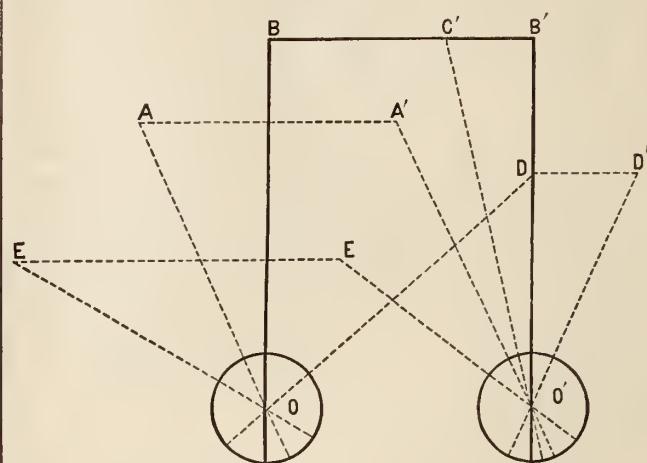

2. The movements of the right eye are restricted in both abduction and adduction.

3. A combination of restriction of movement of the right eye with excessive latitude of motion of the left eye exists.

4. There is a tendency to associated deviation of both eyes to the left, together with excessive abduction of the left eye and restricted abduction of the right, the

adduction of the latter being normal or more probably diminished.\*

This last hypothesis seems most probable. It is indicated in the accompanying figure, in which, when the eyes

are directed slightly to the left, the axes OA and O'A' are parallel without there being any extra tension upon the muscles. On moving to "eyes front," the axes OB and O'B' are still parallel, but are maintained so by an effort of the weak external rectus of O', which has had to pull the eye through the angle A'O'B', while the strong internal rectus of O has no difficulty in carrying it through the angle AOB. Hence, while O is maintained in its position there is a constant tendency of the axis O'B' to fall into O'C', producing homonymous diplopia and parallax. As the eyes are carried still further to the right, this tendency becomes more and more marked, and in extreme "eyes right" the axes OD and O'D' make a distinct angle with each other, producing well-marked and invincible homonymous diplopia. On the other hand, as the eyes sweep to the left, the strongly preponderant abduction of O carries the eye readily through the angle AOE, while, the adducting power of O' being comparatively feeble, this eye is carried through the less angle A'O'E', and a condition of divergence of the axes with crossed diplopia and parallax exists. The indication for operation in such case will be tenotomy of the right internal rectus, in order to prevent the tendency of O' to look toward A' and in order to give the eye with feebler muscular action (and especially with feebler abducting power) the easier task to perform. The operation being performed in such a way that O' now looks straight forward to B', we would have now in "eyes front" a slight tendency to exophoria (readily overcome by the strong adduction of O), and, as the relative abducting power of O' is increased by the weakening of its internal rectus, a much smaller tendency to exophoria.

\* In the statement of these hypotheses, abduction does not necessarily mean absolute abducting power, but rather the net capacity of the eye for turning out—i.e., the maximum power of the external rectus minus the minimum power of the internal rectus. Accepting this definition of abduction with the complementary one of adduction, all the above hypotheses may be reduced to the general statement that in the case under consideration both the abduction and the adduction of the right eye are below the normal, while the abduction and the adduction of the left are in excess.

ency to homonymous diplopia and parallax on rotating the eye to the right.

A number of other cases might be cited in which this test has shown itself useful in determining the dynamic relations of the two eyes and furnishing indications for treatment. It is sufficient to say that in my own practice I have found it a serviceable procedure and one which I would never omit when making an examination for heterophoria.

The corresponding test for the dynamic condition of the superior and the inferior recti—*i. e.*, by placing the eyes in the position "eyes up" and "eyes down"—may be employed, but is difficult of application and is usually conducted only with the visual axes in convergence. The ordinary excursion-test ("eyes left" and "eyes right") can likewise be employed with the visual axes convergent.

The recording of the results obtained by these various tests is much simplified by the use of the following abbreviations, which I have lately employed and have found of advantage as saving both time and space and as rendering it easy to exhibit in tabular form, suitable for ready comparison, the records of the examinations from day to day. Many of these abbreviations are already in use and are only given here for the sake of completeness; others have been used by Dr. Stevens and other investigators in this special field; while others still are my own invention, designed to represent the new terms introduced in this paper.

TABLE OF ABBREVIATIONS.

Ab.—abduction.	E. d.—eyes down; position (of deorsunversion) in which visual axes are parallel and both directed down.
Acc.—accommodation.	E. d'—eyes down in convergence; position in which visual axes converge and are both directed down.
Ad.—adduction.	E. f.—eyes front; position in which visual axes are parallel and both directed horizontally forward.
As.—astigmatism.	E. f'—eyes front in convergence; position in which visual axes converge and are directed horizontally forward.
As. C.—astigmatism corrected.	E. l.—eyes left; position (of sinistroversion) in which visual axes are parallel and both directed to the left.
As. h.—hypermetropic astigmatism.	E. l'—eyes left in convergence; position in which visual axes converge and are both directed to the left.
As. m.—myopic astigmatism.	E. r.—eyes right; position (of dextroversion) in which visual axes are parallel and are both directed to the right.
As. h. m.—mixed astigmatism with predominating hypermetropia.	E. r'—eyes right in convergence; position in which visual axes converge and are both directed to the right.
As. m. h.—mixed astigmatism with predominating myopia.	E. u.—eyes up; position (of sursumversion) in which visual axes are parallel and are both directed up.
At.—atropine, or under atropine.	
b.—base.	
b. d.—base down.	
b. i.—base in.	
b. o.—base out.	
b. u.—base up.	
C.—corrected, correction, or with correction.	
Conv., Cv.—convergence.	
D.—dioptric.	
D. or Di.—diplopia.	
Div.—divergence.	
D'—diplopia in accommodation.	
D"—diplopia with the red glass.	
D  —homonymous diplopia.	
DX—crossed diplopia.	
D. v.—vertical diplopia.	
D. L.—left diplopia; vertical diplopia with the image seen by left eye below.	
D. R.—right diplopia; vertical diplopia with image seen by right eye below.	
E.—eye.	

E. u'—eyes up in convergence; position in which visual axes converge and are both directed up.	Rf. C.—refraction-correction, or with refraction corrected.
Exc.—excursion.	R. g.—red glass.
Exc. T.—excursion test.	R. H.—right hyperphoria.*
Exc. T'—excursion test in accommodation.	S—esophoria.†
H.—hyperphoria.*	S'—esophoria in accommodation.
H'—hyperphoria in accommodation.	Sc.—behind screen eyes move.
H. C.—hyperphoria corrected or correction of hyperphoria.	Sd.—sursunduction.
Hm.—hypermetropia.	Sd. L.—left sursunduction.
Hm. C.—hypermetropia corrected or hypermetropia-correction.	Sd. R.—right sursunduction.
Ins.—insufficiency.	T.—tension.
Ins'—insufficiency in accommodation.	T. n.—normal tension.
L.—left.	Ten.—tenotomy.
L. E.—left eye.	Unc.—uncorrected.
L. H.—left hyperphoria.*	V.—vision.
M.—myopia.	V. M.—monocular vision.
M. C.—myopia corrected, or myopia-correction.	V. S.—single vision.
n.—normal.	V. S'—single vision in convergence.
Op.—ophthalmoscope.	VV.—binocular vision.
P.—parallax.	v.—vertical.
p.—prism; near point.	X—crossed; exophoria.†
P. lat.—lateral parallax.	X'—exophoria in accommodation.
P. L.—left parallax; image moves down when left eye is uncovered.	—homonymous.
P. R.—right parallax; image moves down when right eye is uncovered.	<—less than; after a number, denotes an indefinite amount more than this number.*
P. v.—vertical parallax.	<<—growing steadily less than.
P. X—crossed parallax.	>—more than; after a number, denotes an indefinite amount less this number.
P  —homonymous parallax.	>>—growing steadily greater than.
R.—right.	±—before a number or symbol, denotes positive; after a number, denotes this number plus a fraction less than one.*
r.—far point.	——before a number or symbol, denotes negative; after a number, denotes this number minus a fraction less than one.*
R. E.—right eye.	~—indefinite.
Rf.—refraction.	

The use of these abbreviations is illustrated by the tabular excerpt from my note-books, given on page 118, describing a case which I was permitted to examine through the courtesy of Dr. A. C. Palmer, of Norfolk, Va.

I lay some stress upon the form here employed, because it exhibits the proper order in which the tests should be made. In the columns headed "E. f." we have the record of the tests made in the "eyes-front" position, or that in which the eyes are in a state of equilibrium and in a condition least removed from the natural. The first column, headed "D., &c.," gives the result of an examination made without introducing any artificial element other than that due to the interposition of a red glass. The second and third columns show the record of the parallax and screen tests which are made simultaneously, and which, as before remarked, are to be performed before the prismatic tests for insufficiency. The latter are recorded in the fourth and fifth columns, the test for hyperphoria being made first and that for lateral insufficiency afterward, according to the

principles laid down by Dr. Stevens. After these static tests have been performed there can be made, if desired, the tests with the axes in convergence. These are recorded under the heading "E. f'," the column "D' & c." noting the existence of diplopia or parallax on convergence, and the next column the degree of insufficiency and hyperphoria in accommodation. Then the excursion test is made and the result recorded in the column "E. r. and E. l," and, if desired, the same test can be made with the axes in convergence, the record being placed in the column "Er' and El'." Last of all are placed the columns "Ab.," "Ad.," and "Sd.," in which the prismatic tests for the abduction, adduction, and sursumduction are entered. For the reasons before given, these last tests should be made after all the others.

Without going into a detail of explanation of all the entries, it will be sufficient to amplify one bearing the date of May 29th. Here the record shows that with the red glass there was crossed and right diplopia—that is, the image perceived by the right eye was below and to the left. No movements of the eyes were detected behind the screen, but the patient exhibited a homonymous and right parallax—that is, on removing the screen from the right eye, the candle-image moved down and to the right. The prismatic tests showed a right hyperphoria of 1° and an exophoria of  $\frac{1}{2}$ °. In accommodation there was either no hyperphoria or a tendency to right hyperphoria. On performing the excursion test, both in the position of "eyes right" and "eyes left," the crossed diplopia with the red glass became progressively less, and finally changed to single vision. The abduction was 4° with the refraction uncorrected and 6° with the refraction corrected, and the right and left sursumduction were each 1°.

It will be seen that by employing a tabular form of this sort, which a physician can read at a glance, the results of a long series of observations and trials can be very speedily recorded and most succinctly displayed.

NOTE.—Owing to the lack of distinctive terms to express the different ideas involved, the nomenclature of the motor conditions of the eye is somewhat confused. Abduction, for example, is used to denote (a) the absolute power of movement inherent in the external rectus (*i. e.*, the total capacity for movement outward of the eye without any deduction for the opposing tension of the internal rectus), (b) the net actual capacity for movement outward of one eye (*i. e.*, the difference between the maximum power of movement of the external rectus and the minimum power of movement of the internal rectus), and (c) the net amount of outward movement of both eyes conjoined (*i. e.*, the degree by which they can diverge from each other). The last is properly designated by the term *diverging capacity* or *divergence* [G. T. Stevens]. For the second

the word *abduction* may properly be retained. For the first there is no word existing, and therefore I would propose as its equivalent the term *exokinesis*. The corresponding terms for the inward movements of the eye are *esokinesis*, *adduction*, and *convergence*; for the upward movements, *anokinesis*, *sursumvergence*, and *sursumduction*; and for the downward movements, *catakinesis*, *deorsumvergence*, and *deorsunduction*. Or, arranging in tabular form:

Capacity for movement.	In.	Out.	Up.	Down.
Absolute capacity of a single eye, supposing there to be no opposing tension.	Eso-kinesis.	Exo-kinesis.	Ano-kinesis.	Cato-kinesis.
Net capacity of single eye.	Adduction.	Abduction.	Sursum- duction.	Deorsum- duction.*
Capacity of separation of the eyes from each other.	Conver- gence.	Diver- gence.	Sursum- vergence.	Deorsum- vergence.*

There also seems to be required some word to express the general condition in which the various muscular tensions and movements are so adjusted that the visual axes are directed without difficulty at any desired point, or are maintained in parallelism during distant vision; the condition, in other words, in which the individual movements of each eye are properly performed and are properly co-ordinated with the movements of its fellow. This state of perfect dynamic adjustment, which corresponds to the ideal static condition of orthophoria, is appropriately designated as *isokinesis*. The contrary condition, in which one eye fails to move with the other so that there is difficulty in directing one or both visual axes at an object, may be termed *anisokinesis*.

#### FIVE CASES OF DISLOCATION OF THE HIP.†

BY LEWIS A. STIMSON, M. D.,  
SURGEON TO THE NEW YORK, CHAMBERS STREET, AND BELLEVUE HOSPITALS.

THE importance of traumatic dislocations of the hip joint and the remarkably constant and definite results obtained by experimental study of them upon the cadaver, along the lines indicated by Professor Bigelow, have combined, notwithstanding the comparative infrequency of their occurrence, to make the knowledge of their mode of production and pathology apparently complete, and to give the methods of reduction an exceptional definiteness of plan and execution. On the other hand, the injury so rarely comes under the observation of the practitioner, even of the hospital

\* In practice, the terms deorsunduction and deorsumvergence are not employed, it being found more convenient to speak of the conditions opposed to right sursumduction and right sursumvergence as left sursumduction and left sursumvergence rather than as right deorsunduction and right deorsumvergence.

† Read before the New York Surgical Society, May 8, 1889.

surgeons of large cities, that our knowledge of it is, as a rule, rather theoretical than practical and personal, and it seems desirable that from time to time, as occasion serves, the subject should be reviewed, to the end that the scattered results of individual experience may be brought together to refresh our appreciation and perhaps to improve our treatment. The subject has been recently brought prominently to my mind by five cases that have come under my care during the last year, three of them within the last month, and it is to the record of these cases that I ask your attention. Three were dorsal, two obturator, dislocations.

CASE I.—F., forty-eight years old, a spare, muscular man, was brought to the Chambers Street Hospital, June 8, 1888, having just been knocked down and run over by a wagon. He had suffered a dorsal dislocation of the right hip and a compound intra-articular fracture of the left tibia and fibula. As he lay on his back, the right thigh lay in a posture of flexion, adduction, and inward rotation, its knee resting upon the front of the other thigh, about a hand's-breadth above the left knee. The right trochanter was very prominent, the muscles between it and the anterior superior spinous process of the ilium were raised in a longitudinal swelling, and the muscles of the posterior portion of the thigh were thickened by the shortening of the limb. But little motion could be communicated to the limb, except in the direction of further flexion, and even that was resisted and painful. There was an abrasion on the outer side of the upper part of the leg.

Ether was administered, and a number of attempts to reduce were made by flexing the limb to or beyond a right angle while preserving the adduction and inward rotation, then abducting, rotating outward, and lifting the limb by means of a bandage passed under the flexed knee and over the shoulders of the operator, but without success; the head was firmly fixed behind the acetabulum, and did not move forward in the least. I then sought to enlarge the opening in the capsule by circumduction and rotation, and repeated the effort, but still in vain. Finally, traction was made by Dr. Kimball, the house surgeon, in the direction of the axis of the limb as it lay in its first position of flexion and adduction, while I made pressure inward against the trochanter, and the bone slipped into place.

During the long confinement to bed made necessary by the fracture of the leg the patient recovered entirely from the injury to the hip.

CASE II.—J. S., twenty-two years of age, a large, muscular man, was admitted to the Chambers Street Hospital, February 3, 1889, with a dorsal dislocation of the right hip caused by the overturning of a cab which he was driving. The cab fell upon him, but he was unable to describe the attitude of the limb in the fall, or the direction in which the violence acted upon it. No recognizable bruises.

When I saw him, shortly after the accident, he manifested considerable shock, moaned constantly, and complained loudly whenever the limb was touched. He lay on his back, with the right thigh flexed and adducted, so that its knee lay upon the lower part of the other thigh. The right trochanter was very prominent, and the upper part of the thigh widened.

I drew him toward the foot of the bed until the pelvis projected beyond it, and then turned him upon his face; the left thigh was held horizontally by an assistant; the right thigh hung directly down, the knee flexed at a right angle, and I supported the ankle. After a few moments the muscles of the thigh began to relax, the patient complaining loudly all the time and asking for water. I shook the limb gently from side to side, and, when the muscles appeared to be freely relaxed, gave

a slight push downward with my fingers at the hollow of the knee, and the bone slipped into place with a snap.

CASE III.—G., fifty-six years of age, was admitted to Chambers Street Hospital, April 1, 1889, having just fallen down a hatchway and received a dorsal dislocation of the right hip and a comminuted fracture of the left patella. He presented no appearance of shock, and made no complaint of pain. As he lay on his back, the lower extremities were nearly parallel, the left being slightly abducted, the right rather more adducted and rotated inward. The pelvis was tilted about its transverse axis, so that the thighs were actually flexed upon it, although their full length rested upon the bed, and there was a well-marked anterior curve of the lumbar spine. The upper part of the right thigh presented the fullness and change of appearance noted in the two other cases; it could not be abducted.

He was drawn to the foot of the bed and turned upon his face, with the right thigh hanging down, as in the preceding case. He made no complaint, but kept the muscles of the thigh tense. After waiting two minutes, I placed a five-pound sandbag upon the upper part of the leg, in the hollow of the knee, and asked him to describe his accident. As he talked the muscles could be seen to relax, and on the expiration of two minutes and a half I found, to my surprise, that the head of the bone had returned to its place without jar or sound. The limb could be freely abducted, everted, and extended. He was returned to bed, and a long side-splint applied.

As the fragments of the broken left patella showed no tendency to separate, that limb was simply secured upon a straight posterior splint.

He slept but little during the first two nights, and became very nervous, and finally so delirious that restraint was necessary. The urine was loaded with albumin. He grew better for a time, then worse, and died April 10th, without having shown any noticeable inflammatory reaction at the injured parts. The autopsy showed chronic parenchymatous nephritis, and pulmonary phthisis at both apices.

The rent in the capsule ran along the edge of the posterior part of the cartilaginous rim of the acetabulum for about two inches from the notch, and from its upper part a prolongation ran for a short distance parallel to and in close relations with the tendon of the obturator internus. On the anterior surface of the head of the femur was a broad, shallow contusion caused by contact after dislocation with a piece of bone of new formation developed in the soft parts close against the outer surface of the cartilaginous rim of the acetabulum adjoining the rent in the capsule. This specimen was shown to the society at the meeting of April 24th.

In respect of the symptoms, the first two cases presented the classical ones of flexion, adduction, and inward rotation, but in the third the two limbs lay almost parallel to each other and flat upon the bed; and yet in the latter, flexion of the joint was actually present, but was masked by the tilting of the pelvis, which was itself shown by the anterior curve of the lumbar portion of the spine. This lordosis was a feature better known, I think, to the surgeons of a generation ago than to those of the present time; at least, I have not found it noted in cases reported of late years, and one of the surgeons of this city, forty years ago, was accustomed to say that he could recognize a dislocation of the hip by passing his hand under the small of the back. It seems to be worth bearing in mind, to avoid being misled by an apparent absence of flexion.

Very few specimens of recent dislocation have been re-

ported, and the one obtained from the third case differs from most others in the position and shape of the rent in the capsule, which lies much closer than usual to the rim of the acetabulum. It is entirely unique in the bruise upon the anterior portion of the head of the femur—a bruise resembling that sometimes produced upon the head of the humerus by impact upon the anterior edge of the glenoid fossa in anterior dislocations. Its production in this case appears to have been due to the presence of the abnormal piece of bone developed behind the labrum cartilagineum.

The feature of most practical importance appears to me to be the method by which reduction was effected in the last two cases. It is one which I had once previously employed with success, and which is briefly referred to in Bigelow's monograph upon the hip. Its advantages are that it does not require anæsthetization or the exercise of any force. Although the opposition of the un torn portion of the capsule is an element of prime importance, that of the spasmodically contracted muscles is equally so, and this contraction, when not annulled by anæsthetization, has often proved sufficient to defeat well devised and executed measures to reduce by manipulation. Indeed, the possibility of completely relaxing the muscles by the aid of ether or chloroform has made the reduction of most recent dislocations an extremely simple and easy matter, and has greatly reduced the importance of considerations drawn from the position and influence of the capsule. But, even when the muscles are completely relaxed and the patient is lying upon his back, the surgeon has to overcome the opposition of the weight of the limb; he must not only move it successively into various positions, but he must also lift it, and this, if the patient is large, means the lifting of a weight of forty or fifty pounds while standing in a disadvantageous position and occupied with the necessary manipulations. It was after having become hot and tired in thus reducing a dislocation, one summer day, that the thought occurred to me of making the patient himself do this work, or rather of making the weight of the limb a coadjutor in the reduction instead of an opponent. When, three years ago, the first opportunity to try it came, the attempt succeeded in less than a minute, and the success of the same plan in the second and third cases here reported indicates that it is one likely to succeed in many cases, and that, as it can be employed without anæsthesia or special apparatus, it may save both patient and surgeon much inconvenience and delay. All the apparatus it requires is a support for the body of the patient sufficiently high above the ground to permit the thigh to hang down vertically while the leg is horizontal, and for this a couple of stout planks or the bottom of a farm wagon would be sufficient. Two of the three patients upon whom it was used complained greatly of feeling faint while they were lying prone, but I thought this was to be deemed an advantage, as favoring prompt relaxation of the muscles. The third patient was so entirely at his ease in this position that he was able to give a detailed account of the manner in which he received his injury.

The remaining two cases are *obturator dislocations* of the perineal variety—the only ones I have seen.

CASE IV.—Charles F., aged thirty-two, a large, muscular man, was admitted to the Chambers Street Hospital, April 11, 1889, with a dislocation of the left hip produced in the following manner: While he was reaching up to aid the descent of a box weighing about 1,000 pounds, it slipped and fell upon his back, flexing his trunk upon his thighs and crushing him to the floor; his right thigh was in front, its hip and knee flexed; the left thigh was widely abducted. I found him lying on his back in bed, with the left thigh flexed and abducted so that it stood out almost at right angles from the side of the body, the knee resting on a cushion and pillow, the leg flexed at a right angle with the thigh, and secured by a band at the ankle to prevent involuntary movements. The flexion and abduction of the thigh were each between 60° and 70° from the frontal and sagittal planes, respectively. The distance from the anterior superior spinous process of the ilium to the lower edge of the condyle of the femur was one centimetre and a half less on the injured than on the opposite side when the right thigh was placed as nearly as possible in the same position as the other. The right thigh could not be abducted quite as widely as the left was. The soft parts on the upper inner side of the injured thigh were prominent, and a rounded mass could be felt beginning one inch from the rhaphe of the perineum, extending forward to the line of the adductor longus and backward nearly to a transverse line drawn through the anus. This was not depressible, contrasting strongly in this respect with the easy depressibility on the other thigh between the flexors of the leg arising from the tuber ischii and the adductors. The adductors were rather tense. The leg could not be freely extended at the knee, lacking 20°. The finger in the rectum, when pressed against the inner surface of the obturator internus covering the obturator foramen, could recognize rotatory movements communicated to the thigh. The region of the great trochanter was deeply depressed. Passive movements of the hip could not be made, except slight additional flexion and rotation.

The prominence of the head of the femur near the perineum makes it proper, I think, to classify this case in the perineal variety of obturator dislocations.

After an unsuccessful attempt to reduce without anæsthesia by manipulation in the prone position, ether was administered; the previous attempt had made the head less prominent, and reduction was readily effected by increasing the flexion with outward rotation, making traction in the axis of the limb, abducting, and then lowering the limb beside the other. There was no recognizable jar or sound as the bone returned to its place.

The patient was kept in bed with a long side-splint for nearly two weeks, and was discharged May 2d.

CASE V.—William B., aged forty-three, a strongly built, muscular man, was admitted to the Chambers Street Hospital, April 22, 1889, with an obturator dislocation of the right hip. He was engaged in moving a heavy piece of machinery from a truck and was kneeling upon the ground on his right knee, beside its projecting end, when it overturned sidewise upon him, striking him first upon the left shoulder. As it was falling he threw his body backward and to the right to save his head, and it was probably during this movement, aided by the pressure upon his left shoulder, that the dislocation took place. His only contusions were at the left shoulder and on the inner side of the right knee, where it had been struck by the machinery as the limb rested on its outer side upon the ground. I was at the hospital when he was brought in by the ambulance.

The right thigh was flexed and widely abducted, so far that when the left thigh was placed as nearly as possible in a similar position, the distance between the knees was thirty inches. The position of the limb closely resembled that in the preced-

ing case. The upper adductor region was abnormally full, the trochanter depressed. The finger in the rectum, pressed against the obturator foramen, could indistinctly feel rotatory movements communicated to the thigh. Measurement from the anterior superior spine of the ilium to the knee showed shortening of two centimetres on the injured side. Adduction and extension painful and opposed.

After an unsuccessful attempt to reduce by manipulation in the prone position, ether was administered and reduction effected on the second attempt by the method employed in the preceding case, the head slipping into place with a distinct snap while the limb was being lowered.

The patient was kept in bed for twelve days with a long side-splint, and is now walking about the ward.

The mode of production in the first case, and probably also in the second, was wide abduction of the flexed thigh, and this explains the attitude of the dislocated limb, which differs strikingly in the extent of the abduction and flexion from that found in most obturator dislocations. In several reported cases of the common form the patients have been able to walk immediately after the accident, and in one the patient sought advice only because he found he could not adduct the limb freely. This wide abduction with flexion beyond the normal limit is constant in the perineal variety, and possibly it would be advisable to class all cases presenting that symptom in that variety, even if the head of the femur, as in my second case, should not noticeably impinge upon the perineum.

The ease with which reduction can be effected is gratifying: flexion and outward rotation to disengage the head from the projecting rim of the acetabulum, traction in the axis of the limb to bring it opposite the cotyloid cavity, adduction and extension to turn it into the socket.

In both cases I tried, as in two of the dorsal dislocations, but unsuccessfully, to make the unsupported weight of the limb take the place of anaesthesia to relax the muscles. The patient was laid upon his face with an inclination toward the injured side, so that the abducted limb should hang vertically downward, and then, after the muscles had relaxed, I attempted the same manipulation which subsequently succeeded under ether. But in each case, and although in one the effort was prolonged for fifteen minutes, at the first movement of the limb the muscles contracted powerfully and the limb became fixed. It is true that both patients were exceptionally muscular and their strength was not diminished by shock. Possibly in feebler patients, or if the pelvis was so raised that the thigh would hang nearer to the abdomen, the attempt might succeed.

[Dr. Cole, of the house staff of the Chambers Street Hospital, has recently extended this method of obtaining muscular relaxation to the reduction of anterior dislocations of the shoulder, and it has proved successful in the three cases in which it has been tried. The arm is allowed to hang by the side, with the wrist lightly supported in the surgeon's hand and the elbow flexed at a right angle, and is gently shaken until the muscles are seen to relax; then a smart blow is struck downward with the hand at the fold of the elbow, and at the same time the arm is rotated outward. In each case the head of the humerus instantly returned to its socket.]

## THE SURGICAL TREATMENT OF INVETERATE TIC DOULOUREUX.\*

BY ROBERT ABBE, M. D.

THE procedure to which I invite your attention is not a new one entirely, but so rarely advocated and yet so important that it impresses me as fully worthy of our time to-night.

Fortunately, cases of obstinate tic douloureux are not very common. When they become chronic there are few diseases that produce the agonizing distress of the constantly recurring shocks of acute pain in the cheek, jaw, and often half the head. It distracts the mind from work. It seizes the victim every few moments in the midst of conversation, forces tears and exclamations, produces salivary flow in excessive amount, prevents eating and sometimes sleeping, and brings him to the verge of despair. The time of its continuance is often measured by years, and, while it does not usually wreck the patient's physique, it exhausts his powers of endurance and work.

The store-house of medicinal remedies has been exhausted without reaching most of the cases, and it has not been until recent years that surgery has been able to rescue these sufferers.

In 1851 Dr. J. M. Carnochan operated in the first case for complete resection of the second branch of the fifth pair from the foramen rotundum to the infra-orbital foramen—with the removal of Meckel's ganglion—with complete success. This marked an era which has been proved by numerous other successful cases.

Prior to his publication in 1858 the simple subcutaneous section of the infra-orbital nerve in the cheek had had many ardent advocates and as many opponents, but no one dared nor cared to go back of this point to extract the nerve.

In the early part of the century Brodie speaks of the "*notorious failure of simple nerve section in tic douloureux*," and Velpeax, Stromeyer, and others speak of the momentary relief only that comes from it.

The weight of opinion had led to its practical abandonment. The discovery of the value of resection of portions of nerves in obstinate neuralgias led to the delicate operation of Langenbeck to remove a considerable portion of this nerve from the floor of the orbit. He isolated the bundle of nerves at the infra-orbital foramen in a small incision, and then passed a narrow curved bistoury into the outer side of the orbit below the lid, inward toward the posterior part an inch and a half, when, on turning it down, he cut the nerve in its groove and pulled it out by the infra-orbital end. This method prolongs the period of relief from pain, but recurrence follows.

Nothing so bold as Dr. Carnochan's operation had been previously tried. He operated as follows: A V-incision was first made below the eye, and from its apex a straight cut was extended downward through the entire cheek and lip half way between the nose and the corner of the mouth. The nerve ends were then gathered up at the foramen of exit and a trephine was applied to the front of the jaw, removing the front

\* Read before the New York Clinical Society, May 24, 1889.

bony wall of the antrum. The roof of this cavity, being of thin bone, is readily broken in and the nerve drawn down from the orbital cavity. The back wall of the antrum is next broken away and removed, which exposes the sphenomaxillary fossa, which at this point is little more than half an inch deep. The nerve can now be cleaned away from its cellular surroundings and traced to the foramen rotundum, which is on a line with the inner wall of the antrum. Here it is readily cut square off. The posterior dental nerves and Meckel's ganglion connect in front of this, and thus all communication of the jaw with the nerve centers is cut off beyond the chance of repair.

This method he followed in all his patients. A few years later Dr. James R. Wood added several cases to the list and modified the operation only in not making the cut clear through the lip. Their work, as was usual in those days, was followed by what they called "healthy suppuration" and excellent healing, the antrum being syringed out if needed during the cure.

In 1879 Dr. F. S. Dennis, of this city, collected twenty-one cases of this operation ("N. Y. Med. Journal," June, 1879), and the report made a most admirable showing in favor of this operation so creditable to American surgery. The method is probably the best one for approaching the foramen rotundum, but other methods by Gerster, Luecke, and others of going from the side of the cheek, cutting the malar bone and the zygoma, and working in the narrow fossa from the side, have been tried. They are apt to be more bloody and perhaps less certain of exact feeling of the foramen.

The simplifying of dressings and attainment of primary union in the wounds now possible make certain valuable modifications of the operation practicable, which I have adopted in three cases. The best point is the small skin incision, which leaves a small scar. One inch and a quarter, either horizontally, vertically, or obliquely, over the infra-orbital foramen gives ample room for operating. I have found a gouge better than a trephine for penetrating the antrum, front and back. A narrow, forked, blunt instrument to straddle the nerve and assist in dragging it down into the antrum saves it from laceration.

No bleeding occurs that is not readily checked by sponge-pressure, even the sharp welling-up that occurs when the nerve and its companion vessel are cut. The dressing of the wound is of special importance, and the most perfect result is obtained by packing iodoform gauze lightly into the antrum, the end of a long strip being folded into a small pad to be placed deep in the wound against the foramen rotundum and the rest lightly added on top, and allowed to keep the wound apart on the cheek. After thirty-six or forty-eight hours this gauze is entirely removed and the wound sutured with care.

The anaesthesia of the cheek allows of secondary suturing without pain to the patient. What little exudation may follow this dressing is retained and needs no drainage, primary union invariably resulting if the dressing is made with care. The depressed scar becomes flattened after a few weeks.

Of the three cases coming under my care in the last

year I have reported one only ("N. Y. Med. Journal," Feb. 16, 1889):

**CASE I.**—The man had a unique history, a rod piercing his neck and ascending to the base of the skull, where it injured the fifth nerve and produced hemianæsthesia of his left half face, neck, and scalp. Tic-douloureux ensued in the second branch of the fifth and had continued unabated. He found no encouragement to hope for relief by operation, though he sought it not only here but in Germany. It was so severe that he attempted his life by shooting, but only wounded his chest.

Dr. Hammond treated him by medicines without relief, and referred him to me.

I operated, October 20, 1888, by the method just detailed. Meckel's ganglion was broken up by lacerating the tissues in which it was imbedded. The neuralgia was at once and permanently relieved. I have lately seen him, and he has had no return of pain, seven months after operation.

The man was undoubtedly a sufferer, and was scarcely ever seen without his handkerchief pressed into his cheek and brooding over his infirmity. Now his actions are entirely changed.

The next case was more severe in the character of the pain.

**CASE II.**—John T., aged sixty-five years, a man of rather heavy build and well preserved, who had followed the out-of-door life of a gardener, began, four years ago, to have neuralgic pain of the right upper jaw, first felt in the premolar teeth and radiating from a painful point on the cheek, near the ala nasi, up to the temple and back of the ear and through the jaw. It was paroxysmal at first. He had a tooth extracted one year later, and subsequently others, until all were removed one year ago. A temporary relief occurred for a fortnight, but for the past year pain has been incessant and unbearable. The slightest excitement, or biting on any substance, sucking in ever so little air or cold drink, touching the gum or the roof of the mouth, even talking, brings on an intense paroxysm of pain, causing him to dodge with his head as if to get away from it, and inducing a profuse flow of saliva and often of tears.

Even independent of irritation and occurring at night, the paroxysms come on with equal severity every few minutes, and sleep has only been by short naps. Stormy weather makes the pain worse. He has had to abandon his work. External applications have given a little relief, especially dilute spirit of chloroform, which he has applied so constantly, at night especially, that his cheek has been kept irritated almost to blistering. Internal medication has uniformly failed, and he has come to use opium, in one-grain doses, five times daily for a year or more.

In order to test aconitine, I referred him to Dr. Dana for a while before operating. He returned him to me in two weeks as a typical sufferer with tic douloureux adapted to surgical relief, and on which medicine was useless.

*January 9, 1889.*—I operated before a large class of physicians at the Post-graduate Hospital by Carnochan's method, through a small vertical incision an inch and a quarter in length. The superior maxillary bone was extraordinarily hard in this man, and I chiseled a circle, three quarters of an inch in diameter, with the foramen in the center.

I had some difficulty in breaking through the posterior wall of the antrum on account of the hardness of the bone, but finally drew the nerve well out of the canal and exposed it to the foramen rotundum, where I cut it, and broke up Meckel's ganglion as thoroughly as possible. The wound healed without suppuration, but he had considerable of his old pain for two or

three days. Anæsthesia of the cheek, however, showed the satisfactory removal of the nerve, and in less than three weeks his pain had absolutely gone, leaving him happier than for years. He stopped the use of opium at once. At present, four months and a half since the operation, he remains perfectly well, and nothing that he does can induce the slightest pain. The scar, which was indented, is coming to the surface and is of no importance.

CASE III.—Edward Condon, aged forty-five years. Patient has always been a healthy man until he was taken unaccountably with tic douloureux in the right upper jaw eleven years ago. He had all the teeth of the right upper jaw removed one after another with relief only for a few months. It returned and has continued with more or less severity for ten years past. The punctum dolorosum is near the ala nasi, but the agonizing spasmodic tic radiates through the jaw and the side of his head. For six months past it has been nearly constant, night as well as day. Sometimes he gets five or six hours' consecutive sleep, but if he is suddenly roused the pain is brought on. In eating, speaking, expectorating, breathing cold air, drinking, or jarring the body, spasms are sure to occur. In eating meals he has everything prepared finely chopped and arranged on his plate so that he devours it in the shortest possible time so as to hurry through the agony of it. The flow of saliva is very free and constant.

His treatment has been very varied, and for two years he has been cared for assiduously by Dr. Hammon, who referred him to me, hoping that surgery might do what medicine had failed in.

*January 18, 1889.*—I operated by Carnochan's method, before a large number of physicians, using a short (one-and-a-quarter-inch) incision.

The antrum was packed lightly with iodoform gauze.

*20th.*—Forty-eight hours later. Packing removed and the wound stitched with fine silk. Antrum closed; no drainage.

*24th.*—Fourth day. Primary union has occurred; stitches removed. The patient has been absolutely free from pain since the operation, for the first time so completely in eleven years.

At the present date, after four months and a half, he is still without pain and correspondingly happy.

These three cases afford corroborative proof of the value of deep nerve resection in facial neuralgia. The resection or section of the anterior portion of the infra-orbital is of little use, and, as Brodie and others found, practically worthless, producing at best in a few cases a temporary relief, and in most no relief at all.

Langenbeck's clever and attractive operation on the anterior portion of the nerve is a marked improvement over the simple section at the foramen.

In a most intractable case under Dr. Seguin's care in 1881 he did Langenbeck's delicate procedure with relief for some months, but, on the pain recurring—with all its former fury—he referred the man to Dr. Weir, who operated by Carnochan's method through the antrum, removing the posterior part of the nerve to the foramen rotundum and destroying Meckel's ganglion. The man remained perfectly cured when last seen, three years later.

The inferior dental nerve is much more easily removed. I operated on March 8th on a lady referred to me by Dr. W. C. Campbell, for neuralgia of the right inferior maxillary nerve of two years' duration. The paroxysms were like those of the cases narrated, and quite as distracting and discouraging. I made a one-inch incision only, parallel with

the edge of the jaw, and near its angle. On reaching the bone, I chiseled a long furrow so as to expose the nerve in its canal, and resected an inch of it. The wound closed by primary union. Anæsthesia of the anterior half of the lower lip ensued, but the pain continued for two or three days, when it entirely disappeared and has not returned.

## A CASE OF FOREIGN BODY IN THE ORBIT.\*

BY JAMES P. MARSH, M. D.,  
TROY, N. Y.

THE patient who is the subject of this report is thirty-two years old and a blacksmith by trade. On January 16, 1888, he was struck in the left eye by a chip, which flew off from the hammer he was using. However, at this time it was impossible to ascertain any facts appertaining to the size or weight of this fragment. He came to my office immediately after the reception of the injury, as he was bleeding profusely and was slightly shocked.

Examination of the injured eye revealed a lacerated wound of the conjunctiva, situated in the fold or sulcus formed by this membrane between the ball of the eye and the external canthus. The general contour of this wound was V-shaped. There was no corneal injury, but there existed a rent in the iris, extending obliquely from below upward, running across that part of the iris just below the pupil, but not entering it. I did not at once make an ophthalmoscopic examination, but washed out the conjunctival wound with an antiseptic solution, and proceeded to probe for a foreign body, which I thought must be in the orbit. After as careful and extensive probing as I deemed safe, I could not find anything. At this juncture a professional friend happened to call upon me, and, as he is one of our foremost surgeons, I asked him to try the probe. This he did as thoroughly and skillfully as it could be done, but with negative results. Together we made an ophthalmoscopic examination, finding that the retina had become detached over the greater portion of the external half of its attachment. The patient's vision was about an eighth of the field, and limited entirely to the extreme left side. The macula lutea was involved in the retinal detachment, and hence his remaining sight was of but little use to him. We again probed the wound, with negative results.

The injured eye was placed under the influence of atropine, and cold wet cloths, together with a light bandage, were applied. The patient was placed in a darkened room, and complete mental and bodily rest enjoined. After two days of this treatment the case passed into the hands of one of our leading specialists, who continued the same treatment that I had adopted. The wound also was probed several times without the foreign body being discovered, and finally we were forced to believe that it had in some unaccountable way passed out of the orbit. The conjunctival wound healed promptly. The patient possessed all the movements of the ball, and suffered neither pain nor discomfort, excepting as regarded his defective vision.

On May 2, 1889, the patient again presented himself at my office, and stated that, although there was no pain in his injured eye, something was growing between the lids on that side, and he wished to have it attended to. On examination of the original wound, it was found that it had reopened, and that the V-shaped conjunctival flap had become doubled over in such a

\* Read before the fifth annual meeting of the Second District Branch of the New York State Medical Association, held at Saratoga Springs June 18, 1889.

way as to project between the lids at the external canthus. In the wound nothing appeared, but with a probe I could detect a hard body in apposition with the posterior wall of the eye. With a fixation forceps it could be seized and brought into sight at the bottom of the wound, but, when additional traction was applied, it would slip out from the grasp of the forceps and fall back out of sight. However, under cocaine, I enlarged the wound, and with two forceps succeeded in extracting this piece of steel. The specimen weighs fifty one grains. It measures five eighths of an inch in its longest diameter, nine sixteenths of an inch in its shortest, and is five sixteenths of an inch in thickness. An ophthalmoscopic examination of the eye, made a few days after the extraction of the foreign body, showed that the retina of almost the whole lower external quadrant and of the lower half of the upper external quadrant had been detached, and was now in a state of atrophy. This process involved the macula lutea. The field of vision remains about the same as we found it immediately after the reception of the injury. Although the patient is confident that his sight is improving, I fear that the original prognosis of almost complete loss of useful vision will be borne out.

From the dates given, it will be observed that this bit of steel was carried in the orbit, without the knowledge of the patient, for nearly sixteen months. Although it was probed for at least a dozen times by three different operators, at the time of the extraction there were no evidences of suppuration. This certainly speaks well for the antiseptic precautions employed. Evidently this foreign body was in an absolutely aseptic condition at the time of its entrance into the orbit. This condition, in my mind, was owing to such a degree of heat being generated in the hammer by the repeated blows which had been struck with it as to thoroughly destroy all microbes and spores which might have been adhering to it.

It will, perhaps, seem to some that I should back up this remarkable case by duly attested affidavits, but, not being a newspaper man, and as misery seeks company, I refer the curious to a case mentioned by Carter, wherein a portion of an iron hat-peg, three inches and three tenths in length, remained for twenty days in the orbit without the knowledge of the patient.

Generally speaking, any foreign body which becomes lodged in the orbit induces extensive cellulitis unless promptly removed, but the above-described case is a notable exception to the rule. Dr. Noyes justly remarks that foreign bodies in the orbit are at times very difficult of detection, and narrates a case in which a twig, an inch and an eighth long and as large as a No. 8 Theobald's lacrymal probe, became lodged in the orbit, and that, failing to find it with the probe, he used his little finger as an explorer, yet met with considerable difficulty in locating it. Speaking as regards my own case, I have come to think that I should have enlarged the conjunctival wound and explored the orbit with my little finger.

57 FOURTH STREET.

**Iodized Glycerin.**—“Dr. G. Hammond (*‘London Med. Recorder’*) points out that a mixture of tincture of iodine and glycerin produces a greater effect on the skin than the pure tincture, possibly because the glycerin tends to prevent the evaporation of the iodine, and thus enables the whole of its powers to be utilized.”—*Druggists’ Circular and Chemical Gazette.*

D. APPLETON & CO.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, AUGUST 3, 1889.

SUMMER DIARRHOEA.

THE town of Leicester, England, has for many years had an unenviable prominence in the English bills of health as a “diarrhoeal town.” It stands at the head, more frequently than any other English town, of the lists of mortality-rates by diarrhoeal disease. Local effort to discover and remove the causes of the trouble having failed, the Local Government Board voted to lend its aid, and designated its eminent inspector, Dr. Edward Ballard, to institute an inquiry into the existing conditions in Leicester and other diarrhoeal towns. Dr. Ballard’s report, termed by himself “provisional,” has recently appeared. As will be seen from a brief analysis, given below, his work has not been crowned with very great success; he has been content to give a summary of the best results obtained in England and Germany. His chief conclusion is that the temperature of the soil air is the key-note to the aetiology; for until the mean temperature of the soil at the depth of four feet has risen to 56° F., summer diarrhoea does not become prevalent. The quality of the soil also enters into the account; a town that is founded upon rock, with a thin superjacent soil, will not suffer so much from this disease as a town built upon a loose, porous soil capable of retaining much moisture. A soil containing organic matter from soakage of refuse will favor the occurrence of diarrhoea. So, too, overcrowding in tenements, the occupation of mothers in factories, bad water-supply, and bad sanitation generally will promote the disorder. Improper food does the same; but it is not in the food and drink, he thinks, whether they are proper or improper, that the real causation rests. It is something which, added to them, infects them, and thus the disease arises. Dr. Ballard points to the fact, frequently observed in this country regarding cholera infantum, that breast-fed infants are peculiarly exempt from fatal intestinal troubles when compared with those that are bottle-fed. He finds that the immunity vanishes exactly in proportion as artificial feeding takes the place of the use of breast milk, and that of all the forms of feeding, that with the bottle is the worst. Dr. Ballard believes that this extraneous agent is a micro-organism, not yet detected and isolated, whose habitat is ordinarily in the superficial soil, and which escapes into the atmosphere under certain seasonal influences and, attaching itself to the various food substances, especially to milk, may, by virtue of some of its life processes, produce in them a virulent chemical poison; and that this poisonous substance is the material cause of epidemic diarrhoea. His remedy for epidemic summer complaint is of the nature of a general admonition in favor of wholesome living, of pure drink and food, of a pure atmosphere, and of an avoidance of contaminations from in-

fected persons, from soil, and from sewers. He advises the disinfection of the discharges, as in typhoid fever; also attention to the condition of the sewers by the health authorities.

This report is not in itself a great gain to the subject, since it is admittedly "provisional"; it is a report of progress. But it is valuable, since it commits the great Local Government Board to a continued pursuit of these vastly important inquiries. It means that the subject will be exhaustively studied by experts of the first rank. Dr. Klein, the well-known pathologist to the Brown Institution, was associated with Dr. Ballard, and made numerous autopsies and microscopical investigations. His report concerning the search for a micro-organism is negative. He examined the blood, tissues, and excreta, but could discover nothing that tallied with Dr. Ballard's theory. One fact in Dr. Klein's report has an important bearing on the prognosis of summer complaint—namely, almost invariably the kidneys were found inflamed, even in cases where the duration of the attack had been only a few hours. It will be well to have this discovery tested in this country, by those having opportunities so to do, during the present season. The avoidance of opiates, the use of aseptic foods—breast milk being one of them—and the resort to the seaside and mountain atmospheres of purity, have been suggested many times before; now they are weightily confirmed by Dr. Ballard.

#### THE THEORY OF SUPPURATION.

THE bacteriological theory of suppuration as it is at present accepted will doubtless admit of many modifications before it can reasonably be held to be perfect. Future researches may demonstrate the relative unimportance of the micrococcus as a pus-producing agent, and overthrow all the present theories, even as the theories of the past generation have been overthrown. Professor Paul Grawitz, of Greifswald ("Archiv für pathologische Anatomie und Physiologie und für klinische Medicin," cxvi, 1), by proving that suppuration may be caused by the injection of irritating substances unaccompanied by any micrococcus or ptomaine, has perhaps taken a step in this direction. The experiments were performed mainly on dogs. With the most careful aseptic and antiseptic precautions, a certain quantity of oil of turpentine was injected subcutaneously, and the wound was closed with collodion. Over this a dressing was placed. A swelling with the external characteristics of an abscess was produced which, when opened, was found to contain a pus-like fluid smelling decidedly of turpentine and perfectly free from pus cocci.

This demonstration is interesting because it indicates a possible danger which may arise from the subcutaneous injection of irritant fluids even under the strictest aseptic precautions, but we do not see how it can have great weight regarding suppuration as it is commonly met with, because practically we do not find abscesses of this nature. It proves that substances exist, in addition to the ptomaines of the micrococci, which when introduced into the tissues will produce inflammation with the formation of pus, but it does not in the least intimate

that the ptomaines do not usually occupy the position held by the turpentine in the experiments as excitors of suppuration.

Grawitz also calls attention to the fact that the resisting power of the tissues of different genera of animals to the action of a given micro-organism differs widely, and insists that more attention should be paid to this when deductions regarding suppuration in man are drawn from observations on the lower animals. His remarks would be much more apposite if the question were, "What is the action of a certain micro-organism on the tissues of man?" But this is not the question. If we grant what he says to be true, still the fact remains that in all animals the destructive process known as suppuration is found accompanied by some micrococcus. That the particular micro-organism differs in the different genera does not preclude the possibility of arriving at a very close approximation to the truth regarding the action of the micro-organism constantly present in human pus, by careful observations of the actions of the various micro-organisms that are constant in similar conditions in various genera of the lower animals. Still, analogy is not always a safe guide, and Professor Grawitz may be right in his caution. His work bears the mark of much labor, and, though his results are decidedly theoretical rather than practical, they are worthy of notice.

#### MINOR PARAGRAPHS.

##### THE DIAGNOSIS OF THE SITUATION OF THE PLACENTA BY PALPATION.

On the occasion of a paper being read by Dr. Herbert Spencer before the Obstetrical Society of London, at a meeting reported in the "British Medical Journal," there took place a most interesting discussion on the possibility of diagnosticating the position of the placenta by abdominal palpation. Dr. Spencer reported two cases of placenta situated in the upper segment and seven others of placenta *prævia* of which he had thus been able to determine the position. In three of the seven cases the exact site of the placenta on the front wall of the lower segment had been determined by abdominal palpation, and in two of these the placenta was felt at a time when it was impossible to feel it by the vagina. In the remaining four cases the placenta was shown by abdominal palpation to be absent from the front wall. Dr. Hicks and Dr. Barnes had also been able to locate the placenta by abdominal palpation, but Dr. Matthews Duncan, Dr. Boxall, and Dr. Champneys did not believe in the possibility of so doing. Dr. John Phillips, in a Caesarean section, and Dr. William Duncan, in a Porro's operation, had taken every precaution to avoid the placenta, and yet had cut into it. They, moreover, believed that the presence of the abdominal wall would still further increase the difficulties. In Dr. Spencer's cases the placenta was "felt as an elastic mass of the consistence of a wetted bath sponge," with defined edges, obtruding itself between the hand and the foetal part, of which latter it interrupted the contour and lessened the shock of communicated movements. Barnes had found that, when the placenta was placed in the upper zones and in front, "the uterine wall was thickened and raised at the area of placental attachment, forming a hillock which rose above the level of the smooth surface of the uterus." That this position could further be proved by auscultation, as maintained by Barnes, was doubted by Champneys, Duncan, and Spencer. Dr. Spencer's comparison of the placenta to an elastic mass was felt to be in-

accurate by several of those present. Matthews Duncan had found that, whereas the expelled placenta was a thrombosed cake, the living one was felt to be ill-defined, soft, with a fretted, vesicular surface. Hermann also believed it to be an exception to find the placenta with defined edges. Barnes had seen one that enveloped the foetus like a sac, while Hicks had noted a case where the structure occupied the whole inner surface of the uterus.

#### POISONING WITH ACETANILIDE.

BEFORE the Baltimore Medical Association Dr. J. E. Gibbons recently read a paper on the results of a mistaken dispensing and administration of a one-drachm dose of acetanilide where five grains of antipyrine had been intended. The "Maryland Medical Journal" for July 6th contains a brief account of the symptoms, which were those of cardiac depression, cyanosis, and nausea. The treatment, which removed the threatening prostration, consisted of the use of tincture of belladonna and brandy. The headache, for which the dose was taken, was not relieved, and Dr. Gibbons holds that if the second dose had been repeated in two hours, as the mistaken directions ordered, death would have been the result. There was an error on the part of an apothecary, it is alleged, in writing out the copy of a prescription, causing the substitution of three drachms of acetanilide for half a drachm of antipyrine. It was a case of unauthorized "borrowing" of a prescription by a neuralgic person who had not been prescribed for by a physician. The antidotal doses of belladonna consisted of four drops of the tincture, every half-hour, for four hours, and at wider intervals afterward.

#### ASYLUM CHANGES IN CHICAGO.

THE outcome of the prolonged investigation into the asylum troubles at Chicago has been made public by the action of the County Board of Cook County. This action removes Dr. James G. Kiernan from the position of medical superintendent and appoints Dr. W. L. Noble as acting superintendent. It was in consequence of these troubles and investigations that one of the judges who have participated in them recorded his memorable expression about the malign influence of politics over asylum government, when he urged that the institution must be removed to some other site, "so that the sweet waters of charity shall not be polluted by politics."

#### THE ELECTRICAL TREATMENT OF UTERINE FIBROIDS.

DR. THOMAS KEITH, in the "British Medical Journal," pleads for the treatment of uterine tumors by electricity. His opinion is of value, being that of "one who was the first to lower to a minimum the mortality that so long followed abdominal surgery, and who by the best results yet obtained in hysterectomy—results that Dr. Playfair is pleased to call phenomenal—still retains the position." It is stated that more than a quarter of all women over fifty years of age have fibrous tumors, of which, if operated upon, one in every four or five dies, and of the survivors one tenth become insane. These tumors may in many instances never declare themselves during life, and only be discovered after death. Dr. Keith recalls two such cases in which, in spite of his remonstrance, operations were performed that resulted fatally. On the other hand, in but one case did harm result from the treatment by electricity. Hemorrhage had been brought about by exposure, as a result of which the patient died. Dr. Keith deduces from this the conclusion that, although great care must be used during the time of electrical

treatment, and with the negative electrode more especially, Apostoli's treatment as practiced by him should have a fair trial. Apostoli, as it is well known, uses the constant current, introducing his gold or platinum electrode into the uterus, the vaginal portion being inclosed in a celluloid sheath. His choice of electrode is influenced by the state of the patient. In haemorrhagic or chronic leucorrhœal conditions the positive electrode is employed, while, when a denutritive effect is desired, as in subperitoneal fibroids, the negative is preferable. Between the external pole and the abdominal wall intervenes moist Potter's clay inclosed in tarlatan. By means of this clay Apostoli professes to have entirely done away with the caustic effect of this pole, and thus to have been able to increase the strength of the current used from 50 to 250 milliampères. The results, as given in the thesis of Dr. Carlet (1884), are eminently favorable to the method. It would be well, however, to remember that many fibroids wither spontaneously. According to Sinéty, cases are by no means rare in which there have been fatty degeneration, suppuration, softening, and fragmentation, with subsequent elimination of fibrous tumors, quite independently of intervention, so that when electricity has been used it is as difficult to determine the advantages as the defects that are to be exclusively ascribed to the method.

#### SUICIDE AND LIFE INSURANCE.

THE Washington Life Insurance Company reports a decided tendency to increase of suicides in recent years. Shooting is the means selected in about half the cases. It is more frequent among the young than among the old, and on this account the company's *a priori* expectation had been in the direction of a decrease in this cause. This expectation has been balked, and the writer of the report goes so far as to say that the increase in recent years has not been purely a matter of accident, and that the decisions of the courts have not been such as to discourage suicide among the insured.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 30, 1889:

DISEASES.	Week ending July 23.		Week ending July 30.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	24	6	30	10
Scarlet fever.....	41	11	32	3
Cerebro-spinal meningitis .....	3	3	4	4
Measles.....	67	5	40	5
Diphtheria.....	98	23	82	29

**The Philadelphia "Times and Register."**—We quote the following articles from advance sheets of the "Druggists' Circular and Chemical Gazette," for August, that have kindly been sent to us by that journal:

**"Justifying a Fraud."**—One of the most striking instances of how low a physician, medical editor, and professor can be debased by the improper influences of unprincipled manufacturers will be found in an article on page 278 of the Philadelphia "Times and Register" for July 20, 1889. In this article, on 'A New View of a Certain Form of Substitution,' the editor in a labored argument tries to prove that the manufacturers of febriline, which in our May number we showed to be a most pronounced fraud, were justified in deceiving physicians in regard to its composition. Febriline was put on the market as a

tasteless preparation of quinine. Dr. Eccles showed that it had no quinine in it at all. The 'Times and Register' concludes its argument for fraud in the drug business in the following ingenious but dishonest way: 'Now, if it be pardonable to mystify a patient a little by a bit of clap-trap, and no physician can succeed who fails to array the mental forces of his patient on his side, is it not equally justifiable for the druggist to do the same to the physician, if the conditions are alike?' We do not think that the whole history of medical journalism could show an instance similar to this—one in which fraud and deception are advocated in so barefaced and bold a manner by one who poses as a medical teacher and writer, and who ought to know better than to so insult physicians and druggists. It would be interesting to know if the faculty and trustees of the Medicochirurgical College of Philadelphia indorse this new movement, and if students at that college are to be taught that druggists and manufacturers are justified in using clap-trap and fraud to deceive physicians. It would also be interesting to know if the subscribers and advertisers who are patronizing the 'Times and Register' will approve of this 'new view' to a sufficient extent to continue their support of a journal that openly advocates fraud and deception. Quinidine does not cost as much as quinine, and neither is it worth as much therapeutically grain for grain. It can be bought at a little more than half the price of quinine, but this has nothing whatever to do with the case. It is merely a question of common honesty. The 'Times and Register' chooses to openly take the side of and advocate clap-trap and fraud in pharmacy, and there is no doubt that all respectable manufacturers and physicians will at once take immediate means to let the public know that they do not in any way whatever indorse such dishonest tricks, and that they will consequently refuse to patronize or have anything to do with any journal that advocates practices of that kind."

"*A Medical Journal Trust.*—It is currently rumored that a combination of prominent proprietary and patent medicine houses has been formed to furnish capital to and control what is proposed to be substantially a 'Medical Journal Trust.' These rumors have grown from the announcement sent out a short time ago when several medical journals in Philadelphia were consolidated under the name of the 'Times and Register.' It is said that this combination, which is known as the American Medical Press Association, proposes to gradually absorb all the medical journals of this country. The way this is to be accomplished is for the combination of manufacturers to withdraw their advertisements at the same time from one journal, and use every other means they can to cripple it, so that it can be bought in at a low rate. This plan is to be continued slowly and cautiously, so as to avoid publicity, until all of the journals are gradually taken in. Such a combination, if it should be completed and conducted in accordance with the peculiar honesty and principles that the 'Times and Register' is now advocating, as will be noticed in an article in this issue headed 'Justifying a Fraud,' would certainly make a spectacle that would bring everlasting disgrace on the medical profession of this country and on all who have had anything to do with so unprincipled an undertaking. On any kind of a basis such a 'medical journal trust' would give nostrum mongers a powerful weapon with which to humbug and deceive the medical profession; and its progress will most surely be opposed by all respectable journals, physicians, and druggists, and by the general public."

**The American Association of Obstetricians and Gynæcologists** will hold its next annual meeting in Cincinnati, on Tuesday, Wednesday, and Thursday, September 17th, 18th, and

19th. No formal invitations will be issued to non-members, but the association invites such members of the profession, wherever resident, as may feel interested to attend the meeting and participate in the proceedings.

**The College of Physicians and Surgeons of Baltimore** has filled the vacancies created by the death of Dr. John S. Lynch and Dr. Oscar J. Coskery and the retirement of Dr. A. B. Arnold. Dr. Thomas S. Latimer has been transferred to the chair of principles and practice of medicine and clinical medicine; Dr. Charles F. Bevan to the chair of principles and practice of surgery and clinical surgery; Dr. J. W. Chambers to the chair of operative and clinical surgery; and Dr. George H. Rohé to the chair of obstetrics and hygiene. To fill the vacancies created by these transfers new appointments have been as follows: Dr. Henry Sewall, of the University of Michigan, to the professorship of physiology; Dr. George J. Preston to the professorship of anatomy, with the diseases of the nervous system as a clinical branch of instruction. Dr. N. G. Keirle has been elected lecturer on legal medicine; Dr. George Thomas, lecturer on diseases of the throat and chest; Dr. G. A. Liebig, Jr., of Johns Hopkins University, lecturer on medical electricity; and Dr. J. H. Branham, demonstrator of anatomy. Dr. L. F. Ankrim, Dr. Frank C. Bressler, and Dr. F. G. Moyer have been appointed assistant demonstrators, and Dr. R. G. Davis has been made prosector in anatomy.

**The American Rhinological Association.**—It is announced that the seventh annual meeting has been postponed to October 9th, 10th, and 11th, at which time it will be held in Chicago.

**The International Pharmaceutical Congress.**—The seventh meeting was to have been held in Milan this year, but it has been postponed to September, 1890.

**The Medical Department of the University of Vermont,** at Burlington, held its annual commencement on July 15th. The graduating class numbered fifty-eight. The annual address was delivered by the Hon. Edward J. Phelps.

**The Mississippi Valley Medical Association.**—A change of the time of meeting has been ordered. The association will meet at Evansville, Ind., on September 10th, 11th, and 12th.

**The Medical Society of Pennsylvania** will hold no meeting this year. On account of the great calamity at Johnstown, and for other reasons, it has been thought expedient to adjourn the convention until June 10, 1890.

**Recent Deaths.**—Dr. Theodore Dimon, of Auburn, N. Y., died on July 22d, aged seventy-two years. He was a graduate of the University of Pennsylvania in 1838, and for many years a permanent member in the State Medical Society. He was formerly superintendent of the asylum at Auburn, and surgeon to the Auburn prison. During the late war he was for two years a regimental surgeon. He was a forcible writer and speaker, and influential in sanitary and other public movements.

Dr. Isaac Lea died on July 25th, at Stapleton, N. Y., by his own hand. He was seventy-five years of age and broken in health, mentally as well as physically. He retired from practice about a year ago, after over thirty years of practice on Staten Island.

Dr. James W. Kerr, one of the oldest practitioners of York County, Pa., died on June 11th, after an illness of two weeks' duration. He was born in Lancaster County about seventy-six years ago.

Dr. Joshua Lewis Miner, of Wilkesbarre, Pa., died on July 27th, aged thirty-three years. He was a graduate in medicine

in 1881 from the University of Pennsylvania. He was a member of the Luzerne County Medical Society.

Dr. Schmelzkopf, the surgeon-in-chief of the Wissmann expedition into eastern Africa, was drowned at Zanzibar on or about July 28th.

**The Astley Cooper Prize.**—The subject announced for competition, under this prize, says the "Medical News," is "The Influence of Micro-organisms upon Inflammation." It is open to all comers, has a value of \$1,500, and will remain open until January 1, 1892. The prize will not be given for any competing essay that has more than one author. The essay must be in English or be accompanied by an English translation, and must be sent, before the date given above, to Guy's Hospital, London.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 21 to July 27, 1889:*

GARDNER, WILLIAM H., Major and Assistant Surgeon, by direction of the Secretary of War, is detailed to attend the encampment of the National Guard of the District of Columbia, at Fort Washington, Maryland, from July 22 to July 29, 1889, for the purpose of giving instructions to the medical officers and hospital corps in their respective duties. Par. 1, S. O. 164, A. G. O., July 18, 1889.

STEINMETZ, WILLIAM R., Captain and Assistant Surgeon, now at Baltimore, Md., on leave of absence on account of disability, by direction of the Secretary of War, will report in person to the commanding officer of the Watertown Arsenal, Massachusetts, for duty at that station, relieving Lieutenant-Colonel James C. McKee, Surgeon. Par. 3, S. O. 166, A. G. O., July 20, 1889.

MCKEE, JAMES C., Lieutenant-Colonel, on being relieved at the Watertown Arsenal, will repair to Philadelphia, Pa., and assume the duties of attending surgeon and examiner of recruits in that city. Par. 3, S. O. 166, A. G. O., July 20, 1889.

ROBINSON, SAMUEL Q., Captain and Assistant Surgeon, Fort Hamilton, New York Harbor, is hereby granted leave of absence for two weeks. Par. 4, S. O. 165, Headquarters Division of the Atlantic, July 22, 1889.

BALL, R. R., Lieutenant and Assistant Surgeon. Leave of absence granted in S. O. 87, Department of the Missouri, July 9th, is extended five days. Par. 1, S. O. 167, A. G. O., July 22, 1889.

BALL, ROBERT R., First Lieutenant and Assistant Surgeon. The extension of leave of absence granted in S. O. 167, July 22, 1889, from this office, is further extended ten days. Par. 23, S. O. 169, A. G. O., Washington, July 24, 1889.

By direction of the President, the State of Arkansas, embracing Little Rock Barracks, is transferred to the Department of the Missouri. G. O. 66, Headquarters of the Army, A. G. O., July 19, 1889.

#### Promotion.

EWING, CHARLES B., Assistant Surgeon, to be assistant surgeon with the rank of captain, after five years' service, in accordance with the act of June 23, 1874. July 5, 1889.

**Marine-Hospital Service.**—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service from July 10, 1889, to July 20, 1889:*

VANSANT, JOHN, Surgeon. When relieved, to proceed to Mobile, Ala. July 11, 1889.

MEAD, F. W., Passed Assistant Surgeon. Relieved from duty as acting chief clerk and attending surgeon; ordered to St. Louis, Mo. July 11, 1889.

WILLIAMS, L. L., Passed Assistant Surgeon. Relieved from duty at Cape Charles Quarantine Station; ordered to Baltimore, Md. July 10, 1889.

KALLOCH, P. C., Passed Assistant Surgeon. Granted leave of absence for thirty days. July 15, 1889.

PETTUS, W. J., Assistant Surgeon. When relieved, to proceed to Marine Hospital, Boston, Mass., for duty. July 18, 1889.

WOODWARD, R. M., Assistant Surgeon. Granted leave of absence for thirty days. July 15, 1889.

VAUGHAN, G. T., Assistant Surgeon. Relieved from duty at Boston, Mass.; ordered to Norfolk, Va. July 18, 1889.

STONER, J. B., Assistant Surgeon. Granted leave of absence for twenty-five days. July 15, 1889.

GEDDINGS, H. D., Assistant Surgeon. Relieved from duty at Baltimore, Md.; ordered to Key West Quarantine Station. July 18, 1889.

WERTENBAKER, C. P., Assistant Surgeon. Relieved from duty at Norfolk; ordered to Galveston, Texas. July 18, 1889.

GROENEVELT, J. F., commissioned as Assistant Surgeon, July 11, 1889. Ordered to Gulf Quarantine Station for temporary duty. July 20, 1889.

#### Society Meetings for the Coming Week:

TUESDAY, August 6th: Hampden, Mass.. District Medical Society (Springfield).

## Letters to the Editor.

#### FOREIGN BODIES IN THE EAR.

3211 LUCAS AVENUE, ST. LOUIS, July 25, 1889.

To the Editor of the New York Medical Journal:

SIR: Please allow me to correct an error in your issue of July 13th last, as it may mislead others. On page 41 of that issue, in the history of Case V, it is stated that a forty-eight-inch watch, which had been previously heard at a quarter of an inch distance, each ear, "was then heard an inch distant by each ear, a gain of 300 per cent. in hearing for the watch."

Since "the intensity of sound is inversely as the square of the distance of the sonorous body from the ear,"\* we have in this case the following proportion:

Distance,  $\frac{1}{4}$  inch : 1 inch, or 1 : 4:: hearing 1 : 16, or 100 per cent.: 1,600 per cent., and the sentence should read "a gain of 1,500 per cent. in hearing for the watch."

You will greatly oblige me by publishing this correction.

ROBERT BARCLAY, M. D.

#### NIGHT TERRORS IN CHILDREN.

CORRECTIONVILLE, IOWA, July 24, 1889.

To the Editor of the New York Medical Journal:

SIR: In your journal of the 13th you mention an article by Dr. G. L. Ullman on "Night Terrors in Children," in which he condemns severe treatment. We have had a little experience of our own that would lead us to believe that sometimes a little harshness will be of great benefit.

Our little boy, of four years, has a great imagination and is very nervous; if allowed, he will in the day-time work himself into quite a state of terror. One night about eight months ago he awoke screaming "Rats! rats!" and was very much frightened.

\* Ganot's "Elements of Physics," E. Atkinson's translation, New York, 1872, p. 160.

ened. It was a long time before he would go to sleep, and next morning he refused to take his breakfast in the next room, as he was afraid of the rats in the bedroom. He was carefully taken into the bedroom and all parts were examined to give him to understand that there were no rats there. During the day his nervous state passed off, and he was as well as usual.

In a few nights he had another spell, which was worse than the first.

A visiting relative advised a spanking. She had been forced to do that with one of her own children years before.

Such treatment appeared unreasonable, and we believed it would only add reality to the terror.

A few evenings afterward, when I came home, I found the little fellow sobbing. In reply to my "What is the matter?" he said, "Ma-ma spanked me cause me see rats." He had a spell that had lasted nearly all the afternoon, and the rats refused to disappear until he had been spanked, and that was the last of the rats.

J. G. BILLER, M. D.

## Proceedings of Societies.

### NEW YORK SURGICAL SOCIETY.

*Meeting of April 10, 1889.*

The President, Dr. LEWIS A. STIMSON, in the Chair.

**A Doubtful Case of Fracture of the Femur.**—Dr. FRED. KAMMERER presented an elderly man who was much disabled in the left lower extremity, and of whom the following history was given: Eight weeks before, the patient had been walking along the street, on a level, and, as he thought, had slipped with the left foot, but without falling to the pavement. Immediately he felt a projecting piece of bone at the hip, and at the same time became completely unable to take another step. He pushed the bone back into position, but, being unable to walk, was taken to a store in the neighborhood, and from thence to a hospital. Little pain was felt, either at the time of the accident or afterward. The patient was under treatment at the hospital for six weeks. When the speaker first saw the patient he decided that the lameness was due to a fracture of the left femur. There was a slight inversion of the left lower limb when the patient lay on his back. On rotating the limb the radius of the curve described was less than on rotation of the other limb. With the patient lying on the right side and so relaxing the muscles, it was possible to get motion in a portion of bone corresponding to the trochanter without moving the remainder of the femur.

The slight amount of injury which had been suffered when the disability was acquired suggested that the patient might be suffering from locomotor ataxia. Moreover, he had found the patellar reflex absent, the pupils contracted and not reacting to light, and that the patient had for years suffered from lancinating pains in various parts of the body, and from *crises gastriques*. He would not give any opinion as to what changes might have occurred in the joint previous to the injury. The patient said he had been able to walk well up to that time. That would be rather in favor of the supposition that a fracture of the neck of the femur had occurred without former changes in the joint. It seemed safe to say that this was a lesion due to changes in the bone or joint occurring in locomotor ataxia. There was no cutaneous anesthesia, but, as there had been very little pain at the time the fracture was sustained, it was possible that some of the deeper parts were anesthetic. There was no inco-ordination.

The PRESIDENT appointed Dr. Lange, Dr. Briddon, and Dr. Pilcher a committee to examine and report on the condition present. Somewhat different opinions were arrived at. Dr. Briddon reported that the committee were not agreed as to whether there was present an absorption of the head and neck of the bone due to the trophic changes belonging to locomotor ataxia, or a fracture of the cervix occurring in a tabetic patient. Dr. Lange believed it a spontaneous fracture, probably intracapsular. There was great relaxation of the capsular ligament in consequence of neurotic changes.

Dr. PILCHER reported that he was not prepared to say that there was not a fracture, but it seemed to him that a fracture alone would not explain the condition present. The head of the bone was probably atrophic and partially absorbed. At the time of the crisis a spontaneous dislocation had probably occurred, being much favored by the relaxation of the ligaments about the joint.

**Caries Sicca of the Upper Vertebræ.**—Dr. J. A. WYETH presented a patient probably suffering from this affection, partly to get advice and partly on account of the unique history of the case. The patient was a young man of eighteen and well developed. He had been healthy until twelve or thirteen years old, when he had begun to suffer pain at the back of the neck, which had finally become so violent that he consulted a physician, under whose treatment it had seemed to go away entirely for the time. However, since then it had returned once or twice in slight attacks, and one severe attack two years previous, when the present deformity began to appear. There was no specific complication or tubercular taint. The family history was free from anything which could favor the occurrence of bone disease. He had had the patient under observation for a week, and had discovered no paralysis. He had thrust an aspirating needle into the broad convex swelling at the back of the neck, but only blood had come away. There was only slight stiffness of the neck with a small amount of backward displacement of two or three of the cervical vertebrae.

Sarcoma having easily been excluded, he had decided that the case was one of caries sicca of the upper cervical vertebrae, together with partial displacement. The needle had struck bone at no very great depth. There appeared to be no abnormal condition in the pharynx. At one time the patient had suffered from a spastic action of the left mastoid muscle, with the production of wryneck, and the motions of the neck were quite limited. The patient's friends had noticed an increasing shortening of the neck in front, and creasing of the skin, showing a forward projection of the head. The swelling had improved slightly under potassium iodide. But it was evidently no abscess or other inflammatory process.

Dr. A. G. GERSTER, having examined the pharynx with the finger, said that he found there a distinct backward curvature of the cervical vertebra. It was singular that so much loss of substance and deformity could occur without making pressure on the spinal cord.

Dr. V. P. GIBNEY thought that such a condition might exist for many years without making such pressure when its progress was so slow, since the nervous tissue was able to accommodate itself in time to much altered conditions. Several years ago Dr. Yale had shown several cases presenting a deformity in this same region—one which had lasted a number of years and was difficult of diagnosis. In several of these, lesions had been found after death similar to those that Dr. Wyeth had ascribed to the present case.

The PRESIDENT remarked that a similar case was presented in a man who had been in Bellevue Hospital for a number of years, at first as a patient and subsequently as a helper in the wards.

**Some Disputed Points in the Pathology and Treatment of Perityphlitis.**—Dr. R. J. HALL read a paper with this title. (To be published.)

Dr. R. F. WEIR referred to an opinion expressed by the late Dr. Sands, shortly before his death, to the effect that, while he yet believed that extraperitoneal cases generally occurred, he was convinced that the intraperitoneal variety was much more common than he at one time had thought it was. The speaker in one hundred autopsies, in as many cases of so-called perityphilitic abscesses, had found general suppurative peritonitis present in fifty-seven instances, circumscribed abscesses inside the peritoneal cavity in thirty-five cases (in thirteen of which general peritonitis had also existed), and extraperitoneal abscesses only four times; but in not one of these four instances had he found a minute perforation through the parietal peritoneal wall leading from the extraperitoneal abscess and surrounded by adhesive matter gluing together the structures contiguous at that point. The openings had been in every instance large and ragged, pointing to the abscess having existed for some time prior to the breaking down of the peritoneal wall by an ordinary necrotic process.

Abscesses had been described which burrowed up in the retroperitoneal tissue as far as the kidney, and Copeland had related one instance in which the abscess had burrowed up along the dorsal gutters not only to the kidney, but to the space between the liver and the diaphragm, and had simulated a pneumothorax in this region. The speaker did not believe that such cases had been truly described; according to his observations, they had more probably been cases of abscess within the peritoneal cavity. Already German anatomists had demonstrated the impossibility of reaching the cæcum without opening the peritoneal cavity. He could not understand the existence of extraperitoneal perityphilitic abscesses when our present anatomical knowledge was taken account of.

The speaker also wished to get opinions as to the usefulness of the aspirating needle in connection with this disease. He himself had found it of real value only where the friends of a patient objected to an operation, and the needle enabled one to withdraw pus, so as to convince them of the necessity of a radical operation. But failure to get pus did not prove that none was there. He had seen two cases where the needle had been used on the day before operation, and, when the abdomen had been opened, the track of the needle through the abdominal muscles had been marked by dark-brownish pus and the early stages of an inflammatory process. Such a case showed that there was some inconvenience and risk connected with aspiration.

In reply to a query from Dr. Lange as to whether any member could mention a case of successful operation after general peritonitis had begun, Dr. Weir said that he had operated within twenty-four hours after the occurrence of signs of perforation, when the peritonitis was believed to be rapidly spreading, and had a good recovery, but never when suppurative peritonitis had become general had he had recovery follow the operation. The question was a hard one to answer. Cases occurred where peritonitis apparently was general, and yet lateral laparotomy showed a loosely circumscribed abscess which could be discharged without further infection of the peritoneum. At other times a purulent condition might be encountered, and still be associated with a more or less extensive exudative or suppurative peritonitis. He considered, then, that there was a class of cases between the mild and the fulminant in which the result might turn either way—that is, the process might go on and end in death from general peritonitis, or it might become circumscribed and latent after acute symptoms of several hours' duration. However, in the latter event, the patient was liable

to another acute and perhaps fatal attack at any moment. Since fifty-seven per cent. of the autopsies made showed general suppurative peritonitis, and thirteen per cent. a circumscribed abscess with general peritonitis, general peritonitis therefore being present in seventy per cent. altogether, the early operation seemed to him called for. He believed that, if practiced within twenty-four or forty-eight hours, the early operation might save a number of those who now die.

There was a lack of experience as to the results of early operation—that is, operation in the first twenty-four hours. If it could be proved that it was really better to wait, and trust to the possibility of a circumscribed abscess being finally formed, he was ready to see the pendulum swing to the opposite side and have expectant treatment given the preference; but before that happened he wished we might have the result (which we now did not have) of prompt operation in at least as many as ten cases. He had recently had such an opportunity in the case of a young physician whom he had operated on fifteen hours after the fourth and severest recurrence of acute symptoms of an appendix perforation. He found a small grumous abscess within the peritoneal cavity at the top of the perforated appendix, and the adjacent coils of intestine were spread over with recent lymph, the whole process apparently in a fair way to spread far and wide. He cleaned out all the morbid material, the appendix (the lumen of which had been narrow) was tied off, and the wound was drained and packed with iodoform gauze. The diseased processes thereupon entirely ceased, and the patient had recovered without an unpleasant symptom.

The variations which occurred in the patency of the appendix probably had something to do with the severity of the peritonitis. Normal variations, as well as those resulting from pelvic disease, would account for this. Possibly also the range of motion or freedom of the appendix modified this. His conclusion was that, if the patient's condition would admit of it, in spreading peritonitis of appendical origin, early interference (or within twenty-four or forty-eight hours) would be found in a series of cases to afford the greatest saving of life. At the same time he felt with others that more experience was required to rightly decide the important question.

Dr. C. K. BRIDDON said, in reply to the statement of Dr. Weir, that Bardeleben and Luschka had denied the possibility of reaching the cæcum without opening the peritoneum, that the late Dr. Gurdon Buck, in a monograph on iliac abscess, had advised reaching the collection of pus through an incision exposing the tendon of the iliac muscles as it passes over the pubes and below Poupart's ligament, working one's way upward beneath the iliac fascia. Dr. Buck had done this on several occasions in cases that he regarded as those of abscesses due to tubercular ulceration of the cæcum occurring in phthisical subjects. Of course, in the normal condition of the parts, where, according to Treves, the cæcum was surrounded on all sides by peritoneum, the observations made by the German authors referred to by Dr. Weir were correct.

The speaker said that during the last six months he had operated in five cases of perityphilitic abscess, and in two of these cases it had been possible during the operation to demonstrate the intraperitoneal origin of the trouble.

One of these had occurred in a thin, attenuated boy, ten years old, who was admitted into the Presbyterian Hospital on the tenth day of the disease; there had been a large, fluctuating tumor, reaching at least four inches above the fold of the groin and nearly to the median line. After incising and evacuating a large amount of fetid pus, the retraction of the lips of the incision had permitted a very satisfactory inspection of the interior, and it could be seen that the roof of the cavity was formed by convolutions of intestine matted together by lymph.

The second case had been in an adult woman admitted to the service of the same hospital on the third day of the disease. The invasion, accompanied by chill and vomiting, had been acute in character; there had been pain and tenderness over the whole abdomen, but most severe in the right iliac region, where there was a sense of resistance, but no tumor. He had found it very difficult to determine whether it was a case of diffuse suppurative peritonitis or of circumscribed peritonitis, and had decided to make an exploratory incision. On exposing the peritoneum over the cæcum, the intestine could be seen moving freely under the serous lining of the abdominal wall. On opening the cavity of the peritoneum, the caput coli presented, coated with a layer of recent exudation, and adherent to neighboring coils of intestine. On lifting the caput there was an audible escape of gas which had a faecal odor, and beneath its posterior surface was seen the appendix, not free, but bound firmly down, and on its exposed surface a perforation from which there was a slight escape of faecal matter. The general cavity of the peritoneum was at once shut off with a tamponade of iodoform gauze, and the wound leading down to the perforation left open.

This patient died on the sixth day after the operation, and the speaker was firmly convinced that the exploration in this case had interfered with conservative processes by breaking up adhesions that were walling in the gangrenous appendix. He believed that the majority of these cases were intraperitoneal, and that where the inflammatory process was circumscribed it was better to wait several days before interfering; but that in cases in which no conservative or limiting process was set up, and where we had to deal with a diffuse suppurative peritonitis, laparotomy and toilet of the peritoneum was the best procedure.

Dr. McBURNEY said that his experience had completely satisfied him that all these cases were intraperitoneal. He had operated in the first thirty-six hours of the attack, and had been able to see how an abscess was forming within the peritoneal cavity. It became shut off by adhesions so promptly that it very soon became impossible to say whether it was inside or outside the abdominal cavity. So rapidly did adhesions form, and so soon did the process complete itself, that on the third or fourth day it would be easy to assume and maintain that the abscess was an extraperitoneal one, and this became more and more so as time went on. He himself had never seen a case of perityphlitic abscess formed entirely outside the peritoneal cavity. He had recently seen a fine typical instance of the old extraperitoneal abscess. On the ninth day, as the tumor was large and fluctuating, he opened down upon it by a free incision. From the appearance presented by the interior of the abscess, one would not have said that it had ever communicated with the abdominal cavity. The patient rallied well from the operation, and by the sixth week the wound had closed—all but a small sinus that led down to the seat of the recent abscess, and this it had seemed to him best to leave alone. Shortly afterward, at a time when the patient was feeling quite well and eating regularly, he rolled over in the night somewhat suddenly, immediately felt a violent pain in the iliac region, shortly afterward had a large stool, passed into collapse, and died in twelve hours. At the autopsy the origin of the abscess was found to be intraperitoneal, and a wide opening communicated with the peritoneal cavity. The appendix was found open and ulcerated. It was evident that the adhesions, which for a time had separated the ruptured vermiform appendix from direct connection with the peritoneal cavity, had ruptured and allowed feces to be poured into it.

As regarded treatment, one might well have to explain himself who took very positive ground on either side of the ques-

tion which had been raised. He had heard a certain practitioner remark that he had never seen a case of perityphlitis that did not end in recovery. This was evidently because he did not recognize the fatal cases. The speaker had seen good results follow both with and without operation. Some patients did get well, contrary to expectation, who really had inflammation of the appendix. This, however, was no ground on which to base a refusal to operate in certain cases. Some patients got partly well, but they remained in constant danger of a fresh outbreak until operated on. Sometimes a discharge of pus into the bowel took place after an illness of weeks or months, but the chances of this were too small to be depended on. On the contrary, we were bound to get rid of a source of general infection easily reached. The successes in the operation were now very numerous. It was not fair to say of any case of operation without recovery that if it had been left to its own course adhesions would have formed. Where septicæmia had not become established he would operate early, but he would not operate where the pus had penetrated through the whole cavity, and peritonitis was far advanced.

Dr. F. E. LANGE did not consider that a spreading of the inflammatory process contra-indicated operation. He had reported a number of cases where he had been obliged to make a counter-opening through the rectum into Douglas's space, and in which recovery had been obtained. It was not very uncommon for suppurative peritonitis to become localized after transient symptoms of general peritonitis. The whole question, so very important as it was, whether we should operate early or not, could not be decided one way or the other and laid out in a schematic way. The facts with which we had to deal were that a large proportion of patients would recover under expectant treatment; that a large majority of the cases in which operation had been resorted to were in the later stages of the disease, and that it was really very difficult to select the cases in which operation was to be done at once, and to recognize the cases where it was better to wait. All were essentially alike in being cases of perforative peritonitis, but the result to the patient would depend upon what became perforated, what was infected, what the malignancy and tendency to spread were, or what predispositions were given by the condition of the surrounding tissues. As these elements varied widely in different cases, it was impossible to lay down a rule which should be good in all cases. There were some cases in which early operation would be the immediate cause of death on account of collapse setting in. On the other hand, some patients had been saved by being operated on early. He himself was still in doubt in each acute and severe case that came under his care as to what he ought to do. He had had charge of a number of cases of perityphlitic abscess, and his impression concerning them, as a whole, was that they were like other abscesses in needing to be opened. The operation was comparatively simple and its prognosis good. He had never seen a case in which general peritonitis had become established where recovery had followed early operative interference. After relating the history of a case in which the appendix, which had been giving rise to a succession of severe attacks, was found outside the ascending colon, and another case which had been supposed to be ovarian disease only in which the operation had revealed the presence of a small abscess and a perforated appendix, besides the expected morbid changes, the speaker referred to a third case in which he had operated very early. The patient, a boy of three years, was attacked about five o'clock in the afternoon, and laparotomy was performed at one o'clock of the following day. He found a diffused peritonitis and a perforation of the appendix following ulceration. The patient died after three days. He had helped other operators in the performance of laparotomy early

in the course of acute attacks, and all the patients had died. He could not say as a matter of experience, though from a rational standpoint he must admit it, that it was a good thing to operate early. On the other hand, he had had cases where general peritonitis had been present, as if from a perforation, and had in time become localized, this being followed by the gathering of pus in various places, and opening, and the recovery of the patient. He believed that in just such cases as these an early operation might have spread the infection wider, or else have disturbed the wholesome efforts which nature was making to close in the damaging exudation by adhesions.

Dr. HALL said he regarded the early operation rather as the opening of an abscess to relieve tension and evacuate pus; for an abscess in which pus was once present was not so likely to cause the formation of adhesions as, directly, to break them down. He believed that adhesions formed during the period of inflammation chiefly, and before the beginning of suppuration.

Dr. LANGE thought this was not so. On the contrary, he believed that when perforation took place the escaped matters did not necessarily act on the whole general surface of the peritoneum, but that some coils of the intestines that were near became bound together by adhesions about the foreign matters and checked their further spread. He instanced a case in which ileus besides peritonitis had been present and the patient suffered from stereoraceous vomiting with local signs of suppurative peritonitis apparently due to a perforation. The patient was for a considerable time in a state of collapse, the fever was a marked one, and an operation was out of the question. He accordingly delayed any radical measures; in time there was a gathering of pus at different points, and the patient recovered. He was convinced that death would have followed an operation done during the acute stage of the disease in this case.

Dr. WEIR, Dr. GERSTER, and Dr. WYETH next spoke, after which Dr. LANGE instanced a case where, the patient being very far gone, at an early stage of the disease, very feeble and also corpulent, delay had been decided on in accordance with a consultation, in which different opinions had been held. He was satisfied that the patient's life had in this way been saved. On the second week an incision was made, and the patient in time recovered. He believed that in this successful case related by Dr. Weir, adhesions had formed by which the spread of the process had been stopped before it had gone beyond the power of the body to recover from or control.

Dr. GERSTER thought Dr. Hall's paper had shown that the opening of an abscess within the uninflamed peritoneal cavity was not so dangerous as had been formerly supposed; the escape of pus into the peritoneal cavity had been classed as equally dangerous with perforation, and unnecessary fear had restrained many surgeons from needed operations. Similar experiences had resulted in making gynaecologists much more confident than they had been about operating for pyosalpinx. It had been found that rupture and the escape of pus from a pyosalpinx during operation was comparatively harmless. He considered that if the peritoneum was properly protected, the operation for perityphilitic abscess might be said to have all the elements of safety.

Dr. WYETH called attention to those cases of general peritonitis which were supposed to have originated from a perityphilitis where the consulting surgeon was called in at so late a stage that no diagnosis was possible on account of the general swelling. He had operated in two cases in which a diagnosis of peritonitis had been made, and had found nothing whatever wrong with the appendix or cæcum. In one of these cases the peritonitis had followed obstruction, and in the other no cause could be found, although a large abscess in Douglas's *cul-de-sac* was discovered.

The PRESIDENT remarked that the opinion of a majority of those who had spoken on the question seemed to be in favor of the surgeon's waiting before operating until the formation of pus, and against the immediate operation as understood by some. Since some doubt had been expressed as to the possibility of the occurrence of really extraperitoneal abscesses, he would remind the meeting that such a case had been reported to the society by himself about a year ago, in which a small abscess had formed in the connective tissue opposite the junction of the cæcum and colon between the reflected layers of peritonæum. A small intraperitoneal abscess had also formed behind the cæcum, communicating with two openings in the appendix.

**Abdominal Hysterectomy for Uterine Fibroids.**—Dr. R. ABBE presented the uterus and appendages of a woman upon whom he had operated for this condition, complicated by a suppurative inflammation of the ovary and pyosalpinx. The ovary was of the size of an orange, and the whole mass, representing the uterus, its fibroids, and the diseased appendages, weighed two pounds. The uterine tissue had been removed complete, and the patient had made a good recovery.

## Book Notices.

*De l'hémiplégie dans quelques affections nerveuses (ataxie locomotrice progressive, sclérose en plaques, hystérie, paralysie agitante).* Par Mlle. BLANOHE A. EDWARDS, Docteur en médecine de la Faculté de Paris, etc. Paris: Lecrosnier et Babé. Pp. 7 to 168. [Publications du "Progrès médical."]

THE study of a symptom under the different phases in which it presents itself is always very instructive, but when this symptom is hemiplegia, which is found in so many different diseases, which is often preventable, often capable of amelioration, but always deplorable when it is lasting, its study becomes of the highest importance.

Dr. Edwards, upon a basis of eighty-eight clinical histories of hemiplegia, of which the greater part emanated from that famous source of neurological teaching, the Salpêtrière, makes a good comparative study of this state as it is seen in the four diseases named in the title of her monograph. Her definition of the symptom in question is quite sufficient from a clinical point of view, though necessarily incomplete in an anatomical sense. "By *hemiplegia* is meant a unilateral motor paralysis characterized by functional impotence of the limbs of one side, affecting the upper limb more than the lower, or *vice versa*; accompanied or not by paralysis of the face on the same side, or on the opposite side (alternate paralysis), by paralysis of the muscles of the neck and eyes (conjugate deviation of the head and eyes toward the healthy side), and by paralysis of the tongue with deviation toward the healthy side; complicated or not by paralysis of sensibility, of the muscular sense, and of the special senses, by contractures, by abolition or exaggeration of the reflexes, by tremor, by athetosis, by paralysis of the faculty of language, spoken, seen, written, or heard (aphasia), by paralysis of the pharynx and of the larynx, or by paralysis or contracture of the sphincters."

Forty pages are devoted to clinical histories of hemiplegia occurring in locomotor ataxia and to personal observations and deductions therefrom.

Those histories show, among other things, the frequently short duration of the symptom in these cases. Many localizations of monoplegia and many instances of aphasia occurring in tabes are also shown to be often quite transitory, persisting,

like hemiplegia, only a few days sometimes. In the opinion of Debove and of Stecewitz, this transitory character of hemiplegia is evidence of its tabetic origin.

In the forty pages touching sclerosis multiplex disseminata there are eleven instructive histories of hemiplegia from various sources, some of which show that in this disease also the symptom may be transitory.

The chapter concerning hemiplegia in hysteria is perhaps the best one in the monograph, inasmuch as it sets forth in a striking manner the points of similarity and of dissimilarity of hemiplegia in this great neurosis and in real organic disease. The means of making a diagnosis are given, although not in the most systematic way, and the clinical histories with the author's comments impart a very good idea of hysteria in general.

On the whole, it is a collection of useful observations emanating from the greatest center of neuro-pathological teaching. We here meet again with the phrases and aphorisms of Charcot and his school, which constitute one of the best qualifications of the work.

*Studies in Pathological Anatomy.* By FRANCOIS DELAFIELD, M. D., Professor of Pathology and Practical Medicine, College of Physicians and Surgeons. Volume II. Part 3—Acute Bright's Disease. With Forty-two Plates. New York: William Wood & Co., 1888.

It is safe to say that a more valuable and suggestive paper than this has not been published for many years. For the first time something like a satisfactory classification of acute Bright's disease is proposed. The nomenclature adopted is perhaps a little obscure. The author describes first "acute exudative nephritis," by which is meant an inflammatory process with the exudation of the usual products of inflammation, and with the usual more or less complete destruction of the renal epithelia; second, "acute degeneration of the kidney," which is disease of the epithelia without other demonstrable change; third, "acute diffuse nephritis," in which, in addition to the changes of exudative nephritis, there are from the first "a growth of connective tissue in the stroma" and "a growth of the capsule cells of the Malpighian tuft." These latter features make a lesion necessarily permanent. To each of these forms the author assigns a separate clinical history.

It will be seen that the form called "acute degeneration" may or may not in different cases be regarded as "inflammatory." It is a truly "parenchymatous" lesion. There is no visible change save that in the epithelial elements. There is no exudation into the stroma. Although the epithelial degeneration may be regarded in some cases as an early stage of "inflammatory" disease, it is clear that in many others the process is entirely "degenerative." All quibbling over the definition of "inflammatory" aside, this fact remains: that post mortem we find kidneys showing lesion, and that such kidneys give rise to certain symptoms. These are often slight, but when very extensive degeneration occurs, severe or fatal illness may result.

In "exudative nephritis" there are lesions similar to those caused by inflammation in any part of the body. As in pleurisy, for example, there is an exudation of serum, fibrin, and white cells; so in the kidneys the same exudation is found. The latter organs having no cavity resembling that of the serous sacs, this exudation takes place into the stroma and tubules.

"Acute diffuse nephritis" gives rise to a similar exudation, but, in addition to this, the cells covering the capsules of Bowman proliferate. The lesion has another peculiarity, namely, that the changes are most marked in wedge-shaped areas having their apices directed toward the pelvis. This the author regards as the greatest of all the acute lesions. This also is the "glomerulo-nephritis" of many authors.

The illustrations are microphotographs or reproductions of drawings. The former are probably as good as can be made with existing lenses; the latter are beautiful.

*Du lavage de la vessie sans sonde à l'aide de la pression atmosphérique: ses usages—son application au traitement des cystites douloureuses.* Par le Docteur J. M. LAVAUX, ancien interne des hôpitaux de Paris, etc. Paris: G. Steinheil, 1888. Pp. 5 to 146.

THE author of this work has, with some slight modifications, revived a method of irrigating the bladder which has never attracted special attention, though several attempts to establish its merits have previously been made.

The apparatus used by M. Lavaux consists of an ordinary hand irrigator and a conical hard-rubber "obturator" through the center of which runs a hole fitted by a hollow metallic mandril attached to the end of the tubing of the irrigator. The irrigator being placed at a height of from a metre and a half to two metres above the patient, the obturator is placed in the meatus, the mandril run through it, and the water turned on; the atmospheric pressure overcoming the resistance of the compressor urethrae muscle, the bladder is filled until a sense of fullness is felt, when the patient is allowed to empty the bladder in the natural way. The only novelty in this procedure is in the method of estimating and controlling the amount of pressure used. This is done by having mandrels of different calibers, the author using a series of from 1 to 6, the caliber ranging from 1 to 3 mm. in diameter. By taking the height of the irrigator and the caliber of the mandril the amount of pressure may be estimated. It is difficult to perceive how this possesses any advantage over simply elevating or depressing the irrigator, especially as it is impossible to estimate the amount of resistance to be encountered. The rest of the method is practically identical with that of the late Professor Ultzmann, so that the excellent results obtained by this author (details of which comprise a large portion of the work) are a matter of no surprise.

*A Manual of Diseases of the Ear, for the Use of Students and Practitioners of Medicine.* By ALBERT H. BUCK, M. D., Clinical Professor of the Diseases of the Ear in the College of Physicians and Surgeons, New York, etc. New York: William Wood & Co., 1889. Pp. ix-420. [Price, \$2.50.]

This manual may be regarded as a revised and much improved edition of Dr. Buck's text-book, published in 1880. Some of the chapters have been but slightly altered, but others have been entirely rewritten, and much new matter has been added. Many of the illustrations are also new, and the present edition is much superior to the first. The book consists of fifteen chapters and an appendix, the latter containing an anatomical and physiological sketch of the ear.

In the chapter on diseases of the auricle we think the author errs in not drawing a sharper distinction between pure perichondritis and othæmatoma. In the chapter on diseases of the external auditory canal the author underestimates the frequency with which the operation of displacing the auricle forward, for the purpose of removing a foreign body from the canal, has been done, though it is a rare operation. In the chapters on the diagnosis and treatment of diseases of the middle ear we do not think sufficient importance is given to the necessity of a careful rhinoscopic examination. We think that such an examination should be done in every case. Masses of hypertrophied and adenoid tissue are almost always present in cases of middle-ear deafness associated with chronic naso-pharyngeal disease, and very often are the sole cause of the accompanying deafness. These cases should not be turned over by

the aurist to the rhinologist or laryngologist, as is too often the case. A knowledge of the operative procedures necessary in disease of the naso-pharyngeal region should form part of the equipment of every otologist, and skill in operating in the cavity comes only from practice and experience.

The chapter on diseases of the mastoid is admirable, and the cases cited are of great interest and value.

The chapter on syphilitic and tubercular disease of the deeper parts of the ear is very brief, but contains some points of interest.

Chapter XV, on disease of the labyrinth, is much too brief for the importance of the subject, but the author perhaps errs on the right side in saying that "there are good reasons for believing that the convenient designation 'disease of the labyrinth' can not rightfully be applied to many of the cases of aural disturbances which have been classified under this heading." The book closes with an index.

It is to be hoped that the present manual will have a larger circulation among practicing aurists than was possible for the first edition of the work.

*Diseases and Injuries of the Ear; their Prevention and Cure.*

By CHARLES HENRY BURNETT, A. M., M. D., Aural Surgeon to the Presbyterian Hospital, etc. Philadelphia: J. B. Lippincott & Co., 1889. Pp. 6-7 to 154. [Price, \$1.]

This little book forms one of the series of manuals on "Practical Lessons in Nursing," and was written for the purpose of "enabling many to avoid ear diseases by care," and to show the inexpert what to avoid in the treatment of ear diseases, and thus to escape the evils of improper treatment. It consists of three parts, divided into seven chapters. The first part, divided into two chapters, treats of the gross anatomy and the physiology of the ear. The second part, which treats of the common diseases and injuries of the ear, is divided into three chapters—one confined to the external ear, the second to the middle ear, and the third to the internal ear. The third part, consisting of two chapters, considers the very important subject of aural hygiene and the education of partially deaf children and that of the deaf and dumb. In such a small volume these various subjects must of necessity be very briefly treated of, but the style is clear, and what is said can be readily understood by the general reader, and certainly answers the intention of the author. The value of the simplification of any branch of medical science for the benefit of the laity is, however, open to question.

*Handbuch der physiologischen Optik.* Von H. von HELMHOLTZ. Zweite umgearbeitete Auflage, mit zahlreichen in den Text eingedruckten Holzschnitten. Fünfte Lieferung. Hamburg und Leipzig: Leopold Voss, 1889. Pp. 321 to 400.

NEARLY two years have elapsed since the fourth fasciculus of the second edition of this great work made its appearance. The fifth fasciculus continues the subject of color-sensations, and much space is devoted to the geometric presentation of the color-system. Much new matter has been interpolated, particularly in the discussion upon the subject of principal colors. Pages 335 to 346 have been entirely rewritten, and much of the old matter has been left out. Pages 351 to 384 are almost entirely new matter, and contain several new illustrations. This fasciculus contains the consideration of the entire subject of composite colors, and is a monument of erudition and research. It is to be hoped that the remaining fasciculi will appear more promptly, and that we shall not be obliged to wait too long for the completion of the entire work. The labor already expended upon the parts that have appeared is sufficient evidence of the

thoroughness of the author in the matter of revision. The book when complete will practically be a new work on the science of physiological optics.

*Lectures on the Errors of Refraction and their Correction with Glasses.* Delivered at the New York Post graduate Medical School, with Illustrative Cases from Practice, both Private and Clinical. By FRANCIS VALK, M. D., Lecturer on Diseases of the Eye, New York Post-graduate Medical School, etc. New York and London: G. P. Putnam's Sons, 1889. Pp. xii-241. [Price, \$3.]

This is a well-printed volume of 241 pages, which is rather better supplied with illustrations than text-books of this kind usually are. The lectures are eleven in number, and the subjects embraced in them are the anatomy of the eye, refraction, emmetropia, hypermetropia, myopia, ophthalmoscopy, muscular asthenopia, astigmatism, retinoscopy, and presbyopia. The book is avowedly elementary, but is sufficiently clear to the student or general practitioner who feels enough interest in a comparatively abstruse subject to devote more attention to it than is usually possible in the ordinary college course. It is provided with a copy of Snellen's test-types and a fairly good index.

*The Illustrated Optical Manual; or, Hand-book of Instructions for the Guidance of Surgeons in testing Quality and Range of Vision, and in distinguishing and dealing with Optical Defects in General.* By Surgeon General Sir T. LONGMORE, C. B., F. R. C. S., Honorary Surgeon to the Queen, etc. Fourth Edition. Enlarged and illustrated by Seventy-four Figures from Drawings and Diagrams by Inspector-General Dr. MACDONALD, R. N., F. R. S., etc. London and New York: Longmans, Green, & Co., 1888. Pp. xxii-239. [Price, \$4.50.]

This is a most valuable manual for all surgeons of the army or navy who are called upon to test the quality and range of vision among soldiers or sailors, and in its peculiar scope we believe it to be the only manual of the kind in existence. It is divided into ten chapters, and is quite fully indexed.

The first chapter contains a mass of information, much of it not found in ordinary works on optics, and contains also directions for sight exercises at musketry instruction.

The second chapter considers the subject of errors of refraction, myopia, hypermetropia, and astigmatism, and their influence upon military service.

The third chapter is devoted to a discussion of the subjective and objective methods of examination employed in determining the refraction, particular attention being given to ophthalmoscopy and keratoscopy.

The fourth chapter is entirely taken up with a consideration of the power of accommodation of the eye, including presbyopia.

The fifth chapter is devoted to a consideration of impaired vision connected with strabismus, but, inasmuch as the author goes into the theory of strabismus and a description of the various kinds of squint, the chapter is much too brief for any proper presentation of the subject. The same remark may apply to the sixth chapter, in which color-blindness is considered.

The seventh chapter, on visual acuteness and particular varieties of weak and impaired vision, is very good, though it seems unnecessary to coin a new word, "nephelopia," to signify an impairment of vision due to some opacity of the media of the eye.

The ninth and tenth chapters are of peculiar interest to army surgeons. Here we find a very full consideration of the power of sight required for recruits, with a description of the test-

dots employed for testing it; and a description of the manner of conducting the visual examination of recruits and soldiers, together with an account of the qualities of sight which determine the selection of officers and men for the army, navy, and Indian Government service.

The tenth chapter is practically an appendix, which contains extracts from musketry and other regulations concerning eyesight which affect medical officers.

The book is well written in a plain, readable style, and is sufficiently illustrated for the purpose, and we commend it to the careful perusal of all army surgeons and to every ophthalmic surgeon who wishes to know everything in his specialty.

#### BOOKS AND PAMPHLETS RECEIVED.

**A Treatise on Surgery, its Principles and Practice.** By T. Holmes, M. A. Cantab., Consulting Surgeon to St. George's Hospital, etc. With Four Hundred and Twenty-eight Illustrations. Fifth Edition. Edited by T. Pickering Pick, Surgeon to and Lecturer on Surgery at St. George's Hospital, etc. Philadelphia: Lea Brothers & Co., 1889. Pp. xxiii-33 to 1008. [Price, \$6.]

**The Physiology of the Domestic Animals. A Text-book for Veterinary and Medical Students and Practitioners.** By Robert Meade Smith, A. M., M. D., Professor of Comparative Physiology in the University of Pennsylvania, etc. With over Four Hundred Illustrations. Philadelphia and London: F. A. Davis, 1889. Pp. xiii-938. [Price, \$6.]

**Diseases of Women : A Manual of Non-surgical Gynaecology** designed especially for the Use of Students and General Practitioners. By F. H. Davenport, A. B., M. D., Assistant in Gynaecology, Harvard Medical School, etc. With Numerous Illustrations. Philadelphia: Lea Brothers & Co., 1889. Pp. xiv-25 to 317. [Price, \$1.50.]

**Transactions of the New York State Medical Association, for the Year 1888.** Volume V. Edited for the Association by Alfred Ludlow Carroll, M. D., of Richmond County. New York: J. H. Vail & Co., 1889.

**Transactions of the Medical Society of the State of New York. For the Year 1889.** Published by the Society.

**Cancer and Cancerous Diseases.** By Sir Spencer Wells, Bart., F. R. C. S. **Cardiae Dyspnœa and Cardiae Asthma.** By Dr. S. von Basch. **The Influence of Menstruation and of the Pathological Condition of the Uterus in Cutaneous Diseases.** By Dr. L. Grellety. **Tension as met with in Surgical Practice; Inflammation of Bone; Cranial and Intracranial Injuries.** By T. Bryant, F. R. C. S. **Antisepsis and its Relation to Bacteriology.** By Dr. J. Neudorfer. Volume III. Number 1. New York: William Wood and Company, 1889. ["Wood's Medical and Surgical Monographs."]

**Therapeutische Notizen der deutschen Medizinal-Zeitung.** Herausgeber, Dr. Julius Grosser, 1880-1889. Heft II. Bogen 6-10 (Gelenkentzündung—Pharyngitis). Berlin: Deutschen Medizinal-Zeitung, 1889. Pp. 81-160. [Preis, 1 Mark.]

**The Treatment of Nævus by the Intra-injection of Alcohol.** By Thomas H. Holgate, M. D. [Reprinted from the "Archives of Pædiatrics."]

**Fifty-ninth Annual Report of the Inspectors of the State Penitentiary for the Eastern District of Pennsylvania.**

**Twenty-fifth Report of the Trustees of the City Hospital, Boston, with Reports of the Superintendent and Medical and Surgical Staff, Rules for Admissions and Discharges, Prospectus of Training-school for Nurses, etc., 1888.**

**A Manual of Instruction for giving Swedish Movement and Massage Treatment.** By Professor Hartvig Nissen, Director of the Swedish Health Institute, Washington, D. C., etc. With Twenty-nine Original Wood Engravings. Philadelphia and London: F. A. Davis, 1889. Pp. vii-128. [Price, \$1.]

**Atlas of Venereal and Skiu Diseases.** Comprising Illustrations and Selections from the Plates of Professor M. Kaposi, of Vienna; Dr. J. Hutchinson, of London; Professor I. Neumann, of Vienna; Professors A. Fournier and A. Hardy, and Drs. Ricord, Cullerier, Besnier, and Vidal,

of Paris; Professor Leloir, of Lille; Dr. P. A. Morrow, of New York; Dr. E. L. Keyes, of New York; Dr. Fessenden N. Otis, of New York; Dr. J. Nevins Hyde, of Chicago; Dr. Henry G. Piffard, of New York; and others. With Original Text by Prince A. Morrow, A. M., M. D., etc. **Fasciculi XIV and XV.** New York: William Wood & Co., 1889.

**The Old Hospital and other Papers.** By D. B. St. John Roosa, M. D., LL. D. Second revised and enlarged Edition of "A Doctor's Suggestions." New York: William Wood & Company, 1889. Pp. 320.

**A Clinical Study of Paraldehyde and Sulphonal.** By C. M. Hay, M. D., Morris Plains, N. J. [Reprinted from the "American Journal of the Medical Sciences."]

**A Year's Work in Abdominal Surgery.** By Clinton Cushing, M. D., San Francisco, Cal. [Reprinted from the "Pacific Medical Journal."] **Proceedings of the Academy of Natural Sciences of Philadelphia. Part I. January-April, 1889.**

**Cerebral Localization in its Practical Relations.** By Charles K. Mills, M. D., Philadelphia. (Read before the Congress of American Physicians and Surgeons, September 19, 1888.)

## Reports on the Progress of Medicine.

### CUTANEOUS AND VENEREAL DISEASES.

BY GEORGE THOMAS JACKSON, M. D.

**New Lanolin Ointments.**—Dr. Stern, of Mannheim, has found to be useful three preparations with lanolin, which he names ("Therap. Monatshft," February, 1889): (1) Sapolanolin; (2) lanolin wax-paste; and (3) fluid lanolin injection. The first is a mixture, usually, of two parts of green soap and two parts and a half of lanolin. With this he incorporates all the ordinary medicaments excepting salicylic acid. He has found it specially valuable in the treatment of infiltrated eczema, parasitic diseases, and seborrhœa with thick crusts. With the addition of 10 per cent. of white precipitate it renders excellent service in psoriasis capititis, usually clearing up the disease in from three to eight days' time, and needing only the application of an indifferent ointment to complete the cure. It never discolors the hair. The second preparation is exceedingly useful for an adhesive dressing, and is composed of forty parts each of yellow wax and lanolin and twenty parts of olive oil, melted together and shaken while cooling. It is of a bright-yellow color, and of the thickness of the wax used by the hair-dresser. It can be spread upon the skin, where it sticks. With this can be incorporated nearly all sorts of medicaments, only, when tar is added, a little more wax must be used. It is very useful in eczema of the face when oxide of zinc or boric acid is added to it. In squamous and vesicular eczema the following leaves little to be desired: Salicylic acid, in fine powder, 3 parts; olive oil, 17 parts; yellow wax and lanolin, each 40 parts. For the third preparation the basis is formed by lanolin, 25 parts; oil of almonds, 75 parts. To this can be added various medicaments, for instance: B Zinc sulphate, 0.5 per cent.; water, 4.5 per cent.; lanolin, 20 per cent.; and oil of almonds, 75 per cent.

**Exfoliatio Areata Linguæ.**—This disease has been designated by many names, such as pityriasis of the tongue, chronic excoriation, desquamative syphilide, exfoliative marginate glossitis, and sundry other terms. Exfoliatio areata linguæ seems to be the name given to it by Unna, and is the one adopted by Dr. Mibelli ("Giorn. Ital. del. mal. ven.," 1888, xxiii, 383). The disease is very manifold in its appearance, so that a description that fits one case would not necessarily apply to another. From the observation of four personal cases the author would give the symptomatology as follows: Upon an otherwise perfectly healthy tongue there will appear red spots with smooth surfaces from which the upper layers of epithelium have evidently fallen. Around them will be a whitish ring which is more or less raised. These spots are continually changing their location in a most capricious manner from day to day, and even from hour to hour, and their appearance and exfoliation take place very rapidly. So they come and go, return-

ing again and again to places previously affected which have healed. There are no subjective phenomena, and the course of the disease is benign but most chronic. Its superficiality, its seat upon the tongue exclusively, the entire absence of ulceration and infiltration—these will suffice to distinguish it from aphtha and from catarrhal ulceration. Leucoplakia buccalis differs from exfoliatio areata linguae in the lesion being stationary. Syphilis of the tongue might offer some difficulty in diagnosis to a superficial observer. But the erosions of the tongue in early syphilis are more profound, often dry, sharply limited, fixed in their seat, and not surrounded by a raised whitish margin. In syphilis there is also an inflammatory tumefaction of the connective tissue of the filiform papillæ. In the exanthems, and in recovery from grave illnesses, transient exfoliation of the tongue takes place. But these exfoliations do not assume the typical "area" form, and disappear completely with the recovery from the disease with which they occur. Should the exfoliation continue for some time after recovery from the constitutional disease, the lesion will be single and of irregular, indefinite shape, will occupy a large part of the surface of the tongue, and will not migrate from place to place. The aetiology of the disease is obscure. Some have endeavored to establish a connection between it and menstruation, anaemia, dentition, and catarrhal conditions, but, with the exception of the first of these, the author has been unable to establish any such relation. It has no relation to syphilis. No treatment is necessary.

**Ulerythema Ophryogenes** is the latest creation of the fertile brain of Unna, or at least of his pupil, Taenzer ("Mnthsft. f. prakt. Derm.", 1889, No. 5). In the course of three years Taenzer had the good fortune to observe six cases of this "hitherto undescribed disease of the skin." It begins in earliest childhood with a reddening of the skin of the eyebrows, a feature that continues throughout the disease, and afterward that of the face, the scalp, and, more rarely, the upper arm. The disease at first resembles lichen pilaris upon a reddened skin, but subsequently in some places, and in bad cases everywhere, the skin is highly inflamed, though the inflammation is superficial. Wherever the hairy parts are affected the growth of the hair is interfered with; they come through late and, as it were, in isolated bundles or groups, with here and there evidences of pustular inflammation of the follicles. The skin between the bundles of hair sinks in and becomes atrophied. Eventually total alopecia and atrophy of the scalp may result. In most cases the disease reaches only the first stage, the lichen pilaris stage, in some places, and the second stage in other places, and so remains throughout life. Three of his cases occurred in members of the same family, suggesting the question of heredity or infection from parasites. In one case the eyelids were affected, causing incurving of the lashes and conjunctivitis. Four of the patients had eczema in their younger days. The disease may be considered as presenting itself in two forms, a mild one and a severe one. In the mild form the disease begins on the outer part of the eyebrows, proceeds over the malar process, down in front of the ear, and to the side of the neck, ending upon the extensor surface of the upper arm, and seldom passing over upon the forearm. It begins as a hyperkeratosis with accompanying erythema; the follicles of the skin are occluded by corneous covers, the lanugo hairs and many of the stronger hairs are prevented from growing, and this gives rise to the appearance of a lichen pilaris. The severe form is marked by an implication of the inner part of the eyebrows, the upper lip and a few contiguous regions of the skin of the face, the scalp, and the extensor surfaces of the arms. The formation of cicatricial tissue is now active, always attacking the skin between the hairs, giving rise on the upper lip and eyebrows to a fine linear atrophic network, and on the scalp to a system of confluent bald rings, and ultimately complete baldness. It runs a slow course, with occasional outbreaks of suppurative follicular inflammation. The disease differs from lichen pilaris in its inflammatory character, its permanent erythema, and the final atrophy of the skin. Unna names affections of the skin attended with erythema and the formation of scars "*Ulerythema*" (meaning cicatrization with redness). In this group falls lupus erythematosus. Taenzer adds "*ophryogenes*," because the affection has a predilection for the eyebrows. In the treatment of the disease sulphur and resorcin are said to be efficient for the cure of the milder form, and the bettering of the more severe form. [We can not praise this new dermatological term on account of its

euphony; and we can not forbear protesting against the introduction of new terms into our already burdened nomenclature.]

**The Treatment of Acne.**—Dr. Isaac ("Berl. klin. Woch.", 1889, No. 3) believes that this disease is so far hereditary that in certain families there may exist an anatomical patulousness of the sebaceous glands, allowing of their clogging with extraneous particles. This clogging he regards as the chief cause of the disease. Beer, cheese, and coffee are regarded as specially harmful ingesta, and the latter is supposed to produce acne upon the same principle that bromine and iodine do. In the treatment, naphthol is recommended after Lassar's formula: Naphthol, 10 per cent.; precipitated sulphur, 50 per cent.; green soap and vaseline, each 20 per cent.; which is to be spread on the face and left on from half an hour to an hour. This is followed by some redness of the face and scaling. It is to be repeated till all the skin peels off. If too much reaction takes place the use of the paste is to be discontinued and the face powdered or anointed with a mild ointment. In obstinate cases the following is commended: Powdered chalk, 5 per cent.;  $\beta$ -naphthol, camphor, vaseline, each 10 per cent.; green soap, 15 per cent.; precipitated sulphur, 50 per cent. Resorcin also is excellent, and is used in twenty per cent. strength in Lassar's paste.

**The Treatment of Squamous Eczema of the Back of the Hand.**—This disease is believed by Unna ("Montshft. f. p. Derm.", 1889, No. 4) to be a seborrhœal form of eczema, in common with those forms of eczema known previously as "baker's itch," "bricklayer's itch," and the like. In most cases, he says, seborrhœal affection of other regions will be present at the same time—pityriasis capitis, an oily condition of the face, an intertriginous eczema, and so on. In the way of treatment it is recommended to cover the affected part with a thin layer of cotton batting soaked in the following solution: Resorcin and glycerin, each 10 parts; dilute alcohol, 180 parts. This is to be diluted with equal parts of water when used, and is to be applied in the evening. Over it is to be bound a large piece of gutta-percha tissue, so as to envelop the whole hand and keep the batting moist all night. In the morning a zinc-oxide paste, either with or without sulphur, tar, or resorcin, is to be applied, and renewed once or twice during the day. For washing the hands, the patient should use only warm water and avoid fatty soap. While caring for the eczema, the seborrhœal affection of other parts must be treated.

**Herpes as an Infectious Disease.**—The only form of herpes that heretofore has been generally recognized as infectious is that improperly named herpes tonsurans or circinatus—that is, ringworm. But it has been suggested from time to time that zoster (herpes zoster) might be an eruptive fever similar in many ways to the other exanthems. Now, Török ("Montshft. f. prakt. Derm.", 1889, viii, 54), who writes from Unna's clinic, and who, it is fair to surmise, represents Unna's idea in this matter, maintains for all varieties of herpes an infectious character. He cites the following series of cases: On November 14, 1888, a zoster patient with constitutional disturbance was admitted into Unna's wards. Toward the end of the month two women in the same ward had herpes labialis, with fever, headache, and weakness as prodromal symptoms. Then a boy and a girl broke out with herpes. Five weeks intervened between the first and last case, all being herpes vulgaris, excepting in the boy's case, where, besides the herpes facialis, there was a group of vesicles on the abdomen, just below the ribs, which might have been taken for a zoster. The author even indulges in fancies of a virus in doses of varying strength, the milder producing herpes febrilis, and the stronger zoster, and explains the usual single attack of the latter by the thorough saturation of the system by the virus. He also holds that zoster and herpes are only varieties of the same disease. [According to this, when zoster arises from injury, the part must have been inoculated with the virus at the time of the injury!]

**Pityriasis Pilaris.**—Dr. Boeck, of Christiania, gives us a study of this disease ("Montshft. f. p. Dermat.", 1889, viii, 97) founded upon a case. The disease occurs with special frequency and markedly developed upon the dorsal surfaces of the fingers, the hands, and forearms, which is probably due to the strongly developed lanugo hairs of these regions, whose root-sheaths are specially affected in this disease. Around each of the lanugo hairs is formed a solid cornaceous mass, which presses both down into the hair follicle and up above the level of the skin. The skin is usually of normal color, but very rough, and feeling

like "goose-skin" from contact with cold. It may be paler than normal. After a time hyperæmia may set in about the hair follicles and spread over the entire skin. If this takes place, the "goose-skin" appearance will be less marked. Besides the regions named, any part of the body may be affected, excepting the palms and soles, where there are no lanugo hairs. It occurs on the usual hairy portions of the body. It may begin also as red macules and patches with a smooth skin, but even then it will be easy to see evidences of corneous formations about the lanugo hairs. The whole body may be affected with this form of the disease. Usually the general health is not disturbed, but, if the disease becomes universal, there are malaise and nervousness. Itching may be present, and the lymphatic glands may swell. The disease may last indefinitely, and is subject to relapses. The hyperæmic cases, when they become general, bear a close resemblance to pityriasis rubra, and end by desquamation. For treatment, arsenic in large doses and cod-liver oil are recommended for internal administration, and Unna's "Zinklein" locally.

**Alopecia Areata following an Operation on the Neck.**—In the light of Max Joseph's experiments in producing alopecia areata by cutting out the second cervical ganglion in cats, the report by Pontoppidan ("Monatshft. f. prkt. Derm.", 1889, viii, 51) of a case of the same disease occurring in a child following an operation in the neck is of special interest. The operation was for the removal of an enlarged cervical gland in the left carotid region. The external jugular vein was wounded in the operation so that a tampon had to be applied to check the bleeding. On the second day following the operation there was discovered a paralysis of the left sympathetic shown by ptosis and contracted pupil; there were also choreic movements of the left arm during sleep. Three weeks after the operation, when the bandages were first removed, there were discovered a number of symmetrical spots of alopecia areata. These subsequently increased in size till the occipital region was entirely bald, the area being bounded above by a sharp horizontal line running from the crown of the head forward around the head so that there was only a strip of hair on the temples before the ear, and only a narrow line of hair on the neck. This distribution corresponded to the regions supplied by the occipitalis major and minor, and by the posterior branches of the auricularis magnus. In this case there was a nerve injury in a region corresponding to that operated on by Joseph, and the case is instructive as showing the nervous origin of some cases, at least, of alopecia areata.

**The Pathogenesis of Alopecia Areata.**—This vexed question is once again discussed; this time by Mibelli ("Giorn. ital. del. mal. ven.", 1888, xxiii, 416). He shows how little dependence can be put upon the results of the microscopic investigations into the pathology of the affection thus far made, as the findings of the most able of the investigators do not agree among themselves as to either the parasite or the lesion of the hair. Experimentally, it has not been possible to convey the disease directly from man to man, or from man to animal; and the results obtained by section of nerves are of uncertain value. Joseph's experiments in the production of hair-fall by resection of the second cervical nerve led Mibelli to a series of investigations in this direction. In the first series, in 1887, he obtained in three cats a fall of hair in circumscribed areas by following Joseph's method, which was evidently due to nervous influence. A second series of experiments led him to uncertain conclusions, so he undertook a third series. His subjects were cats, as he found that they were the easiest to operate upon, and full-grown ones were preferred. The operations were done under chloroform. An account of fifteen out of thirty experiments is given. Microscopical examination of pieces of sound skin as well as skin from which the hair had fallen, both taken from the same animal, showed, in two cases, no difference in structure except the absence of hair from the bald places. In no case were changes found sufficient to justify a diagnosis of atrophy of the hair follicle or papilla. In one animal there was a marked alteration of the epidermis from the bald patch, the rete being notably swollen, having many cells with circumnuclear dropdowns, the interspinous spaces being much dilated. In numerous places there were appearances similar to those presented by vesicles in rapidly spreading dermatitis or acute eczema. As to the results of the experiments upon the hair-fall, one of the most striking was the disparity of the effects obtained. In some animals extirpation of the

second cervical ganglion produced a fall of hair in circumscribed areas, both in the region of distribution of the cutaneous branches of the affected nerves (six cases) and also in parts more or less distant (three cases). In other animals the same operation was followed by hair-fall from regions outside of those supplied by the nerve operated upon (four cases). In yet other animals the operation was completely without result (five cases). The date of the hair-fall varied greatly; it occurred at any time from the ninth to the forty-seventh day after the operation. In most of the cases there was no change in the skin of the bald spot; in one case there was a superficial abrasion; in another there were soft crusts in the center of the bald spot; and in another a true eczema appeared along with the fall of the hair. These differences can not be explained by differences in the animals themselves or in the operations. The fact that the hair is regenerated after a time in the bald areas disproves Joseph's hypothesis that its fall is due to destruction of the trophic nerves going to the part, because when a peripheral nerve is separated from its ganglion it falls at once into degeneration, and can not be brought to life again; nor could the atrophied hair papillæ renew their functions. On account of such inflammatory alterations in the skin as he met with in his experiments, he is inclined to attribute the hair-fall to a lesion of nutrition of the skin, but not to a pure tropho-neurosis; rather an alteration in the vascular system. Inflammatory changes in the skin following the removal of the anterior lobes of the brain of a dog have been observed by Goltz. The same result has followed the cutting away of the occipital lobes. This has been noted by other experimenters. It is probable that excision of the second cervical ganglion may produce disturbance of the nerve centers, and this last produce the changes in the skin and the hair-fall. That the skin recovers shows that the disturbance is a passing, functional disorder of the nerve, interfering with the blood-supply to the affected part.

**Piedra.**—This, to us, rare disease has been studied by Dr. Juhel-Renay ("Annal. de derm. et de syph.", 1888, ix, 777). The affected hairs when they are of a certain length appear like lanugo hairs, and curl up upon themselves. At unequal distances along the shaft there are little elevations, more readily perceptible to the touch than to the sight, of a dark chestnut color, and easily cut through with the scalpel. They resemble the nits of pediculi, but are very much smaller. The microscope shows them to form a more or less complete annular sheath to the hair, and they are often transparent enough to allow of the hair being seen through them. They appear greenish-yellow in glycerin. As many as twenty-three were found upon a hair two feet long. They are composed of an agglomeration of spores compacted together by the solidifying of a fatty substance. The spores are larger than those of the trichophyton, of nearly double the size, and of very varying shape. Through them run little staff-like columns. He has not been able to find mycelia in any of the cases examined. The parasite does not penetrate the hair, but is stuck on the surface. It bears no relation to trichophytosis or favus.

**The Treatment of Favus with Oleate of Copper.**—Mibelli recommends ("Boll. dei cult. del. sc. med.", 1888; "Giorn. ital. del. mal. ven.", etc., 1888, fasc. iii, p. 329) the daily rubbing into the scalp, deprived of crusts, of twenty-per-cent. oleate of copper, then covering the head with a light protective covering, and every two or three days washing with tincture of green soap. He has cured some cases by this method without epilating.

**The Treatment of Tinea Tonsurans.**—In 1885 Harrison, of Bristol, Eng., first advocated the treatment of this disease by means of two solutions, one of liquor potassæ and potass. iodide, and the other of mercuric chloride. This was said to yield good results, but was troublesome to use. Now ("Brit. Med. Jour.", 1889, i, 465) the same physician gives us a modified procedure as follows: Every night and morning there is to be rubbed into the diseased parts a little of an ointment composed of caustic potash, gr. ix; carbolic acid, gr. xxiv; lanolin and oil of cocoanut, each 3 ss. The hair is not to be shaved, and a cure is to be looked for in from one to three months. During the treatment the whole head is to be anointed with an ointment composed of boric-acid ointment and eucalyptus ointment, each 3 ij; oil of cloves, 5 ss.; oil of cocoanut up to 3 yj. The other children of the family are to have their heads anointed with the same ointment. Favus may be treated on the same plan.

**Syringo-cystadenoma** is the name given by Unna to a variety of tumor of the skin described by his assistant, Török, in the "Monatshefte für prakt. Dermat.," 1889, No. 3. The study is founded upon a case of some seventeen years' standing occurring upon the chest and abdomen of a man thirty-three years of age. It began in the neighborhood of the axilla and spread forward and downward. The eruption consisted of a number of small, round, hard, raised papules of the color of the skin. These papules tended to grow larger and to become of a bluered color. It was unattended by subjective symptoms. Histological examination showed the tumors to consist of spaces, tubules, and epithelial nests, which in a more advanced stage changed into cysts and canals, on account of which the name cystadenoma was given. The build of these bodies, especially the configuration of the tubules, and the appearances of the epithelium of a portion of them, point to the sweat glands as their probable origin. It is probable, also, that they originate in embryonal sweat glands, as no connection could be found between them and glands already formed.

**Xeroderma Pigmentosum.**—A case of this rare cutaneous disease is reported by Brigidi and Marcacci in the "Giorn. ital. del. mal. veu. e della pelle," 1888, xxiii, 281. The patient was a girl, eight years old, in whom the disease began in the fourteenth month of her life, and without apparent cause. It was located upon the face, the neck, a part of the back, and the arms. The eruption consisted of a great number of macules of a black or brown color like lentigines, and of various shapes. Between these macules were sown, as it were, linear or stellate, more or less bright-red macules, which were true teleangieictases. Upon the face were some corneous growths, and near the nose and upon the cheeks were slight ulcerations. The affected skin was dry and scaly. Various attempts at treatment were without effect. A list of forty-one monographs and journal articles is appended to the article, which will be useful to any one studying the subject.

**The Treatment of Sarcoma Cutis.**—Funk, of Warschau, at the close of a clinical study of sarcoma ("Montshft. f. prakt. Derm.," 1889, Nos. 1 and 2), recommends arsenic energetically administered in the treatment of multiple sarcomata. When the tumor is solitary, it should be excised. When ulceration has taken place, a ten-per-cent. iodoform ointment will render good service.

**Purpura and Malignant Growths.**—Dr. Harris, of Manchester, reports ("Med. Chron.," Feb., 1889) some interesting cases of hemorrhages into the skin and mucous membranes taking place in connection with sarcomatous growths occurring in various parts of the body, and explains their occurrence upon the theory that they are due to emboli from the growth lodging in the capillaries of the skin.

**Leprosy and its Contagiousness.**—While living in Africa, Dr. Daubler visited what he calls "Robben" Island. This small island lies off the coast of South Africa, and contains eighty-four lepers, and it is upon these as well as those of South Africa that this study ("Monatsheft f. p. Dermat.," 1889, No. 3) is made. Fifty-eight of them were men. The men and women lived in different parts of the island. There were only three Europeans affected with the disease, and all of these were men. The first cases were brought to Africa by the Chinese. On the island the accommodations in the hospital are not sufficient to accommodate the lepers of the neighboring Cape Colony, and so there are many lepers at large spreading the disease. From Cape Colony leprosy is spreading into the heart of Africa. On the island most of the cases are of the tubercular variety, only a quarter of them showing the anaesthetic form. In two cases the evidence pointed conclusively to the inoculation of the disease by vaccination, the lymph having been taken from a person who subsequently died of leprosy. The resident physician, Dr. Wynne, has succeeded several times in inoculating mice and rabbits with anaesthetic leprosy.

**Syphilitic Deposits in the Human Tongue followed by Epithelioma.**—Dr. Wheeler reports ("Med. Press," Jan. 23, 1889) a case of epithelioma of the tongue of a man forty-eight years old. Ten years before its appearance he contracted syphilis that left a deposit in his tongue which had been brought nearly to a disappearance five times by anti-syphilitic treatment, but finally became epitheliomatous, as proved by microscopical examination.

**Hereditary Syphilis.**—A study by Neumann runs through Nos. 4 to 9 of the "Wien. klin. Wochnsht." for this year. It is founded upon

a hundred and twelve carefully observed cases. This valuable contribution is too long for abstracting, and we must content ourselves with giving the author's conclusions as follows: 1. A syphilitic mother may infect her unborn child in every period of her disease, whether she has acquired it before or after conception. 2. While it is possible for the foetus to inherit syphilis when the mother becomes infected after conception, it is rare; and very rare when the infection takes place late in the period of pregnancy. 3. If the infection of the mother occurs after conception, the father at that time being syphilitic, the influence upon the child is intense, as it either dies *in utero* or is born with some specific manifestation. 4. When syphilis is acquired by the mother late in pregnancy, the child usually escapes. 5. When infection and conception occur at the same time, in half the cases the foetus dies. Nevertheless, quite a large number of the children escape entirely, in spite of both the parents being syphilitic. This is contrary to the opinion generally entertained. 6. The further removed the time of infection is from the time of conception (antedates it), the better chance there is for the child, provided the mother undergoes an active course of treatment. 8. The best chance for the child is when the mother has acquired the disease late during the pregnancy, and the father was not syphilitic at the time of the conception. The poorest chance for the child is when conception and infection occur at the same time, or the father at the time of conception has recent syphilis. 9. A child may acquire syphilis from the father. 10. It is not advisable to bring on an abortion in a case of late infection of the mother. 11. Tertiary syphilis does not produce sterility in the woman. 12. A protracted mercurial treatment is favorable to the child. Of the hundred and twelve cases studied, in but forty-four were the children born alive, and most of these died soon after.

**Syphilitic Reinfection.**—Dr. Ducrey, of Naples, reports in the December number of the "Giornale italiano delle malattie veneree e della pelle" for 1888 a case of syphilitic reinfection in a woman forty-six years of age, married, and without children. She gave a clear history of her first attack of syphilis and of a subsequent infection with soft chancrea acquired from her husband. Ten years after marriage, and some eleven or twelve years after primary infection, she had intense headache and an eruption of circumscribed nodules and pustules upon the scalp, which ulcerated and became serpiginous. At this time the husband contracted syphilis from another woman. His symptoms made the wife suspicious, and, experiencing discomfort in the genital region herself, she went with the husband to the clinic, and was found to have an initial lesion, inguinal gland enlargement, a macular syphilitide over the body, and other signs of fresh infection. The course of the freshly acquired disease was a stormy one, with a great deal of constitutional disturbance, a general outbreak of pustular lesions, and intense osteoscopic pains.

## New Inventions, etc.

### EXPRESSION IN THE TREATMENT OF TRACHOMA.\*

By A. E. PRINCE, M. D.,  
JACKSONVILLE, ILL.

It is my pleasure in this paper to call your attention to a method employed in the treatment of chronic follicular trachoma which has found its way into few of the journals and none of the text-books, but which, in my opinion, takes the lead among the remedies employed against this intractable disease. This process is the expression or enucleation of the follicular contents.

The first reference to this subject which is to be found in literature occurs in Graefe's "Archiv für Ophthalmologie," 1883, in which Mandelstamm, a Russian oculist, speaks of the efficacy of squeezing, in the treatment of trachoma, by means of the thumbs. "The lid being everted and held by the thumb of the left hand, the nail of the right thumb is placed in the retro-tarsal fold. The two thumbs are now

\* Read before the Illinois State Medical Society, May 23, 1889.

pressed against one another, including the lid and part of the reflected mucous membrane, thereby squeezing out the follicular contents and breaking down their walls." This announcement of Mandelstamm's made little if any impression, and the idea might still have remained dormant but for an accidental discovery made by Dr. F. C. Hotz, of Chicago, two years before the appearance of the publication of Mandelstamm. He published his observation in the following words, in Knapp's "Archives of Ophthalmology," June, 1886: "At this time," he says, "an exceedingly nervous patient with follicular trachoma and acute pannus came under my care. A violent spasm of the orbicularis set in when I turned the upper eyelid, and, as I pushed the everted lid upward in order to obtain a better view of the retro-tarsal portion, I observed that the contents of the numerous trachoma follicles were squeezed out by the pressure of the orbicularis, in the form of gelatinous plugs, and, by assisting this pressure a little with the thumb, I succeeded in thoroughly emptying all the follicles. The next day I was actually surprised by the remarkable improvement. All acute irritation was gone, the photophobia and the heavy pressure of the lids had disappeared, the eyes were opened without discomfort, and in a few weeks the patient was discharged as cured."

This article appealed so forcibly, as both rational and practical, that I was led to adopt the method at once, and have subjected it to three years of almost daily trial and in the various stages of trachoma.

To appreciate the indications for squeezing in the treatment of trachoma, it will be well to bear in mind the natural history of the disease. Though the lines are not closely drawn, in the course of the disease three overlapping stages may be recognized:

1. The inflammatory.
2. The follicular.
3. The cicatricial.

In the first the epithelial structures are principally affected and the enlargement of the papillæ has led to the term papillary hypertrophy.

In this stage, in my opinion, squeezing is contra-indicated. The inflammation is acute, and the treatment has not been found to shorten the disease. With the subsidence of the acute process, which may be shortened by scarification and astringents, one is able to observe the characteristic of the second stage.

The hypertrophied papillæ may be seen interspersed with the follicles, which, by their color and increasing prominence, lead to no possible mistake in the diagnosis. With the further progress of the disease they become the ruling factor of the process. They infiltrate the hypertrophied papillæ and may be seen in masses or folds corresponding to those of the conjunctiva. They may be more or less extensive, in one case being limited to a few follicles and in another omnipresent with the conjunctival area, resembling the ovary of a fish. Lying beneath the epithelial surface, they are by it protected against the irrational caustic treatment which has so often been seen to result in the deplorable destruction of the tarsal and retro-tarsal mucous surface, resulting in ptosis, entropion, and blepharo-phimosis. The poisonous contents of these follicles, rather than the roughened surface, are to be held accountable for the recurrent ulcers of the cornea, which result from the corneal invasion of septic agents.

The presence of the follicles in the tissue stimulates the secretion of a protective exudate, the organization of which results in the cicatrization which characterizes the third stage.

So long as the follicles remain to excite irritation, the cicatrization continues. The second stage may thus be seen to lap over the third, which is often prolonged months or years by the presence of more or fewer follicles which, being situated deep in the tarsus or concealed in the retro-tarsal fold, resist the efforts of nature or elude the vigilance of art. The curative method of nature is that of siege, and many cases of trachoma result in spontaneous recovery, but with a loss of a large portion of the mucous surface which has been transformed into cicatricial tissue. The caustic method of the past has imitated the method of nature and secured the end in a shorter time by artificially destroying the epithelium and hastening the cicatrization. This irrational procedure has been pushed still further by some of the prominent French surgeons, who have advocated the excision of the retro-tarsal folds, maintaining that the disease is not cured until the whole area of trachoma development is destroyed.

The mycological development of the last decade has changed all this. After the primary stage of epithelial inflammation, the diseased germs infest the follicles, and the problem is, therefore, to remove them as they develop with the least possible destruction of the mucous membrane.

By mechanically squeezing the area, underlying which the follicles may be seen, the pressure causes a rupture of the surface permitting the extrusion of the follicular contents, and is followed by healing with no loss of tissue. In the secondary stage this may require repetition one or more times, because there are often numerous small follicles which are not sufficiently developed to permit of their removal. But if the case is seen in the cicatricial stage, when the battle of supremacy is being waged by the two contending forces, a single squeezing is often sufficient to reverse the balance of power and effect a permanent cure.

The method of effecting this deserves some comment.

The failure of Mandelstamm's suggestion to obtain re-recognition was probably due to its narrow limit of availability. Squeezing between the thumbs is not applicable to the lower lid, and is available in the treatment of the upper lid in only a small proportion of very chronic cases. Hotz, in his article, speaks of having used an old-fashioned iris forceps.

For the first two years of my experience with the method a curved clot forceps was employed, but so often was it found ineffectual in removing the concealed follicle that an attempt has been made to supply a need which it is believed exists.

In the construction of an efficient trachoma forceps three qualities have been deemed essential: First, that the shape should render every point of the conjunctival surface accessible; second, that sufficient strength should be possessed to express the follicular contents when occurring beneath the tarsus; third, that the terminal extremity should be of round or oval wire to prevent laceration of the mucous membrane, which is always delicate and often atrophied.

These requirements were communicated to George Tiemann & Co., who have produced this forceps, which has been found to meet the demand. Since receiving it a few months ago I have effected a cure in a number of chronic cases which had resisted treatment, in which the follicles were wholly inaccessible by means of the thumbs or any forceps in my possession. By means of this instrument it has been found possible to reach the commissural angles of the retro-tarsal folds, the caruncle, and the plica semilunaris, and, besides, to remove the granulations from under the bulbar conjunctiva though extending to the limbus cornea.

The hemorrhage in these operations is generally slight and believed to exert a favorable influence on the disease. The pain, in considerable measure, may be controlled by an eight-per-cent. solution of cocaine hydrochloride, and still more effectually by the use of bromide of ethyl, which, when properly administered, secures anesthesia in from thirty to sixty seconds, which lasts but from one to two minutes, and seldom leaves so much as a headache.

It must not be understood that squeezing is considered a substitute for all other treatment. Many cases of this persistent disease will test the patience of the patient and the tact of the physician in conducting the disease through the second stage until there are no new crops of follicles to be squeezed out. It will be found necessary to exercise intelligence in the selection of agents to control the inflammatory conditions of the lids as well as the complications of the cornea and iris which may exist.

Attention to the general health must not be overlooked; neither must the condition of the lacrymal drainage be ignored. The surgical indications furnished by entropion and blepharo-phimosis must also receive efficient and prompt attention, for the eye is but an organ of the physical economy and is dependent upon the general condition as well as the local environment for the successful operation of its special function.

## Miscellany.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the abstract of sanitary reports received by him during the week ending July 26th:

CITIES.	Week ending—	Estimated population,	DEATHS FROM—										
			Total deaths from all causes.	Cholera.	Yellow Fever.	Small-pox.	Varioloid.	Variola.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Measles.

**Diagnosis of Brain Cysts.**—“Professor Edmond Souchon, of New Orleans, has suggested that in cases in which the diagnosis of cyst or abscess of the brain is doubtful, the brain may be explored with a fine aspirating needle introduced through a small hole made in the skull with a watchmaker’s drill, furnished with a gauge and screw so adjusted as to prevent the ‘bit’ from penetrating too deeply after working through the bone. He has performed the operation several times on dogs, and these animals, after recovering from the chloroform, did not seem to have been in any way affected by the operation, and remained afterward in perfect health. In an animal killed before recovering from the chloroform there were seen only small extravasations under the scalp and under the pia mater. Professor Souchon thinks that the ‘bit’ used should be large enough to make a hole in the skull to admit a needle twice the size of an ordinary hypodermic needle.”—*British Medical Journal*.

**Propeptone or Hemialbumosuria in Measles.**—“Propeptone, or hemialbumose, is known to exist in the urine in many diseases in addition to osteomalacia, in which it was first found by Dr. Bence Jones. Thus it has been detected in abscess of the liver, septicæmia, hip disease, peritonitis, endocarditis, parametritis, spinal curvature, Bright’s disease, and in the puerperal state. Dr. Loeb, of Frankfort, now writes that he has found it in the urine of nine patients with measles out of twelve cases of the kind in which he examined the urine for it. The method of testing employed by him is as follows: Sulphuric acid added to the urine drop by drop causes, if propeptone is present, a copious,

white, flocculent precipitate, which disappears on heating, but reforms if the liquid is allowed to cool. Acetic and hydrochloric acids will give a similar reaction. It must be remembered that an excess of acid will redissolve the precipitate; therefore it is necessary to be careful to add it slowly. As a rule, in the cases of measles examined the reaction was obtained for about two days at the beginning of the affection after the temperature had begun to go down, but before the rash had disappeared. Dr. Loeb found in several of his cases some enlargement of the liver, which he thinks may have some connection with the change in the urine. He also suggests that perhaps the skin affection is connected with the formation of propeptone, as it has been found in patients suffering from various affections in which the skin is impaled; thus Leube found it in urticaria, Ter-Gregoriantz in diffuse dermaatitis, and Lassar was able to produce it in animals by rubbing petroleum ointment into the skin. Regarding the relation of propeptonuria to the condition which gives the so-called dinitro-benzolizie acid reaction which is frequently found in typhoid, scarlatina, advanced phthisis, and other febrile diseases, Dr. Loeb has found that its presence does not always imply the existence of propeptonuria, though in many cases the former condition coexists with it.”—*Lancet*.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

**Authors of articles intended for publication under the head of “original contributions” are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters’ hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.**

**All letters, whether intended for publication or not, must contain the writer’s name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author’s name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.**

**Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies’ regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.**

**Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.**

**All communications intended for the editor should be addressed to him in care of the publishers.**

**All communications relating to the business of the journal should be addressed to the publishers.**

## Lectures and Addresses.

### A CLINICAL LECTURE ON IRRIGATION OF THE STOMACH.

DELIVERED AT THE

NEW YORK POST-GRADUATE MEDICAL SCHOOL, JULY 2, 1889.

BY JAMES K. CROOK, M. D.,  
INSTRUCTOR IN CLINICAL MEDICINE AND PHYSICAL DIAGNOSIS.

This morning, gentlemen, I wish to call your attention to a therapeutic procedure in the management of certain gastric diseases which, I have reason to believe, is not resorted to as often as it should be. I refer to irrigation of the stomach, or, as it is sometimes called, lavage. A careful examination of our principal medical journals for several years back, in addition to conversations on the subject with a considerable number of physicians in active practice, convinces me that this method of treatment is suffering from an undue neglect. It was introduced, about twenty years ago, by Kussmaul, who employed it in cases of gastrrectasis, or dilatation of the stomach, and a majority of those who have since adopted it have limited its use to that particular affection. There is no doubt, however, that its range of application is capable of much greater extension. Indeed, I have no hesitation in saying that it should be given a trial in every case of chronic dyspepsia in which medicines have failed, provided there is no contra-indication to its use. We are safe in assuming that most of these patients have more or less gastric catarrh, and, at any rate, we can do no harm by the exceedingly safe and simple operation which I will show you presently. The chief advantages of lavage are as follows: 1. Owing to a loss of peristaltic power, often present in simple dyspepsia and always in dilatation, the stomach is unable to rid itself properly of ingested material until long after the period of normal digestion. This condition has been termed by Rosenbach insufficiency of the stomach. This stagnating and fermenting material, in some instances, will remain in the stomach for days at a time, as shown by the vomiting of substances known to have been ingested a long time previously. The stomach is liable to become greatly irritated in this way, and inflammation may even be developed. By the timely employment of the tube all this material may be washed out, and the stomach thoroughly cleansed and allowed a period of perfect repose. We may thus in many cases restore the lost elasticity and muscular contractility of the organ. 2. In cases of simple gastric catarrh it relieves the stomach of the superabundant mucus, and perchance bile, that may be present. 3. By reason of its safety and simplicity, an intelligent patient may be readily taught to use the tube himself. Washing of the stomach should be performed at least six or eight hours after eating, when the organ is supposed to be empty. For this reason an early morning hour before the first meal is commonly chosen. It should be performed every day at first, then every other day, dropping to once a week, and finally discontinuing altogether. Tepid water should be used, to which, if desired, may be added certain medicaments—bicarbonate of sodium, car-

bolic acid, creasote, hyposulphite of sodium, Lugol's solution, etc. The prognosis is, of course, most favorable in cases of simple dyspepsia and early dilatation. In old cases of gastrrectasis we can expect palliation only. The best results are seen in cases of gastric insufficiency, the criteria of which I have mentioned.

With these preliminary remarks, we will now devote ourselves to the patient who presents himself. He informs us that he is thirty-four years of age and a brass-moulder by occupation. On February 21st he came under my observation, giving a history as follows: For about a year past he had been suffering from flatulence, pyrosis, obstinate constipation, and cardiac palpitation. The latter symptom especially was so severe and constant that the patient was firmly fixed in the belief that he had heart disease. He had applied to several physicians, but had failed to obtain relief. I found him in a very melancholy frame of mind, as he had begun to lose hope of ever getting well. He was put under treatment, and various remedies prescribed for the relief of his symptoms. There was no improvement, however, and at the end of two months he was rather worse than at the beginning of my treatment. On April 24th I resorted to irrigation of the stomach, and have continued it at gradually increasing intervals since that time. For the past month it has been performed at intervals of two weeks, and to-day I think is about the last time it will be required. If you will question the patient, you will learn that the symptoms began to abate immediately after the first washing, and his improvement has continued steadily ever since. He has gained in weight, his appetite is greatly improved, and he has a regular daily evacuation from his bowels. He has not been troubled for three weeks with cardiac palpitation, and the pyrosis has disappeared entirely. This improvement I attribute to the periodical irrigations of his stomach, although certain dietetic and hygienic precautions have doubtless had some influence. His nourishment has consisted chiefly of fresh milk and tender beefsteak, broiled underdone, chopped fine, and thoroughly masticated, with stale or toasted bread. Latterly he has been allowed a mutton-chop, the white meat of fowls, and an occasional lightly cooked, poached egg. Saccharine, amylaceous, and fatty substances have been excluded as far as possible. Such notorious dyspepsia breeders as boiled cabbage, rich cake, pies, strong tea, fat pork, etc., have been given a wide berth. The patient has been allowed a glass of claret for dinner, but no other stimulant whatever. The only medicines taken since employing lavage have been a little bismuth and pepsin, with a few grains of aromatic powder to correct occasional spells of flatulence occurring in the intervals of the irrigations. I may say that the patient has been exceedingly tractable, and, I believe, has obeyed my instructions to the letter.

The instrument I employ is a large-sized soft-rubber tube about thirty inches in length, and having two eyelet holes in the distal extremity. It is exactly similar to a large-sized Jacques urethral catheter, being of the size marked 19 A. (American scale) by Tiemann, of this city. Some employ a longer tube, having a funnel connected with

its proximal extremity, known as the Fancher tube, but I prefer the one I have here, attaching it by means of a short glass cylinder to the hose of an ordinary fountain syringe, which I hang on a convenient hook in the wall above the level of the patient's head. After anointing about twenty inches of the distal portion of the tube with vaseline I pass it back to the patient's pharynx, instructing him at the same time to swallow. The end of the tube readily engages in the upper extremity of the oesophagus, and by a little gentle, continuous pressure it gradually passes down into the stomach. When I first passed the tube in this case there was considerable retching, and even a little vomiting, but by repeated use the patient has acquired a toleration for it, and you will notice now that it produces no sign of annoyance or discomfort. In some cases we will have to exercise no little patience and perseverance at the first attempt at introduction. Sometimes the patient will vomit the tube as quickly as it is placed in position. Such cases are not common, however, and tolerance is usually quickly acquired. In obstinate cases a four-per-cent. solution of cocaine may be applied to the pharynx and fauces by an atomizer before introducing the stomach-tube. Having the tube *in situ*, I now connect it with the syringe, at the same time filling the latter with simple tepid water, which, as you see, passes rapidly from the bag into the stomach. After I allow about two pints to run in, the patient expresses a sensation of fullness in the region of the epigastrium, so I cut off the flow by means of a stop-cock on the hose of the syringe. I now disconnect the hose from the syringe and depress the former, holding it over a vessel placed ready to receive the fluid from the stomach. A reverse current is immediately established on the principle of the siphon, and the contents of the stomach pass very readily through the tube into the receiver. There is no solid matter in the stomach, as the patient informs us that he took nothing for his breakfast except a cup of chocolate with a little milk. You will notice that the flow is occasionally interrupted and stops altogether at times. This is due to flocculi of phlegm and mucus in the stomach, which engage in the tube and arrest the current. This mucus was very abundant at first, but has progressively diminished until now it amounts to very little. It may be driven through or disengaged from the tube by instructing the patient to bear down; by gentle but firm pressure over the epigastrium with the hands; by shifting the position of the tube, withdrawing it slightly, and returning it; or, finally, by connecting it with the syringe again and allowing more water to enter the stomach. While the water is flowing into the stomach it is a good plan to walk about the room with the patient, holding the syringe on a high level and instructing him to lie down a little while and to agitate his body in such a way that the fluid reaches every portion of the gastric mucous membrane. I continue to replenish the water and allow it to flow out again until six or eight pints have been consumed. You will see that it now returns from the stomach perfectly clear and contains no mucus whatever. In the last installment of water I dissolve fifteen or twenty grains of salicylate of sodium as a safeguard against renewed fermentation. Just here I will mention another application for irrigation. We

now know this man's stomach to be perfectly empty. By percussion of the epigastrium we may, if we desire, ascertain the condition of affairs in that region, carefully noting the areas of tympanitic resonance, dullness, etc. Now, if we introduce another pint or two of water and percuss again, we shall find a new area of dullness which corresponds to the lower border of the stomach. If we find this line persistently an inch or two below the level of the umbilicus, it is fair presumptive evidence of gastric dilatation. By repeated examinations we can make out any changes occurring in this level and thus estimate to some extent the value of treatment. If the stomach is regaining its lost muscular power and elasticity, the lower border will gradually return to its normal position just above the umbilicus.

Feeling convinced that this patient's stomach is thoroughly cleansed, I withdraw the tube gently, and the operation is completed. In the present case, as in others I have treated by lavage, the operation is followed within a few minutes or half an hour by two or three watery evacuations. This has occurred even in cases of obstinate constipation. It is doubtless caused by a certain quantity of water escaping from the stomach into the duodenum and passing through. It is probable also that in some cases the lower end of the tube passes through the pylorus if we introduce it too far, so that the duodenum receives a considerable proportion of the fluid. At any rate, this watery evacuation of the bowel is probably a favorable occurrence, and is usually regarded in that light by the patient. A gentleman of the class asks whether the dietary precautions in this case may not be responsible for the favorable result. While by no means underestimating this part of the treatment, I think a sufficient answer to the question is found in the fact that the same restrictions were observed for weeks before employing lavage, but with no improvement whatever in the symptoms. Before dismissing the subject, I should state that there are certain contra-indications to the use of the tube. It should not be used: 1. In cases of aneurysm of any of the great thoracic vessels. 2. In cancer of the oesophagus or cardia. 3. In cases of recent haematemesis, haemoptysis, or gastric ulcer. 4. In very nervous or hysterical patients, and in cases of great debility and prostration with a tendency to syncope. Of course, in cases where we wished to secure an immediate evacuation of the stomach, as in cases of poisoning, we should have recourse to the pump.

**Induction of Premature Labor.**—“Dr. Chenevière, in the ‘Revue médicale de la Suisse Romande,’ gives an account of a simple method which he has employed for inducing premature labor. The cervix is brought into view with a speculum, and about twenty small iodoform tampons are passed through the os uteri by means of a thick sound. The plug reaches rather above the internal os. A larger plug is then placed against the vaginal portion to keep the cervical plug in position. Three cases are given in which the method was adopted. In the first, pains came on in two hours, and the labor was terminated in fourteen hours; in the others, more than one plugging of the cervix was necessary, labor taking place on the following day. In one case some of the tampons were only passed several hours after the expulsion of the fetus and placenta; and the author therefore thinks it well to have the tampons counted to avoid the possibility of any being left behind.”—*British Medical Journal.*

## Original Communications.

### AN ANALYSIS OF NINETY CASES OF SIMPLE CHRONIC GLAUCOMA, WITH SPECIAL REFERENCE TO THE EFFECTS OF IRIDECTOMY ON THE ACUITY OF VISION AND THE VISUAL FIELD.\*

By CHARLES STEDMAN BULL, M. D.,

PROFESSOR OF OPHTHALMOLOGY IN THE UNIVERSITY OF THE CITY OF NEW YORK;  
SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY; CONSULTING  
OPHTHALMIC SURGEON TO ST. LUKE'S HOSPITAL.

The remarks embodied in this paper are based upon a careful analysis of ninety cases of simple chronic glaucoma which the writer was enabled to follow out for a varying length of time subsequent to operation. They embrace all the facts in regard to each case which have any bearing upon the subject of the effects of iridectomy upon the acuity of vision and the state of the visual field. The cases extend over a period of about seventeen years, were all examined and treated by the reporter, and the conclusions drawn are therefore derived merely from his own personal experience.

Of the ninety cases under consideration, forty-four were in males and forty-six in females, the cases being nearly equally divided between the sexes. The age of the patients varied between twenty-four and eighty-six years.

In the decade between twenty and thirty there were two cases; between thirty and forty, seven cases; between forty and fifty, sixteen cases; between fifty and sixty, twenty-four cases; between sixty and seventy, thirty-three cases; between seventy and eighty, four cases; and between eighty and ninety, four cases.

Of the ninety patients, seventy-seven were Christians and only thirteen were Hebrews. This is contrary to the usually accepted belief that the Hebrew race is peculiarly prone to this disease.

The refraction of the one hundred and eighty eyes of these ninety patients varied as follows: Simple hypermetropia existed in one hundred and five eyes, simple myopia was found in ten eyes, and emmetropia existed in six eyes. Simple hypermetropic astigmatism was found in ten eyes. Compound hypermetropic astigmatism was met with in twenty-four eyes, and compound myopic astigmatism in two eyes. In two eyes a condition of phthisis bulbi prevented any measure of the refractive condition, and in eighteen eyes the advanced state of the cataract present was an obstacle to the same end.

The cornea was more or less cloudy in the right eye in five cases and in the left eye in five cases.

The anterior chamber was shallow in one eye in thirty-four cases and in both eyes in forty-one cases. It was of normal depth in twenty-five eyes, and was entirely abolished in twenty-eight eyes.

The iris was more or less movable in all the cases except in those eyes in which the condition was that of absolute glaucoma.

The lenses were entirely clear in one hundred and twenty-two eyes—sixty-three on the right side and fifty-nine

on the left side. There were slight peripheral opacities in the lens in thirty-five eyes—nineteen on the right side and sixteen on the left side. There was cataract in an advanced stage in eighteen eyes—in six cases in the right eye and in twelve cases in the left eye.

Phthisis bulbi existed in one eye in two cases. In one of these cases the eye had been lost in childhood from purulent conjunctivitis, and in the other case the loss of the eye was due to traumatism, and occurred in childhood or early youth.

The glaucomatous excavation of the optic disc was very deep in one hundred and six eyes, moderate in depth in forty-eight eyes, and in seven eyes there was no excavation demonstrable, though there were both diminution of vision and narrowing of the visual field.

The condition of the field of vision varied greatly, and is worthy of close and attentive study. In five cases it was contracted in one eye and normal in the other. In eighteen cases it was contracted in one eye, and either telescopic or entirely absent in the other. In thirty-nine cases it was contracted in both eyes. In seven cases there was no measurable field in one eye, and in the other there was absolute glaucoma. In twelve cases it was contracted in one eye moderately, and there was absolute glaucoma in the other. In six cases there was no measurable field in either eye. In three cases there was no limitation of the field in either eye. In one case there was absolute glaucoma in one eye and a perfectly normal field in the other.

Among the ninety cases, or one hundred and eighty eyes, there were twenty-two eyes afflicted with absolute glaucoma—nine on the right side and thirteen on the left side. In each of these cases the other eye was the seat of simple chronic glaucoma.

The intra-ocular tension was increased in both eyes in seventy-five cases. It was increased in the right eye alone in eight cases and in the left eye alone in six cases. The tension was normal in both eyes in three cases, in the right eye alone in four cases, and in the left eye alone in eight cases. The tension was diminished in the right eye in two cases.

One of the most doubtful points in the history of the development of simple chronic glaucoma is the determination of the interval between the outbreak of the disease in the two eyes. In the majority of the cases the patients are unable to determine how long an interval existed between the beginning of the attack in the two eyes, and in many instances the statement of a simultaneous attack in both eyes is of very doubtful value. Among the ninety patients under consideration, sixty-four were unable to give any opinion as to the length of interval between the attacks in the two eyes, and many of these stated vaguely that the disease began simultaneously in both eyes. In twenty-six cases the interval was known with tolerable accuracy, and varied between two months and twelve years. In twenty-eight cases the right eye was the first attacked, and in twenty-two cases the disease began in the left eye.

In all the ninety cases the only operation done was an iridectomy, always broad and usually upward, and in the majority of cases the instrument used was the ordinary

\* Read before the American Ophthalmological Society at its twenty-fifth annual meeting.

lance-knife. In no case was the operation followed by an extraordinary amount of haemorrhage, nor by any symptom pointing to malignant complication. In forty-five cases a simultaneous iridectomy was done on both eyes. In seventeen cases an iridectomy was done on one eye, and was followed at a varying interval by an iridectomy on the fellow-eye. In eight cases an iridectomy was done on one eye only, the other eye remaining normal as long as the patient was under observation, which, in many instances, extended over a period of years. In two cases two iridectomies were done upon one eye, with an interval between them. In one case an immature cataract was extracted at the time of the operation of iridectomy. In one case a sensitive atrophied stump was enucleated, preliminary to an iridectomy on the other eye. In twenty cases an iridectomy was done on one eye, the other eye being blind from absolute glaucoma.

In all these cases of simple chronic glaucoma the chief interest centers in the state of the acuity of vision and the *prognosis* as to the results of an operation. To this end an accurate history was kept of each case, with special reference to vision and the visual field, before and after the operation for a varying length of time, which, in some cases, extended over a period of years, and the result is very far from encouraging, as the cases show a condition of the vision and visual field worse than had been anticipated.

One hundred and fifty-four operations were done on the one hundred and eighty eyes under consideration. Vision was temporarily improved by the iridectomy in both eyes in two cases and in one eye in six cases; but in all eight cases, after a few months, a steady loss of vision and narrowing of the field set in, and continued progressively as long as the patients were under observation. Vision remained unchanged, neither better nor worse, after the operation for a period of one year or longer, in both eyes in eight cases and in one eye in twenty cases. Vision grew slowly and steadily worse after the operation in both eyes in forty-one cases and in one eye in twenty-nine cases. Vision grew rapidly worse after the operation in both eyes in two cases and in one eye in eight cases.

One point in connection with the effect of the operation upon the resultant vision is of some importance, and sufficient attention does not seem to have hitherto been called to it. In those cases in which the lens shows peripheral opacities, whether due to the natural senile change or directly to the interference with the nutrition of the lens induced by the glaucoma, the question would naturally arise, What effect has the iridectomy upon the lenticular opacities? Peripheral opacities of the lens existed in thirty-five of the one hundred and eighty eyes considered, and repeated examinations showed that the operation had materially hastened the growth of the cataract in twenty eyes, or more than fifty per cent.

Another point elucidated by a study of these cases is that the effect of the operation varies as to vision according to the stage of the disease at the time of the operation. If we limit arbitrarily the early stage of the disease to the first six months, and regard everything beyond this as belonging to the later stages of the disease, it will be seen that the earlier the operation is done the more likely are we to

obtain a good result; but to this there are not a few marked exceptions. It will be well in this comparison to regard every case where the existing vision has been maintained after the operation as a good result. A comparison of the results of operation in these cases shows that an early operation gave a good result in both eyes in four cases and in one eye in eight cases. But the reverse of this is somewhat significant—viz., an early operation gave a bad result in both eyes in four cases and in one eye in twelve cases. Now, when we come to consider the later stages of the disease, we find that a late operation gave bad results in both eyes in thirty-four cases and in one eye in twenty-six cases. The reverse of this is, however, significant—viz., a late operation gave a good result in both eyes in three cases and in one eye in eleven cases.

In analyzing the histories of these cases, both individually and collectively, it will be found a difficult matter to draw any satisfactory conclusions as to prognosis after operation. Many of the cases of simple chronic glaucoma are of long duration, even when left entirely untreated. Experience has taught most operators that a large iridectomy often causes serious optical inconvenience, even when the vision is fairly good, and that in many instances, when the field is much contracted, an iridectomy causes a still further diminution in the size of the field. Furthermore, the state of tension is no reliable guide in forming a prognosis, and bears no constant relation to the condition of the iris or anterior chamber, or to the acuity of vision and state of the visual field. The depth of the excavation in the optic disc bears a very inconstant relation to both the degree of vision and the state of the field, and is almost equally at variance with the condition of intra-ocular tension. It is no uncommon experience to find an almost typical glaucomatous excavation in an eye with perfectly normal vision and visual field, and without another symptom of glaucoma. Yet in these cases Nettleship hints that such an excavation may be of importance, as tending to prove that chronic glaucoma may begin rather in the optic nerve than in the ciliary region, and argues that such suspicious appearances may precede the outbreak of rapid glaucoma. (See "Royal London Ophthalmic Hospital Reports," xii, 2.)

There are several known causes for the failure of the operation to stay the progress of the disease. One of these is some unfavorable process going on in the vicinity of the wound, especially in aged patients or in those in a bad state of health. Another is a more or less marked displacement of the lens by the operation, owing to undue violence or to a weak suspensory ligament, which in its turn leads to the development of cataract, especially in eyes with peripheral opacities already existing in the lens. Another cause, not infrequently seen after an iridectomy done simply for optical purposes, is a slowly progressive haziness of the cornea, extending usually from the site of the wound. This I have not myself met with in any case of glaucoma. Another not infrequent cause, resulting directly from the operation, is the continued contraction of the field of vision.

The opinion is held by some authors that when glaucoma occurs in a myopic eye, it does so early in the patient's life. This has not been my experience. Among the one hundred

and eighty eyes under consideration, myopia or myopic astigmatism, or both, was met with in fifteen eyes, occurring among nine patients, and of these nine patients only two were under sixty years of age. This result is directly at variance with the latest statistics published by Nettleship. With regard to the opinion that the prognosis in such cases is especially bad, my experience is not sufficient to justify any conclusion.

The prognosis after operation is also influenced by the condition of the patient's health, and probably also by the location and size of the wound. The farther back from the corneal margin the wound is made, the larger will be the segment of iris removed, and the less the liability of the formation of anterior synechiae. There are certain opinions held by most ophthalmologists in regard to the so-called cystoid or "filtering" cicatrix—namely, that in desperate cases it is a favorable condition, by allowing free percolation of fluid through the lips of the wound and beneath the conjunctiva and thus aiding in keeping the tension low. This is undoubtedly true in so far as the maintenance of normal tension has a direct influence upon the maintenance of the existing vision. But this is only one of the factors interested in the preservation of the existing vision, and not a few cases of simple chronic glaucoma show a diminished tension from start to finish; and these cases, in the reporter's experience, all end unfavorably.

*Conclusions.*—In endeavoring to draw some rational conclusions from the study of ninety cases, it seems wise to begin with a quotation from Priestley Smith, to whom ophthalmologists owe so much of their knowledge of the pathology and pathology of glaucoma:

1. In considering the expediency of an operation in simple chronic glaucoma he says: "In every case of chronic glaucoma the responsibility of advising an operation is a heavy one, and should on no account be undertaken without a full explanation to the patient or his friends of the almost positive certainty of blindness on the one hand, and of the uncertainties which beset the operation on the other. Having regard to the age of the patient, the impossibility of great benefit, and the possibility of a painful and accelerated progress, a prudent surgeon will only operate on the express desire of the patient to receive the only possible chance of benefit, however small it may be." Armed with the preceding precaution, it seems to be our duty to operate in cases of chronic progressive glaucoma, and the earlier the better.

2. If the disease in a given case seems to be stationary and is still in the primary stage, and if it be possible to test the vision and the visual field at short intervals, delay in operating is permissible, but a weak solution of eserine or pilocarpine should be used daily, merely as an aid in controlling the course of the disease. The examination of these patients should be at short intervals, and should invariably include the tests for visual acuity and the careful examination of the visual field.

3. If the disease exists in both eyes, but with useful vision in both, the eye in which the disease is the more advanced should be operated upon without delay; and the surgeon will be guided in his treatment of the fellow-eye by the result of the operation on the first eye.

4. To insure the best result, the incision should be made well in the sclerotic, with a narrow cataract-knife or a very broad lance-knife, and the entire segment of iris, from one end of the incision to the other, should be carefully torn or excised from its insertion.

5. The most carefully performed iridectomy by skillful hands is sometimes followed by the rapid loss of what sight still remains, sometimes partial, but, unfortunately, sometimes also total.

6. A successful result is, in the majority of cases, more likely to follow the operation if it is performed early in the course of the disease, but the preservation of the existing degree of vision even in these cases is not invariable.

7. As regards the question of symmetry, it is probable that in the large majority of cases—perhaps as much as eighty per cent.—the disease is sooner or later present in both eyes, and a careful study of the cases seems to establish the fact that there can be no specified or certain interval of time which insures the second eye against an attack.

8. If the patient is old and feeble, and one eye is still free from the disease for a year or more after the other eye has become affected, it may be considered prudent to avoid an operation on the affected eye, as it is probable that the unaffected eye may remain free during the remainder of the patient's life.

9. The condition of the field of vision is no constant guide, either in forming a prognosis as to the progress of the disease or in deciding as to the time of operation.

10. The acuity of vision bears no constant relation to either the success or the failure of the operation.

11. The anterior chamber is usually shallow, is occasionally entirely absent, but is often apparently normal in depth. The condition of the chamber gives no reliable hint as to the state of the vision or the visual field, nor any indication as to prognosis.

12. The appearance and motility of the iris appear to have some bearing upon the prognosis, though not perhaps to the extent believed by Nettleship. The latter states that in the cases in which the iris reacted rapidly to eserine the operation proved successful. This has not always been the experience of the reporter; but in the majority of the cases in which eserine caused rapid contraction of the pupil, the visual acuity was fairly good and the field was not seriously limited.

13. The depth of the excavation in and the color of the optic disc seem to have no close connection with the defect in vision or with the limitation of the visual field; nor do they offer any constant guide as to prognosis, or to the effect of an operation upon the progress of the disease.

14. The condition of the intra-ocular tension is a very uncertain guide in deciding the time for operating. It may be normal or increased, or even diminished. It does not seem to bear any constant relation to the degree of visual acuity or to the state of the visual field. The steady maintenance of an increased tension, however, without any diminution, almost invariably indicates the necessity for an immediate operation, and this necessity is especially indicated if the tension is continually on the increase.

15. The health and age of the patient exert a decided influence upon the effect of the operation, and any marked evidence of senility is distinctly unfavorable to operation.

### A CASE OF SARCOMA OF THE THYREOID GLAND.\*

By J. SOLIS-COHEN, M. D.,  
PHILADELPHIA.

*Pressure on the Right Sympathetic Nerve; Unilateral Tonic Spasm of Laryngeal Muscles; Intermittent Clonic Spasm of Opposite Side; Compression Stenosis; Tracheotomy; Hemorrhage from the Gland Twenty Months later; Pressure upon the Left Sympathetic Nerve; the Functions of the Compressed Pneumogastrics aroused by Irritation of the Trachea; Death from Disturbance in the Functions of the Two Pneumogastrics.*

X. Y. Z., of Wyoming Territory, a stock raiser, aged about forty-five years, applied to me July 18, 1887, at the instruction of his physicians, with a swollen neck, dyspnoea, right-sided ptosis and contracted iris, abnormal warmth of the same side of the face, and with frequent right-sided perspirations of both neck and face. His clinical history was as follows: He was reared in a limestone district, and had always led an active outdoor life. His mother had had a goitre, which he thinks was the cause of her death. A brother and sister have disease of the throat, which he thinks is due to swellings in the neck.

Somewhere about 1871-'72 he began to notice that in running he got out of breath much sooner than any of his companions, and that his neck was getting thicker and thicker, so that within from five to six years it increased fully two inches in circumference. His general health continued good. In 1874 he suffered pain for the first time. This pain was a neuralgia of the right eye, which had been more or less continuous since, and at times excruciating. In 1881 he had erysipelas of the right side of the face, and about one month after recovery therefrom his right upper eyelid drooped and the ptosis had been continuous. In 1885 he noted that the right side of his face was hot, and this heat had been continuous since. This heat had been attended by frequent perspirations of the right side of the face and neck, sometimes several times a day.

The patient was a sturdy man of medium height, with an irregular, dense, nodulated tumor of the thyreoid gland, larger on the right side, with several enlarged cervical glands to the exterior of the tumor, and with considerable collateral effusion into the surrounding connective tissue. This effusion he stated was much less since he had left the high altitude of Colorado. He had considerable continuous dyspnoea, and had had a few suffocative spasms. The outline of the lower portion of the larynx and of the trachea could not be defined. He had contraction of the right pupil, ptosis of the right upper eyelid, and redness and heat of the right side of the face, with frequent perspiration of the same territory. The right vocal band was immobile in the median line (Fig. 1), and the movements of the left band were feeble, but sufficient for respiratory and phonatory purposes. The diagnosis made was that of malignant tumor of the thyreoid gland with stricture of the trachea by compression. The ptosis, contraction of the pupil, heat of the face, and perspiration I attributed to the results of pressure upon the sympathetic nerve; and the spastic contraction of the vocal band in the middle line to the result of pressure or irritation upon the recurrent laryngeal nerve.

A tentative treatment with arsenic internally and with injections of diluted red iodide of mercury ointment over the mass soon produced improvement in breathing and marked diminution in the bulk of the tumor, especially in the nodules at its periphery.

On August 1st I noted for the first time clonic spasms of the left vocal band, rendering the slit for breathing very narrow, but without producing as much disturbance of breathing as I had noted in similar conditions. I attributed this spasm to reflex irritation from traction on the right pneumogastric by the contraction of the mass, rather than to any direct implication of the recurrent nerve of the left side. The patient reported that he had nearly choked the night before, apparently from something which he had swallowed; but I attributed this to spasm. I deemed it most prudent to send him at once to a hospital, where I performed a prophylactic tracheotomy without anaesthesia a few hours later.

On the right side of the middle line, the skin, the intermediate tissues, the thyreoid gland, and the wall of the trachea were all one continuous mass. The trachea was away over to the left side of the neck, and was bent upon itself in its descent behind the sternum. The incision had to be made directly through the enlarged isthmus of the gland. This structure was so calcified posteriorly as to necessitate the use of the curette to scrape a way through to the trachea. After the trachea had been opened a terrific hemorrhage took place from a portion of the tumor which had penetrated the left side of the trachea. This hemorrhage was so sudden and so profuse that, had the patient been unconscious, he would in all probability have perished through inability to obey instructions necessary—to place his neck in a favorable position and to cough out the blood as it flooded the air-passage. On account of the bend in the trachea, it was found impossible to introduce the cannula with the aid of the ordinary pilot conductors. Troussseau's dilator and Golding-Bird's dilator both failed; but with the three-valved dilator of Laborde, fortunately at hand, it was found practicable to keep the opening patent and to push the impeding swelling to one side, so as to admit of the introduction of the tube. The patient professed to have experienced no pain whatever during the operation, pain having probably been deadened by the attending excitement. The condition of the parts was such as to justify the inference that the cervical vessels were involved in the growth, thus precluding attempts at extirpation of the mass in the future.

The neuralgia of the right eye ceased with the operation and did not return, and the heat and perspiration of the face diminished considerably. The ptosis and contraction of pupil remained uninfluenced.

Before the wound was dressed, the exposed portion of the diseased gland was dusted with potassium-chlorate powder. This produced considerable disintegration of a portion of the mass which discharged through the external wound, and the size of the tumor diminished to such an extent that, at the end of two weeks, the length of the tube had to be lessened by nearly half an inch, and the tracheal opening had receded a little toward the middle line of the neck.

I kept the patient under observation for about six weeks, during which time he progressed very satisfactorily in every way, except that the clonic spasm of the left vocal band soon became tonic, with permanent occlusion of the glottis to a very narrow slit totally insufficient for respiration (Fig. 2). It ap-

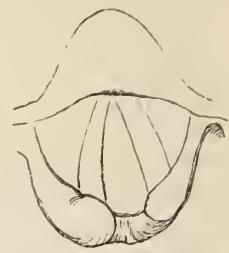

FIG. 1.—Immobility of the right vocal band in the median line.

\* Read before the American Laryngological Association at its eleventh annual congress.

peared in this instance, as I have noticed in similar ones, that as soon as the artificial opening in the trachea insured access of air to the lungs in sufficient quantity, the forced contractions of the dilating muscles of the glottis, in the struggles for breath, subsided, and the spasm became permanent and unopposed. I considered the condition to be spasm of the laryngeal muscles, rather than paralysis of the posterior cricoarytenoids, because of the tense condition of the edges of the vocal bands and the backward position of the arytenoid cartilages—physical conditions which require active contraction of portions of the posterior cricoarytenoid muscles. The voice was excellent as to modulation, but weak in intensity, ready in tone, and produced only with considerable expiratory effort.

About one month after the tracheotomy the patient complained of regurgitation of undigested food about three hours after the mid-day and evening meals. Whether this was due to pressure of the tumor upon the oesophagus, or to the presence of a diverticulum, remained undetermined, as the condition soon subsided and did not recur.

The patient returned to his home with his tumor diminished to fully one half of the bulk it had acquired previous to the operation. The trachea had not receded from its position somewhat to the left of the middle line. The contracture of the glottis had become permanent and apparently complete, so that there was practically no room for respiration through it.

Several months after his return to Wyoming Territory I received a letter from his physician, under date of February 15, 1888, in reply to a letter of inquiry, that "the patient was doing nicely, and coughed but very little, the enlargements on the neck having reduced considerably in size and being quite soft. The right pupil remained slightly contracted, and he suffered from occasional attacks of facial neuralgia. He was in good spirits. His weight was one hundred and forty-five pounds, a gain of twelve pounds since he had left Philadelphia. His appetite was fair. He underwent active exercise without much difficulty. He slept well, and, in short, was doing nicely—much better than he had dared to anticipate."

About one year later, February 2, 1889, the patient returned to me to learn whether anything could be done to disengage him of his tube, the presence of which, interfering with his convenience, was the only thing he complained of. He felt perfectly well and vigorous. His neuralgias and other pains had almost ceased. The ptosis and contracture of the iris were as formerly. The tumor had enlarged somewhat. The larynx and trachea were fully an inch to the left of the middle line.

The glottis was oblique, from right to left, and practically air-tight, the vocal bands being in tense apposition (Fig. 3), and remaining quiescent on the strongest efforts at inspiration.

The larynx showed no indication of structural disease. The voice was good and well modulated. While no encouragement could be given as to any hope of dispensing with the tube, I thought something might be done constitutionally to reduce the bulk

of the tumor, and therefore put the patient on a course of Zittmann's decoction of sarsaparilla, under the influence of which the tumor diminished considerably in size in about two weeks, especially as regarded some enlarged lymphatic glands on the right side and just above the clavicle.

Some bloody oozing from the top of the wound was now noted on changing the cannula, but I could not determine its

source. It did not occur every day, and did not seem to be due to any erosion of the tissues. Despite my desire that the patient should remain with me, he insisted on returning home to shear his sheep, shipping himself a quantity of Zittmann's decoction, and carrying the formula for its manufacture with him, so that its use could be continued under the supervising sanction of his own physician.

Some three weeks after his departure I received a telegram that he was on his way to Philadelphia, his throat bleeding badly. Arrangements were made for his instant admission to Jefferson Medical College Hospital on his arrival. He arrived March 22d, looking well, but pale. The wound was not bleeding. He told me that the oozing of blood at changes of the cannula had gradually become more copious, and that, after a serious hemorrhage, his physician had thoroughly cauterized the track of the wound with nitrate of silver, and had started him off to Philadelphia with strict injunctions not to remove the cannula under any circumstances until he had reached me—a most judicious procedure and advice, as the sequel proved, all oozing having ceased for two days. I allowed him to remain a day without disturbing the tube. On the next day, in the presence of the late Professor S. W. Gross, whose co-operation I had requested in anticipation of trouble, I removed the tube. Blood poured out from the fistula as from a little pitcher. After a moment of consultation, we cut down upon the parts without anaesthesia, exposing them freely, but we could find no bleeding vessels. The hemorrhage was parenchymatous from the left side of the body of the gland, which formed part of the fistula. We then cauterized the parts freely with the thermo-cautery, which restrained the hemorrhage in great measure, but not wholly. Then the cannula was replaced, after having been wrapped in a tampon of gauze, into which a considerable quantity of Monsel's salt had been rubbed. This controlled the hemorrhage satisfactorily, and the cannula was not removed until the fourth day. There was no further hemorrhage. There was considerable dyspnea after these procedures, and the parts became somewhat swollen. I noted contraction of the left pupil. This and the dyspnea indicated an additional pressure on the left sympathetic and pressure upon the pneumogastrics. The dyspnea would come on suddenly, there would be an arrest of respiration, and then the face would become pale and then livid, consciousness becoming benumbed and occasionally abolished. Sometimes this condition would be preceded by spasmodic, irregular, diaphragmatic respiration. Any irritation of the mucous membrane of the trachea would relieve the dyspnea, reddening the face, and arouse the patient's consciousness. The dying functions of the nerves were aroused the most effectively by passing down a loop of wire—in fact, the wire of the brush used for scrubbing the cannula. This had been first used for the purpose of drawing out any clotted blood which might have been occluding the trachea. Relief by its introduction was so marked that the patient begged for its almost continuous presence in the trachea. He could recognize the spot in the posterior wall at which the loop of wire would be most effective, and would grasp the physician's hand to prevent its being moved therefrom. When it was withdrawn from time to time, the phenomena of arrest in respiration would supervene. Inhalations of oxygen gave but momentary relief to the dyspnea. For three or four days there was little sleep, and that fitful and irregular, respiration being maintained chiefly by the presence of the foreign substance in the trachea, and the patient sank from exhaustion on the evening of the fourth day. A promised autopsy was prevented by the interference of relatives after they had arranged to permit it.

The marked feature in this case was the rousing of the pneumogastrics by titillation of the tracheal mucous membrane and

FIG. 3.

the continuous presence of a foreign body—a condition which I had never observed, and of another record of which I have no knowledge.

THE RELATION BETWEEN  
FACIAL ERYSIPelas AND ERYTHEMA  
ON THE ONE HAND,  
AND INTRANASAL PRESSURE  
ON THE OTHER.\*

By GEORGE W. MAJOR, M. D.,  
MONTREAL, CANADA.

It is my firm conviction that facial erysipelas is sometimes produced by nasal causes acting independently of external infection. This decision has been arrived at as the result of careful observations extending over a number of years. I believe that a definite relation exists between many cases of erythema and erysipelas occurring on the nose, or in its neighborhood, and inflammatory conditions within the nasal chambers, more particularly when they are productive of pressure.

If such is the case, then it becomes our duty to distinguish erysipelas and erythema of an intranasal origin from the same diseases dependent upon other causes. The importance of accurately establishing the origin of these attacks can not be overestimated when we consider that success will often depend upon its recognition. The majority of subjects of facial erysipelas doubtless convalesce under local and constitutional measures even though the exciting cause is unknown and therefore is allowed to persist. The duration of the illness will be greater and the liability to extension and complications will be manifestly increased, not to mention the tendency to recurrence. If, therefore, a removable cause can be demonstrated as productive of facial erythema and erysipelas, we shall find ourselves in a better position to arrest the course of the disease when present, and in the future to prevent it altogether. This is my apology for briefly placing on record the four following cases, with a few remarks thereon:

CASE I.—In March, 1884, M. C., a young lady, aged twelve years, was referred to me by Dr. Arthur A. Browne, of Montreal, for the treatment of a troublesome nasal catarrh. On examination of the nose, I found a general hypertrophic condition present. The right middle turbinated body was very much enlarged, turgid, and abnormally sensitive to the touch. It was in contact with and pressing upon the nasal septum. On the cheek bone of the same side there was a dark, dull red and elevated patch of erythema of the area of a half-dollar. On inquiring into the history, I learned that this eruption had lasted for five months, that it had first made its appearance during a severe cold in the head, and that a nose-bleed seemed to diminish its prominence; a variety of local and constitutional remedies had been adopted without success. The probability of pressure being the cause at once suggested itself to my mind. Scarification and punctures of the middle turbinated tissue relieved the sensitiveness of the parts locally and diminished the redness of the facial patch. Soothing local collunaria also gave further relief. Subsequently a series of galvano-cautery appli-

cations permanently removed the pressure, and with it the erythematous blush gradually vanished. No local treatment was adopted for the eruption, nor were any constitutional means employed. There has not been at any time since a recurrence of the disease.

CASE II.—In February, 1885, I saw, in consultation with the late Dr. R. Palmer Howard, a case of facial erysipelas in a child of four years. The disease had commenced on the bridge of the nose and had extended to the cheeks. The condition had lasted for five days and showed no inclination to yield to the usual local and constitutional remedies. The child's stomach had become irritable and refused to retain anything whatever. On examining the nasal chambers, I found both nostrils obstructed with swelling, the result of an acute cold, and suggested the abandonment of all local and constitutional medication and the substitution therefor of warm alkaline nasal injections. In the course of twelve hours the swelling in the nasal chambers showed considerable reduction, and *pari passu* the erysipelatous blush. In twenty-four hours all trace of the disease had disappeared.

Dr. Howard knew of my views relating to intranasal pressure, and willingly acceded to the change in treatment.

CASE III.—In the winter of 1884 I saw, in consultation with Dr. Browne, W. C., aged twelve years, suffering from erysipelas of the nose and cheeks. This child had frequently suffered from erysipelas having its origin always in the same region, though generally spreading to other parts of the body. Some of these attacks had been of most serious and alarming character. I had previously seen him in consultation when suffering from this disease, and had suggested to the medical attendant the likelihood of a nasal origin.

I ordered nasal injections alone, and had the satisfaction of seeing the disease disappear in the course of thirty-six hours. When convalescent I destroyed the hypertrophied turbinated tissue, and have been informed that no recurrence has taken place.

CASE IV.—In February of this year A. J., female, aged thirty-six years, was referred to my clinic at the Montreal General Hospital for an erythematous patch occupying the left cheek bone. She stated that it had already lasted four months and that it had so far resisted all treatment. A nasal examination revealed a swelling of the left middle turbinated body exerting pressure on the septum. After deeply puncturing the swelled tissue and allowing of a free flow of blood, a nasal cleansing solution was ordered. In a week the patient reported herself free from the disease.

I have notes of two more similar cases occurring under my own observation, and of four kindly furnished by colleagues, but abstain from making any use of them beyond their mere mention.

During an extended experience of nasal operative work common to all in our specialty, I have but once met with facial erysipelas succeeding a surgical operation in the nasal chambers. It was in a case of nasal polypi, and any interference invariably produced erysipelas. The man, however, came of a family in which erysipelas was a usual complaint. In the cases above referred to the erysipelas always commenced on the bridge of the nose, and was greatest on the side of greatest pressure. There was no condition present in the nasal chambers that I could recognize as of an erysipelatous nature in any of them. Medical literature, in so far as I have been able to ascertain, is barren of any reference to the matter to which I have thus briefly referred.

ACUTE MULTIPLE ADENITIS (SEPTIC?);  
ŒDEMA OF THE LARYNX, WITH SPONTANEOUS CURE.  
*LARYNGOSCOPIC APPEARANCES.\**

BY S. W. LANGMAID, M. D.,  
BOSTON.

ON Tuesday, April 30, 1889, I was summoned by telegraph to visit Mrs. R. at a city sixty miles from Boston. The case was supposed to be one of amygdalitis. I arrived at the hotel at which Mrs. R. was temporarily staying, and when she had been ill for eight days, at half-past five in the afternoon.

The patient, a lady about forty years old, was in bed, propped up by pillows, very restless, with anxious expression, breathing with difficulty, with dry, croaky inspiration. There was no lividity of the face, or other indication of impending suffocation; but I was informed that during the preceding twenty-four hours there had been at times danger of strangulation. The submaxillary glands were much enlarged, as were those lower down in the vicinity of the larynx. The whole region of the neck was swollen, and the tissues in front of the larynx and trachea were thickened. The pulse was feeble, but not rapid. The temperature was 99° F. The voice was fairly loud and clear.

Mrs. R. was able to get out of bed and allow me to make a laryngoscopic examination by sunlight illumination. The mouth and pharynx were normal. There was no enlargement of the tonsils, no membrane, and nothing unusual in the naso-pharynx. The epiglottis was very erect, normal in shape, and only slightly congested. A tumor, apparently as large as a filbert, in which the arytenoids seemed to be incorporated, occupied the posterior arytenoid space, and covered two thirds or more of the glottis. The anterior third of both vocal cords could be plainly seen approximated and scarcely moving during inspiration. Nothing abnormal was discovered in the lungs. My diagnosis was œdema of the vestibule of the larynx, caused by the pressure of the enlarged cervical glands; cause of adenitis unknown, but diphtheria suspected, of which no trace now remained in the throat, mouth, or naso-pharynx.

The attending physician was an irregular practitioner, and had not looked in the throat during the first four days of Mrs. R.'s illness. Another physician had been called the day previous to my visit, who had ordered poultices to the neck, after which the dyspnoea seemed to be slightly relieved. No nourishment had been taken for days because of inability to swallow, but the mouth and throat had been constantly washed and gargled with milk and Apollinaris water. No other treatment seemed to have been used, except hypodermic injections of morphine, which the patient demanded, and which she had been accustomed to take occasionally for attacks of severe headache.

Mrs. R.'s condition seemed most critical. Dr. George W. Gay, of Boston, was telegraphed for, and asked to bring tracheotomy instruments. The patient was closely watched, the throat frequently gargled with milk and water, which seemed to assist in expelling small quantities of viscid mucus, and nine or ten ounces of milk were swallowed. Stimulants were refused by the patient.

I determined to wait as long as possible before attempting any operative procedure, but, should suffocation seem imminent, I hoped to be able to reach and open the laryngeal tumor with a curved bistoury, and, if necessary, afterward open the trachea.

Dr. Gay arrived four hours later, and, having examined the patient, agreed that it was best to delay any operation, as there

had been no glottic spasm during the day, and the voice remained good. The poultices were continued, and ten grains of quinine and a mixture of chlorate of potassium and chloride of ammonium were given at Dr. Gay's suggestion. Up to midnight, when we left Mrs. R. with her attendants, no change had occurred; but at four o'clock in the morning I was called, with the report that something had broken in the throat. I found that several handkerchiefs had been saturated with a thin mucoid discharge, which was being incessantly hawked up, and which at first was faintly tinged with blood. It was noticed that the dry, sonorous inspiration was more moist in character and less noisy. The patient was informed that through such a discharge great relief would probably be produced, and was again left with her family. The discharge had been so copious that Mrs. R. feared she "would be drowned by it."

Three hours later a laryngoscopic examination was made. It has been said above that at the previous examinations a tumor was seen in the region of the arytenoids and posterior arytenoid space, below which a portion of the vocal bands was plainly visible. Now, nothing could be seen except the erect epiglottis, almost doubled upon itself laterally, and from the recess so made muco-purulent matter welling up.

The dyspnoea was greatly relieved, quiet inspirations being accompanied by moist bubbling sounds. The swollen neck seemed to be softer.

The patient was left in the charge of Dr. T. C. Morril, who had seen her the previous day.

Upon my return late in the afternoon, I was disappointed to find the respiration still somewhat noisy, and that there was no change in the laryngoscopic appearances. The epiglottis was still bent laterally upon itself, and purulent matter was still flowing. There had been constant expectoration during the day and one attack of vomiting, during which half an ounce of pus had been ejected. Milk had been taken in fairly large quantities, and the patient's strength had not diminished.

A restless night was passed, but with increasing freedom in inspiration. In the morning the neck was less swollen and softer, and the epiglottis had resumed its normal shape. Pus was seen welling up behind the interarytenoid space. The arytenoids themselves had not regained their normal contour, but were not œdematosous. The discharge of pus continued in diminishing quantities for several days. On the seventh day from my first visit Mrs. R. was removed to Boston. The neck had at this time nearly resumed its natural size, but considerable induration of the tissues in the vicinity of the larynx still remained. The interior of the pharynx and larynx showed only slight alteration of color. On May 10th Mrs. R. was able to be moved by special car to her home at Baltimore.

This case has seemed worthy of presentation to the society for several reasons:

1. On account of the obscurity with regard to the origin of the adenitis with consequent œdema.

2. The unusual sequel to such a condition—viz., the spontaneous rupture of the œdematosus tumor and safe evacuation of its contents, together, probably, with that of a suppurating gland or glands in the neighborhood.

3. The opportunity which was afforded by laryngoscopy for observing the exact condition during the dangerous stage of partial glottic occlusion and fixation, as well as the reassuring appearances after the evacuation of the tumor and glands.

When I first saw Mrs. R. I had no doubt that the adenitis was septic from diphtheria. When told that no

\* Read before the American Laryngological Association at its eleventh annual congress.

membrane had ever been seen or expectorated (I supposed then that careful examinations had been made of the mouth and fauces during the first days of the attack), and the perfectly clean, pale condition of the mucous membrane of the whole upper respiratory tract had been observed, under excellent illumination, I was forced to abandon that hypothesis. The fact that eight years previously a gland had suppurated and discharged on the back of the neck did not help to clear up the mystery of the present acute multiple adenitis. The only history immediately antedating the severe seizure was that Mrs. R. had not seemed quite well for two weeks, and on the day previous had been "chilly" and had a slight "soreness of the throat."

It has seemed, however, to Dr. Gay and myself, since then, that there must have been a very limited diphtheria, all traces of which had disappeared by the eighth day. The account which I obtained from Mrs. R., to whom no mention of diphtheria had been made, after her removal to Boston, lends support to such a view, for she said that at the commencement of her illness she had a "sore throat," and she saw on one side of the back of the throat a red place on which there was a white covering. The urine was free from albumin.

The spontaneous rupture of an oedematous swelling in the region of the larynx is probably rare. Intralaryngeal puncture sometimes, but tracheotomy generally, is required. Intubation, if instruments were at hand, would be in such a case as this the remedy *par excellence*, it seems to me. The importance of laryngoscopic examination in this case can hardly be overestimated, for if it is granted that the rational signs were enough to guide the surgeon to the diagnosis and conduct of the case, it will not be denied that the added information with regard to the situation and nature of the obstruction made the instant and succeeding treatment more exact, and added greatly to the knowledge of the pathological conditions.

#### AN OEDEMATOUS FORM OF DISEASE, OR SEPTIC OEDEMA OF THE UPPER AIR-PASSAGES.\*

By W. C. GLASGOW, M. D.,

ST. LOUIS, MO.,

ADJUNCT PROFESSOR OF THE THEORY AND PRACTICE OF MEDICINE IN THE  
ST. LOUIS MEDICAL COLLEGE; PROFESSOR OF DISEASES OF THE CHEST  
AND THROAT IN THE ST. LOUIS POST-GRADUATE SCHOOL OF MEDICINE.

DURING the winter of 1886 I reported to the Medico-chirurgical Society of St. Louis the existence of an unusual form of throat disease which had been more or less prevalent for two years, and which at that time prevailed to such an extent that it could not fail to attract attention. I called it then rheumatic or oedematous sore throat, from the great similarity of certain of the symptoms to those seen in the ordinary angina rheumatica. I also drew attention to the fact that in certain of these cases patches of exudation were seen in the throat, and I was inclined to consider that these conditions had a common cause. The exudative cases bore a certain similarity to the diphtherias, but the surrounding

condition of the throat was utterly dissimilar from that seen in diphtheria. At that time, however, I had not given these cases a sufficient study, and waited to see what further observations would develop. In 1887 Dr. Boislinière, my assistant in the clinic at the Post-graduate School of Medicine, published in the "St. Louis Courier of Medicine" a short article entitled "Oedematous Sore Throat," in which he embodied my views and treatment of the disease. During the winter of 1887 and 1888 these cases were very numerous, disappearing almost entirely during the late spring and summer months, appearing again in the early part of the past winter. About the 1st of January of this year they again appeared, and they have continued during the spring, through the present month. During March and April the cases were unusually prevalent, and the disease might well be called epidemic. I call it epidemic rather than endemic, as I have seen many cases that have originated in different parts of the country. I have also learned from Dr. Seiler, of Philadelphia, that he has seen similar cases in that portion of the country. During the prevalence of this disease I have noticed the disappearance of the ordinary forms of catarrhal inflammation of the throat—a condition which is usually so prevalent during the spring months.

The appearance of the throat in this oedematous form of disease is characteristic, and will always define the disorder. In all cases we find on inspection a pale, swollen, oedematous condition of the fauces. In some this is limited to certain parts, while in others the entire mucous membrane of the fauces is involved in the process. The oedema is a solid oedema, and differs from the usual serous oedema seen in catarrhal inflammations. To the touch the mucous membrane feels firm and waxy, lacking the moist elastic sensation of a normal mucous membrane. A peculiar glistening appearance is very marked in many cases, and I have seen the palate, when the light was thrown at an angle against it, appear as though set with minute brilliants. In the majority of cases the soft palate is the site of the oedema. In some it is so much swollen and thickened that speech is impaired, suggesting the change caused by paresis of the palate. A lesser degree of oedema is more frequently seen. In these cases the action of the palate is not much impaired, but on phonation the uvula is seen to retract with ridges and folds in the mucous membrane, suggesting the impression that the muscles are unimpaired, while the mucous membrane is infiltrated with some foreign substance. The palatine folds and the lower edge of the palate appear at times translucent at the edges. The naso-pharyngeal space and the nasal mucous membrane are also found in the same condition. The nasal mucous membrane presents most frequently a swollen, very dry appearance. In two cases the naso-pharyngeal space was almost obliterated through the great oedema of the membrane. The epiglottis and the different parts of the larynx are also affected. I have seen four cases where the epiglottis was converted into a solid, swollen mass, and in very many cases the oedema of the posterior surface of the larynx could be quite distinctly seen with the mirror. In four cases the true cords were markedly oedematous. They ap-

\* Read before the American Laryngological Association at its eleventh annual congress.

peared as swollen, glistening bands with an almost translucent appearance. In another case one, and in still another both false cords were found swollen and enlarged. The two cases in which the solid oedema of the larynx was seen in life died suddenly with symptoms of spasm of the glottis or sudden laryngeal stenosis. In both these cases the post-mortem examination showed a swollen, oedematous condition of the epiglottis and interior of the larynx, which did not subside with death. A peculiarity of this oedema is the rapid and great increase which seems to take place from slight causes. In some cases it disappears almost as rapidly as it arises. In others, however, it lasts for months, slowly subsiding, showing, however, in its course acute exacerbations with an increase from time to time.

An enlargement or swollen condition of the veins is a marked appearance in all cases. Most frequently this is the case with the palatine veins, especially those at the root of the uvula and the pharyngeal veins. Sometimes this venous enlargement is so great as to cause purpura-like spots, and the mucous membrane appears mottled, the dark spots contrasting with the pale surrounding surface. In two cases I have seen these purpura spots in the trachea, and both these cases showed recurrent haemorrhages. In one case an enlarged vein was distinctly seen on the cord. A peculiar secretion is characteristic of this disease. In some cases it is scanty and in others it is very profuse. It is characterized by its viscid, gluey nature. When it is taken on the finger and the finger pressed against the thumb and again separated, a glue-like thread is formed, which is so tenacious and elastic that the fingers can be widely separated without breaking the thread. Ulceration is occasionally seen, and when it occurs there seems to be a loss of tissue by absorption rather than by destruction. In one case a large ulcer occupied the lateral and naso-pharyngeal wall, extending toward the wall of the pharynx. In three cases the soft palate presented a loss of substance. In one the anterior pillar of the palate was perforated, forming a button-hole. Ulceration of the epiglottis was seen in four cases. In one the loss of substance originated at three different spots, and continued until the greater part of the epiglottis had disappeared. In another the ulceration extended through the mucous membrane, but did not involve the cartilage. The former case died of tuberculosis, and in the latter the ulceration healed and was followed in the course of three weeks by a similar ulceration of the soft palate. In this case there was no history of syphilis.

In certain cases we find, in addition to the oedematous condition, patches of exudation in different parts of the throat. In some cases this is limited to minute white or yellowish-white points, and in others patches of varying extent are formed. These are seen most frequently on the tonsils, both of which are usually involved. These patches on the tonsils usually commence as isolated points, and the exudation in some cases coalesces, forming a complete covering of the tonsil. In other cases we find the whitish points in the pharynx and on the pillars of the palate. In one case there was a small patch on the right tonsil and an elongated patch on the pillar of the palate, the soft palate partially covered, and the uvula enveloped as a finger in a

glove. This patient recovered after a six weeks' illness. In another a patch existed on the hard palate, two distinct patches on the epiglottis, with one on the posterior surface of the larynx. This patient had a syphilitic history. The patches disappeared in four weeks. These patches have a yellowish-white appearance, are usually firmly attached to the membrane, and can not be removed except by force, when a bleeding surface remains. If untouched, they gradually fade away, the exudation growing thinner until they only show a thin opaline patch resembling a mucous patch. Some of these cases would be called diphtheritic, but the symptoms of the disease and the appearance of the throat must preclude such a diagnosis. In all, in addition to the patch of exudation, we find the surrounding tissue in a condition of oedema, and more or less of the sticky, gluey secretion is present.

In six cases I have seen spots of mycosis; in three they were on both tonsils and on the base of the tongue, with points on the posterior pharyngeal wall. In three the two tonsils were alone involved. Microscopic examination showed *Leptothrix buccalis*. Glandular enlargement of the neck is frequent.

In most cases the glands are simply swollen, but in others they become enormously enlarged. In some cases they are hard and tense, and gradually soften and disappear as the patient recovers. In one case, with massive oedema and ulceration of the lateral pharyngeal wall, the submaxillary glands attained the size of a goose-egg. This varied in a remarkable manner from time to time, both in size and hardness, at times becoming so soft as to suggest suppuration, changing again to the hardness of a sarcomatous gland. In this case the glands on both sides of the neck were involved. In two cases suppuration of the glands took place.

The symptoms of oedematous sore throat are both constitutional and local. The constitutional symptoms are most prominent and are often present when the local symptoms are wanting. The attack commences suddenly in a condition of previous good health. There is a feeling of intense languor and weakness, slight exertion producing an unusual fatigue; the mind is dull and a condition of apathy prevails; a condition of mental inertia is often present. During the day there is great drowsiness, while insomnia is frequent in the same individual. An unusual and excessive irritability is often noticed. Pain is general throughout the body, the muscles and joints being specially involved. A headache of varying intensity is present. It is usually frontal but sometimes it is occipital. In many cases it is simply a dull, heavy feeling of fullness in the head; in others it is intensely violent, with throbbing pain. Pain in the back, especially about the sacrum, is a characteristic symptom; from this point it radiates toward the hips or into the pelvis. Occasionally the site of pain is more in the lumbar region. Pains in the chest are frequent. The pain is often intensified at night. In many cases we find a soreness or tenderness about the muscles, with a hyperesthesia of the skin, this soreness being limited to single groups of muscles or a circumscribed spot, with a constant tendency toward a shifting of the site.

The joints have a feeling of stiffness, and in some cases there is great swelling and tenderness of single joints, resembling inflammatory rheumatism. There is this difference, however, that the pain and the tenderness of the joint may only remain a few hours, and then it will entirely subside, to again appear in another joint. There is also the absence of the general constitutional symptoms of the rheumatic affection. Cramps, especially in the fingers, legs, and toes, are often experienced. Some patients complain of a tingling or numbness of the extremities. Black stools are very frequently seen, and in a few cases bloody urine was passed. The general appearance of the patient is suggestive of the disease. The skin is of a dirty-white hue, suggestive of chronic malaria. The superficial veins are engorged, and this is especially seen in the veins of the forearm and in some cases in enlargement of the temporal veins. The blood is of a dark Prussian blue, and this change often attracts the attention of the patient. The fever varies greatly in different cases. In the simple oedematous form of the disease the temperature rarely rises above 101°. This may remain for twenty-four to thirty-six hours. This is often preceded by a chilly sensation; in three cases a decided rigor was seen. In exudative cases the temperature may rise to 103° F., or even more. A typical case commences with a chill, a rise of temperature which may continue for twenty-four to forty-eight hours, which then subsides, continuing at about 100° to 101° during four to six days. I have noticed that where the exudation is confined to the tonsils the fever continued rarely more than twenty-four hours, but where it involved the pharynx it continued from five to seven days. The pulse is always increased in rapidity; it is full, soft, and compressible. Sweating is a very prominent symptom. This occurs especially at night, and is accompanied by a chilly sensation resembling true night-sweats. The disease is certainly in a measure contagious. I have often seen different members of a family develop it in succession. Sometimes one member will show the simple oedema and others will have the exudative patches. In the children's ward of the Mullenphy Hospital all the children were affected, and all recovered.

The local symptoms vary in different cases and depend on the part of the throat involved. In some they are very marked, in others they are entirely wanting. When the nasal mucous membrane is affected, a complaint is made of a feeling of fullness and dryness of the nostrils. When the palate and palatine folds are involved there is frequently pain on swallowing, and it is especially noticeable that the pain is greater on swallowing saliva than on taking food. In fact, the taking of food in some cases seems to produce a certain amount of relief. In cases where there is great oedema of the palate the pain is often so intense as to almost preclude the taking of nourishment. One patient told me that every attempt at deglutition produced a sensation as though a knife were drawn across the throat. But this intense pain is only found in cases where the oedema is great. In the large majority of cases the pain is slight and complaint is made more of a feeling of dryness or a fullness of the throat. It is noticeable that the pain is always increased toward evening and during the night, di-

minishing, and in some cases almost entirely disappearing, during the morning hours, to be again experienced at the same hour of the afternoon the next day. In oedema of the posterior larynx there is a feeling of fullness with constant desire to swallow, and a sensation as though a foreign body was lodged at this point. Again, a sense of oppression is often experienced in the upper portion of the chest, and there is a constant tendency to sigh. In some cases I have seen an intermittent character given to the pain, it occurring with greater intensity on alternate days. In oedema of the vocal cord there is always more or less change of the voice. It seems to lose in strength and clearness. In two cases, although the speaking voice was little impaired, the singing voice had entirely disappeared. With the subsidence of the oedema the patients who are professional singers regain their voices in the natural strength and purity. The characteristicropy, gluey secretion is sometimes so profuse that constant hawking and expectoration are necessary. This is also found even with scanty expectoration, the sensation being produced by the feeling of fullness. Haemorrhages are quite frequent; usually they are small in quantity and recur frequently. In three cases I have seen profuse haemorrhages in which the expectoration of blood continued through several days. The blood is usually black, clotted, and may be mixed with a viscid secretion, but often it is simply a pure dark blood. When the larynx is affected, cough is a frequent symptom. It may occur in an incessant hack. In other cases there are violent paroxysms. The cough at times bears a great resemblance to the cough of whooping-cough, the inspiratory stridor being especially marked.

Without proper treatment the acute symptoms in the oedematous form will continue from three to five days. A comparative state of well-being then comes in which the symptoms are greatly mitigated. This is followed by another attack. I have seen cases who have suffered in this manner for four months in whom the acute exacerbations occurred about every three weeks. In cases with exudation I have seen the patches remain from one to six weeks.

*Diagnosis.*—The oedematous form of the disease can only be confounded with that due to a catarrhal inflammation. The pronounced constitutional symptoms and the characteristic appearance of the throat will differentiate the conditions.

In the exudative cases, where the exudation patches are prominent on the tonsils, we should naturally think of simple follicular amygdalitis. The general symptoms are in a measure similar and the appearance of the tonsils is not unlike that of amygdalitis. Close inspection, however, will show the minute white points in different parts of the fauces, and the condition of solid oedema, which is always present, is not found in simple amygdalitis. The tonsils are never enlarged to the degree seen in amygdalitis, and, instead of the red, hyperæmic condition, we find rather an unnatural pallor of the membrane. The characteristic sticky secretion is also wanting. When the exudation is extensive, especially when it is on the pharyngeal wall and the palate, the close similarity to mild diphtheria will give us a good deal of anxiety. The presence of the solid oedema of the fauces

and the character of the secretion will help the diagnosis. The behavior of the patch seems to me to give positive and definite information toward a diagnosis. I have never seen paralysis follow in these cases of exudative pharyngitis.

The treatment of the oedematous form of disease of the throat is very simple. It consists in saturating the system with the benzoate of sodium. I usually combine it with the liquor ammonii acetatis. I have found it to act as a specific remedy in the disease. As a local remedy I have found the bicarbonate of sodium in conjunction with a little carbolic acid to act as a soothing, pleasant gargle. Under this treatment the symptoms promptly disappear, and the patient recovers. In some cases, when the joints are prominently involved, the addition of the salicylate of sodium seems to be of service. Although quinine moderates the symptoms, I have never found it to produce permanent relief. After the subsidence of the acute symptoms I have found the mistura ferri et ammonii acetatis, often combined with arsenic, to be very useful in overcoming the anaemia which always remains after the acute attack has subsided.

From a study of these cases of oedematous disease of the throat, I am convinced that we are considering a constitutional disorder rather than a local disease, and that the condition of the throat is simply one of the manifestations of a general condition. In a paper I am preparing for publication I have endeavored to show an analogous condition existing in the lungs to that seen in the throat. The solid oedema found in the lungs resembles in many respects that seen in the fauces. I maintain that this analogy is strictly legitimate, from the fact that I have seen this condition of the fauces to exist in connection with the pulmonary form of disease, and also from the fact that there are frequent alternations of the two forms in the same individual. Post-mortem examinations have proved that the pathological changes in the body are such as are only found in septic conditions, and cultures of the lung tissue show the presence of various micro-organisms.

Hence I would consider the pathological changes in the throat and lungs to be simply manifestations of a general septic condition, dependent probably on some pathological change in the blood.

The appearance of the disease in certain portions of the year, followed by its complete disappearance for many months, leads me to think of an atmospheric influence in producing it. The recognized fact that patients suffer more and are more prone to relapses in cloudy or rainy weather and improve in the bright sunshine, seems to strengthen this supposition. I have thought at times that it might be a manifestation of influenza, a disease which, as is well known, sweeps over the country in waves and then entirely disappears. The symptoms of influenza, as portrayed by Graves and others, bear a striking similarity to those seen in this septic oedema. Its long continuance during several years is, however, not in accordance with the epidemics of influenza which have been described.

**Albuminate of Quinine.**—"This salt is formed in yellowish-white flakes. It is insoluble in water alone, but soluble in water containing hydrochloric acid; also in a solution of pepsin. It is tolerated by the most sensitive stomachs."—*Druggists' Circular and Chemical Gazette*.

## Correspondence.

### LETTER FROM LONDON.

*Report of the University for London Commission; Intercollegiate Lectures between the London Medical Schools; the Treatment of Asphyxia by Submersion.*

LONDON, June 4, 1889.

THE Report of the University for London Commission has at last appeared. As was expected, the commissioners have decided against the request of the Royal College of Physicians and the Royal College of Surgeons for a charter to grant degrees in medicine and surgery, and they are, on the whole, in favor of modifying the existing London University so as to make it meet the admitted needs of the present day. The following extracts show that the commissioners have fully appreciated the causes of the agitation on the subject: "No city in the United Kingdom or, perhaps, in the world offers so good opportunities for clinical instruction as London. Clinical instruction forms an important part of the training of medical students. It is therefore important that a large number of these students should spend a considerable time in London before they are qualified to practice, and they would naturally so spend it unless there was some cause tending to draw them away from London. But medical students are generally anxious to obtain the degree of Doctor of Medicine. A man who can call himself a doctor of medicine possesses certain practical advantages over a man, however distinguished, who can not. . . . The great majority of London students, if they take a degree at all, take it elsewhere than in London, and that is a fact which the highest representatives of the medical profession view with regret. It is injurious, not to the men themselves only, but to the public. In addition to these considerations, the educational wants of the largest and most populous city in the world appear to make it a proper seat for a great teaching university. In such a university the medical faculty would have advantages not perhaps attainable anywhere else in the same degree."

In another part of the report the commissioners suggest that an interchange between the different medical schools, based on the plan of the combined intercollegiate lectures at Oxford and Cambridge, might be introduced with advantage. In this, no doubt, they are quite right; their suggestion would appear to be intended to apply only to the more strictly scientific subjects of the students' curriculum, but I am not sure that it might not be made to apply to all the subjects with advantage. Something of the kind has indeed already been attempted, for some years ago four schools—St. George's, Charing Cross, Middlesex, and the Westminster—arranged to send all their students who were candidates for the preliminary scientific examination of London University to the Science Department of the South Kensington Schools, with what success I never heard. For clinical instruction I would have the schools remain, as at present, quite distinct, but, for the purpose of systematic lectures, I am sure a great deal of amalgamation might be brought about with the greatest benefit to the students.

The Royal Medical and Chirurgical Society is about to reopen the question of the best method of treating the apparently drowned; it is now some thirty years since a committee of that society investigated the question with great care and issued a report which has ever since been a leading authority, and the time seems, in the opinion of some, to have arrived when the whole question might be reconsidered, so Dr. Howard will have a chance of having his "direct" method directly compared with the older and more popular plans.

THE

# NEW YORK MEDICAL JOURNAL,

*A Weekly Review of Medicine.*

Published by  
D. APPLETON & CO.Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, AUGUST 10, 1889.

## POST-MORTEM SWEATING.

SUCH a condition is reported in the "Lancet" for May 25, 1889. The patient, a man of forty-two, had for nine months been suffering from albuminuria. Microscopical examination of the urine showed no casts, but abundant urates. There was no dropsy or ascites. Ten days before his death he was suddenly seized with uremic coma and left hemiplegia, which last persisted unchanged until the end. The temperature was normal, with the exception of the last few days, when it ranged from 102° to 104° F. This elevation continued till within six hours before death, when it steadily sank. Treatment to produce diaphoresis gave slight results. The skin, though not absolutely dry, was almost destitute of sweat during the earlier days of the fatal attack. Hypodermatic injections of pilocarpine were given on four occasions, the dose being gradually increased. The last injection (of one third of a grain) was given three days before death. This produced a fair amount of sweating for about twenty minutes, but was not repeated, on account of the excessive bronchial secretion it caused. Forty-eight hours later, just before death, the patient began to perspire profusely. This continued till the end, even when the surface temperature was decidedly abnormal. While the body was receiving proper care, nothing unusual was noted, but sixteen hours later it was noticed that the sheets and pillows were absolutely saturated with sweat, and the skin felt moist and clammy. Thirty hours after, the sweating had ceased and the linen was drying. Post-mortem discoloration was well marked, even when the body was first seen.

The late Dr. Carpenter is cited as stating that post-mortem secretions are known to take place, and as explaining their occurrence by saying that the capillary circulation may be maintained for a short time after somatic death has taken place. The only instances in which this form of circulation seems to have been observed in the adult, says the author, Mr. John A. Cones, are those given by Dr. Bennet Dowler, in the "New Orleans Medical and Surgical Journal" for January, 1849. Rapid death from acute disease had been the rule, and the capillary circulation continued for a few minutes, but not for any lengthened period. It seems to have been Dr. Carpenter's opinion, the author continues, that the material for post-mortem secretions might be supplied by the blood in the vessels at the time of death, the gland cells themselves continuing their molecular life some time after the suspension of the general circulation. Mr. T. Bell ("History of British Reptiles," quoted by Mr. Cones) says that when he was engaged in the dissection of the poison apparatus of a rattlesnake, the animal having been dead for some hours and the head taken off immediately after

death, the poison continued to be secreted, as the dissection proceeded, in quantities sufficient to be wiped off with a sponge.

These theories of post-mortem sweating scarcely satisfy the author of the paper, who thinks it reasonable to suppose that the glands and lymph spaces were fully charged with fluid, as the patient was sweating freely up to the time of death, and mechanical pressure may have forced this fluid out. Experiments on the influence of irritation of the chorda tympani on the secretion of the submaxillary gland show that the secreting cells do not derive the materials for their secretion directly from the blood, but indirectly through the lymph spaces that surround the alveoli. These spaces are reservoirs. If filled during the experiment, the gland will continue to secrete after the head is removed from the body. It might seem that the quantity was too great to be thus accounted for, but the number of sweat glands and lymph spaces all over the body is considerable. In a person of ordinary stature, according to Sir Erasmus Wilson, there are about seven million sweat glands, with an aggregate length of perspiratory tubing of about twenty-eight miles. Is it, the author asks, unphysiological to suppose that a rise of temperature after death, as well as post-mortem sweating, may be due to an autogenetic stimulus in the cadaver which excites the governing nerve centers into action? Certain cells or groups of cells (according to Carpenter's theory) die at longer or shorter intervals, those higher in the scale of development ceasing their function first. The highest center regulating thermic functions is the thermotaxic or inhibitory. This is destroyed before the lower, which it controls; the thermogenic and thermolytic centers then come into action, producing a rise of temperature. Experimenters have arrived at the conclusion that the secretion of sweat is entirely under the influence of the nervous system, and independent of modifications in the circulation (Straus). In limbs of animals previously rendered exsanguine, profuse sweating has been produced by stimulation of the main nerve-trunk, and in recently amputated limbs; and also on stimulation of the medulla oblongata after ligature of the aorta. Abundant sweating has been induced by faradaic stimulation of the nerves of a limb, while injections of pilocarpine in the dead subject, or into a recently amputated limb, have given negative results.

## SYPHILIS FOLLOWING TATTOOING.

RECORDS of an outbreak of this kind form the substance of an interesting paper in the "British Medical Journal" for May 4, 1889. Twelve hearty, fresh-complexioned young men of robust health, all soldiers, between the ages of eighteen and twenty-two years, who had been in service from three to twenty-four months, acquired syphilis through the carelessness of a former comrade who used saliva in the process of tattooing, or put the needles in his mouth. Marked and unmistakable syphilitic manifestations appeared within from thirteen to eighty-seven days. Instead of the one chancre, that usually follows poisoning produced in the ordinary way, there were, in one case, four distinct rupial ulcerations within the area of a

circle an inch and a half in diameter. The severity of the secondary phenomena bore no relation to the number of points of ulceration. The most intractable case presented only one ulcer. Although both arms were sometimes tattooed, and on the same day, in no instance did ulceration occur on more than one arm. Five of the men presented a distinct rupial form of the disease, and one had secondary rupial lesions at the seat of the chancre. In no case in which rupial ulceration formed was there merely a single sore; they ranged from two to four in number. In no case did rupia appear on other parts of the body.

The author of the paper, Surgeon F. R. Barker, states that he had always regarded rupiae as tertiary manifestations, never having seen them appear at the seat of a primary lesion. Finding in the article on syphilis, by Mr. Jonathan Hutchinson, in the "Dictionary of Practical Surgery," the statement that rupia never occurs very early among secondary phenomena (its usual place being from six to twelve months after the chancre), the author sent a photograph of one marked case to Mr. Hutchinson, from whom he received the following reply: "I have repeatedly seen primary chancres, when occurring on the naked skin, assume more or less closely the features of rupiae. You will see one of those figured in my 'Clinical Illustrations,' in connection with syphilis from vaccination, in which the sores have much this aspect. I may admit that I have never seen the simulation quite so clear as it is figured in your photograph." The rupiae, when seen, were of the form of rupia prominens, resembling limpet shells, and, falling off, they left a plane, not an excavated, base. There was uniformity in the symptoms in about the following order: Enlarged glands, rash, sore throat, condylomata, and mucous tubercles.

#### CIDER AND CANCER.

IT is the fate of many of the good things of this life to be accused of producing evil. Blessings, like public benefactors, have their revilers. Our immediate progenitors, who seldom or never partook of the luscious tomato, for instance, handed down to us the opinion of their time that "love-apples" caused cancer when eaten. This opinion uttered to the millions of tomato-eaters of to-day would only provoke a smile of pity for the speaker. But another article of food has recently been incriminated as a cause of cancer, although not on this side of the Atlantic, we believe. No medical authority has given support to such an hypothesis so far as we know, but a writer in the "Normandie médicale" has taken pains to show that the popular fear in regard to cider is unfounded. One of the best points in Dr. Prieur's article is the exposition and denunciation of the custom of certain cider-makers of putting impure water with the crushed apples when in the press, to dilute the cider and render it less alcoholic. He quotes from Dr. Denis-Dumont, who saw producers of "cider" take greenish water from a barn-yard pool near by and pour it into the cider-press. And this, it is to be presumed, was in Normandy, where the cider has the name of being the best in the world. In their igno-

rance the makers of this vile, not to say death-dealing, mixture believed that when the apple-juice fermented all impurities would be eliminated. It is not surprising, therefore, that such cider might produce disease of some kind, though not cancer.

But from such a solution of ptomaines and such a cultivation of microbes to the pure juice of the apple or to that juice diluted with pure rain water (which is quite a legitimate mixture) there is a decided step. To accuse well-made cider of favoring the invasion of human tissues by cancer is *prima facie* absurd. Nothing short of precise laboratory experiments will convince the scientific mind of the present day that cider is to this extent noxious. And, besides that, we must now *chercher le microbe* in the cider capable of producing carcinoma, just as in cases of suicide or murder it has long been the custom to *chercher la femme*. Now, who would be bold enough to accuse the innocent *Saccharomyces cerevisiae* of transforming itself into the formidable *Bacillus Scheurellii*? Who, with the bright memory of delightful champagne suppers still fresh in his mind, could insinuate that the minute furnisher of the *mousseux* nectar was double-faced and double-natured, and caused excruciating suffering as well as exquisite pleasure? No; let cider, like tomatoes and other good things, be taken plentifully and fearlessly, and let the magnesic and selenitic waters that are sometimes added to cider be more dreaded than the pure juice of the apple.

#### MINOR PARAGRAPHS

##### OIL OF EUCALYPTUS IN HEADACHE.

THE "Medical News" of July 20th has an article on the use of eucalyptus in headaches of various types, after other means had failed, recording a measure of success that will induce many physicians to make a trial of this drug in rebellious cases. The authors of this article, Dr. Morris J. Lewis and Dr. G. E. de Schweinitz, of Philadelphia, report eight cases, all benefited, and refer to others treated by Dr. Weir Mitchell and Dr. Sinkler with satisfactory results. The dose given was five minims, from four to six times daily. In one case twenty minims were given as an attack was coming on, and, in the patient's opinion, prevented it. The best results were obtained in cases where the dose was taken early. The authors suspect that a malarial cause existed in some of their cases, and their first success was in a case of that nature, the drug being prescribed for malarial trouble rather than for the neuralgic symptoms. The "sudden and surprising improvement" in this instance led them to make further use of the drug, even in cases where there was no malarial history. Their impression is that it will be found that headaches of the congestive type will be the ones best suited to the use of eucalyptus. They did not succeed with the drug in one case where the attack was brought on by an indiscretion in diet, although the patient obtained relief at other times; and in one case of ciliary neuralgia failure is reported; also in two others where there was organic disease of abdominal viscera.

#### A MALPRACTICE SUIT.

A SUIT for malpractice against a New York physician having been tried before a jury, \$1,000 damages were found against him. In the General Term, however, the case has taken a turn in the physician's favor. Presiding Justice Van Brunt wrote the opinion, in which Justice Daniels and Justice Barrett con-

cur. After reviewing the testimony, the judge says that the case seems absolutely barren of proof that there was "any neglect or want of skill on the part of the defendant" whereby any permanent injury had been inflicted upon the plaintiff. A new trial was ordered. The plaintiff received an injury in 1886 by being struck by an ice-cart and knocked down. Not having progressed so favorably as he wished, he brought suit for damages on an allegation of unskillful treatment.

#### DEAD DOGS FOR MEDICAL STUDENTS.

SOME medical students having asked the Mayor of New York to allow them a certain number of condemned dogs from the pound, for experimental purposes, that functionary, as the newspapers report, has duly considered the request, also the protest of a certain humane person who dreads the cruelty to which the dogs might be subjected by the students, and has come to the conclusion that he will allow the students a supply of dead dogs, but no live ones. This generosity is about equal to Artemus Ward's as exemplified in his answer to a person who had asked the privilege of seeing his show without paying—"No, you can't go in without paying, but you can pay without going in."

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending August 6, 1889:

DISEASES	Week ending July 30.		Week ending Aug. 6.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	30	10	45	14
Scarlet fever.....	32	3	27	4
Cerebro-spinal meningitis.....	4	4	3	2
Measles.....	40	5	36	2
Diphtheria.....	82	29	70	19

**The Waldo Memorial.**—The citizens of Cairo, Ill., have caused the construction of a monument at Mound City in memory of Dr. Roswell Waldo and of his services in that community during the yellow-fever epidemic of 1878.

**The Virginia Medical Society** will hold its twentieth annual meeting at Roanoke, beginning on September 3d, Dr. E. W. Rowe, of Orange, presiding.

**The University of Michigan.**—The medical department has met with a loss in the resignations of Dr. Donald Maclean and Dr. Frothingham, formerly the professors of surgery and of ophthalmology. Dr. Charles B. Nancrede, of Philadelphia, has been invited to take the chair of surgery.

**New Hospitals.**—A new hospital will soon be erected at Ann Arbor, Mich., a grant of \$50,000 having been made for that object by the last Legislature. The city has voted to give \$25,000 also, and will issue bonds to that amount. At Memphis, Tenn., a new public hospital will be built under the direction of St. Mary's Roman Catholic church.

**The Lehigh Valley Medical Association** will hold its ninth annual meeting at Glen Summit, Pa., on Friday, the 16th inst., under the presidency of Dr. George N. Best, of Rosemont, N. J. Among the titles in the programme are "Evolution in the Causation of Disease," by the president; and "Railroad Shock and its Treatment," by Dr. Francis X. Dercum, of Philadelphia.

**An Infants' Summer Hospital** has been established by the citizens of Rochester, N. Y., at Charlotte, on Lake Ontario. Dr. E. M. Moore is president of the association, and Dr. George

W. Goler is the attending physician. Any child suffering from intestinal trouble is treated free of charge. There are accommodations for twenty patients, and many children who would otherwise have received no medical treatment have been cared for.

**The Minnesota State Board of Health.**—Dr. J. H. Phillips, of Preston, Minn., has been appointed to the board of health, to succeed the late Dr. D. W. Hand, of St. Paul. Dr. Phillips was a member of the State Legislature in 1888.

**Recent Deaths.**—Dr. Oscar J. Coskery, of Baltimore, died on July 5th, of general tuberculosis. He was born near that city in 1843, and graduated from the medical department of the University of Maryland in 1865. He served in that year as an assistant surgeon of volunteers. He was a member of the State Medical Faculty and of the staff of St. Joseph's Hospital, and in 1872 became professor of surgery in the College of Physicians and Surgeons, of Baltimore. He was a frequent contributor to the journals, chiefly on surgical subjects. He was the author of an essay on hospital construction.

Dr. William Thomas Ennett died on June 15th, a very short time after the expiration of his term as president of the Medical Society of North Carolina.

Dr. Charles Corning Lathrop died in Denver, Colorado, on May 28th, aged forty-three years. He had been a resident of Denver for nearly all his professional life, and was well known from having been for several years the permanent secretary of the State Medical Society.

Dr. Thomas W. Battle, of Columbus, Ga., died on June 16th, aged seventy-three years. He was a graduate of the University of Pennsylvania, in the class of 1840.

Surgeon-General Francis Day, of the India Medical Service, died at Cheltenham, England, on July 10th. He saw active service with the Madras Army, but became identified with the study of the fishes of India. He was made the inspector-general of the fisheries in India, and was the best-known naturalist in that country. He was the author of valuable and standard books on ichthyology.

Dr. Charles Elam, of London, died on July 9th. He was the author of eleven books and numerous minor articles, dealing chiefly with nervous, mental, and psychological questions. His book entitled "A Physician's Problems" was the best known of his essays.

**Dr. Lewis A. Sayre** has lately received a diploma of honorary membership in a St. Petersburg medical society.

**The Deutsche Poliklinik.**—At a recent meeting of the executive committee of the German Poliklinik the following figures were presented showing the work done since the opening of the institution, in 1883: Total number of patients cared for, 60,711; of consultations, 189,163; of prescriptions, nearly 123,000. The report also shows that for the last three months there have been more than 1,000 new patients a month. It will not be long, the committee believe, before they will have to appeal to the public for a larger building.

**Italian Medical Societies.**—Two medical meetings, according to the "Raccogliatore medico," will be held simultaneously in Padua from the 16th to the 21st of September: the thirteenth congress of the Italian medical societies and the third congress of the united societies for hygienic research.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 28 to August 3, 1889:*

BRECHERIN, LOUIS, Captain and Assistant Surgeon. By direction of the Secretary of War, so much of Par. 1, S. O. 159,

July 12, 1889, A. G. O., as directs his return to his station at the close of the encampment of the Illinois National Guard is amended to direct him to report in person not later than August 20, 1889, at Fort Robinson, Nebraska, for duty at that place. S. O. 174, Headquarters of the Army, A. G. O., July 30, 1889.

HALL, WILLIAM R., Captain and Assistant Surgeon. Granted leave of absence for ten days. Par. 5, S. O. 80, Headquarters Department of Dakota, July 27, 1889.

ROBINSON, SAMUEL Q., Captain and Assistant Surgeon. The leave of absence granted by Par. 11, S. O. 165, from these headquarters, is hereby extended ten days. Par. 8, S. O. 172, Headquarters Division of the Atlantic, July 30, 1889.

MAUS, LOUIS M., Captain and Assistant Surgeon (Fort Porter, N. Y.), is hereby granted leave of absence for twenty days on surgeon's certificate of disability. Par. 2, S. O. 173, Headquarters Division of the Atlantic, August 1, 1889.

HARRIS, H. S. T., First Lieutenant and Assistant Surgeon. By Par. 9, S. O. 176, A. G. O., August 1, 1889, the leave of absence granted in S. O. 140, A. G. O., June 18th, is further extended two months.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending August 3, 1889:*

BRYANT, P. H., Assistant Surgeon. Ordered to temporary duty on ironclads, Richmond, Va.

**Marine-Hospital Service.**—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the two weeks ending August 3, 1889:*

HUTTON, W. H. H., Surgeon. When relieved at Mobile, Ala., to assume command of the Service at Baltimore, Md. July 23, 1889.

PURVIANCE, GEORGE, Surgeon. When relieved at Baltimore, Md., to assume command of the Service at Philadelphia, Pa. July 24, 1889.

GAASSAWAY, J. M., Surgeon. Ordered to New Orleans, La., for temporary duty. August 2, 1889.

GOLDSBOROUGH, C. B., Surgeon. Granted leave of absence for thirty days. July 29, 1889.

VAUGHAN, G. T., Assistant Surgeon. Orders to Norfolk, Va., revoked; to proceed to Cairo, Ill., for temporary duty. August 1, 1889.

GROENEVELT, J. F., Assistant Surgeon. Relieved from duty at Gulf Quarantine Station; ordered to Mobile, Ala., for temporary duty. August 3, 1889.

## Proceedings of Societies.

### AMERICAN LARYNGOLOGICAL ASSOCIATION.

*Eleventh Annual Congress, held at Washington on Thursday, Friday, and Saturday, May 30 and 31, and June 1, 1889.*

The President, Dr. ETHELBERT C. MORGAN, of Washington, in the Chair.

**Report of the Removal of a Supernumerary Tonsil.**—The PRESIDENT read a paper on this subject.

Dr. J. N. MAOKENZIE, of Baltimore: In connection with the case reported by Dr. Morgan, I would briefly refer to a case

which I reported some time ago, an account of which has not yet been published. It was a case of tumor of the pyriform sinus, which was removed with the wire snare. Upon microscopical examination, it was found to be composed of the lymphoid tissue so graphically described by Waldeyer and his pupils. I have on several occasions removed growths from the tonsils, and once from the anterior faecal pillar, but I am sorry to say they were not examined microscopically. They would doubtless have shown a similar structure to that found in the pyriform sinus.

Dr. D. BRYSON DELAVAN, of New York: This subject has been so thoroughly and carefully worked out by Dr. Morgan that it has given me considerable interest to try to recall a similar instance. While I remember to have seen it stated that supernumerary tonsils may occur, yet, after a careful search through the literature, I was able to find but the two cases referred to by Dr. Morgan. I have seen several cases of tumor of the tonsil, which were distinctly pedunculated and easily removed, but which proved to be largely of a fibrous structure. It seems possible that these fibrous tumors, which are not uncommon, may be degenerated supernumerary tonsils. In the case reported there had been considerable growth, the tumor increasing markedly in size during three or four years. It may be that these fibroid tumors begin as supernumerary tonsils, and later, becoming rich in fibrous structure through the irritation to which they are exposed, assume the character of the former growth.

**The Relation between Facial Erysipelas and Erythema on the One Hand and Intranasal Pressure on the Other.**—Dr. G. W. MAJOR, of Montreal, read a paper with this title. (See p. 148.)

Dr. J. O. ROE, of Rochester: I have seen a number of cases of erythematous rash about the face which was due to the cause described by Dr. Major. This was well pronounced in a case recently seen—that of a girl twenty-three years of age. She had an erythematous rash upon the face, very red, and studded with blebs and blotches, giving a very conspicuous appearance. She had been treated with constitutional remedies by two or three distinguished men, without benefit. They afterward referred her to me, and I found in both nostrils that the middle turbinated bodies projected firmly against the septum. I removed the projecting portions, rendering the passages free, and there was an immediate subsidence of the erythematous trouble, and it has now entirely disappeared. I can not agree with Dr. Major that erysipelas is due *per se* to intranasal pressure. Erysipelas is caused by a distinct germ, and is an infectious disease. Those who have intranasal difficulty with erosions are more liable to become infected by these disease germs. As we know, erysipelas may come from the infection of a scratch, but the latter is quite different from the erythematous rash which may be excited by simple local irritation.

Dr. MAOKENZIE: I can not agree with Dr. Major in regard to the silence of medical literature upon this subject. I think that it has been pretty fully discussed in the last five or six years. I know that some centuries ago, in the time of Willis and Sylvius, this erythema of the nose and face was discussed in separate chapters, and was attributed to intranasal changes. I have myself discussed the subject pretty thoroughly in Wood's "Reference Hand-book," published in 1887. The Germans have reported cases of so-called erysipelas and erythema of the external nose and cheeks as exceedingly common. I have seen erythema very often, but I have not seen a case of true erysipelas. The so-called cases of facial erysipelas from intranasal changes seem to me to be rather an accentuation of the act of blushing. It is a sort of chronic blush. It can hardly be called true facial erysipelas.

**Dr. DALY:** I am not a believer in the theory of intranasal pressure. I believe that the conception of the theory is not good, and consequently the super-structure is on a bad foundation. The evils, whatever they may be, that we recognize as coming from so-called intranasal pressure, are evils that in reality arise from intranasal turgescence. There is no question in my mind that the condition which my friend Dr. Mackenzie speaks of as an accentuated blush, a prolonged blush of the parts—a very pretty idea—is, when divested of all superfluous mystery, largely due to hypernutrition from a turgescut and permanently dilated and enlarged blood-supply.

During the past year or year and a half I have had under my professional care two cases. One of these was a very well marked case of erythema of the skin of the nose and extending out upon the cheek. I was, however, not consulted by the patient on account of the skin disease, but for a condition which he spoke of as intranasal catarrh. I resorted to prompt surgical measures, removing the turgid condition of the intranasal structures—in a word, cutting off the blood-supply by destroying the blood-vessels; and, as a result, the condition of which he complained as catarrhal was removed, and subsequently also the erythema disappeared. I met the man, who was from a neighboring town, a few weeks ago, and did not recognize him. The turgid and red condition of the nose had disappeared, and he presented quite a respectable appearance and was altogether much pleased with himself.

The second case was of a somewhat similar character in a young lady. She had erythema of the external surface of the entire nose, with a horseshoe-shaped patch around it of the same kind extending down to the outer angle of the mouth on each side. She had been told that it was due to menstrual disorder. I lost sight of that opinion after finding that there was sufficient intranasal deformity to warrant interference for stenosis. After relieving surgically almost complete stenosis of one naris and partial stenosis of the other, the erythema disappeared. In this case, by the way, there was copious haemorrhage, almost causing death, after one of the operations with the saw. I had said to the patient that a little bleeding would do no harm. She went to her home, two miles and a half in the country, and there bled copiously, but assured her friends that the doctor had said that bleeding would not matter. She bled well into the night, when my assistant was sent for, and found her almost *in articulo mortis*. She, however, recovered, and is now perfectly healthy and a handsome girl, with good nasal respiration, with no defect of skin or complexion.

I do not believe in chronic facial erysipelas, and think that the term is a misnomer. I regard erysipelas as essentially an acute inflammatory disease of a specific type, and depending oftener upon an acute constitutional disorder than a local one, and as diverse from the condition of chronic erythema as possible—in fact, I don't believe such a thing as chronic erysipelas exists at all.

**Dr. F. I. KNIGHT,** of Boston: Without repeating what has been said, and well said, upon this subject, there is one point which the gentlemen seem to have overlooked. This is in regard to another condition which may serve as a cause of erythema of the nose and face. It is one which I always search for and frequently find—namely, necrosis. When a patient presents himself to me with a localized strong blush on the nose or cheek, I look for necrosis, just as in a case of unilateral profuse purulent discharge I look for a foreign body or necrosis. The worst cases that I have seen have been where there was decided necrosis. Here the erythema has been removed by giving free vent to the purulent discharge and keeping the parts clean.

**Dr. DELAVAN:** In four cases of this affection that I have seen the erysipelas has been very severe. The first case was a

girl, seventeen years of age, who had recurrent attacks of erysipelatous swelling over the alæ of the nose and extending over the cheeks. These attacks recurred every two or three weeks. I thought that some necrotic process might be the cause of this condition, but I failed to find it. I found, however, marked turgescence of the nasal mucous membrane. The condition was treated topically, and in time, with the subsidence of the catarrhal trouble, the erysipelatous attacks disappeared and did not recur.

Another case was that of a girl, fifteen years of age, who suffered from adenoid hypertrophy at the vault of the pharynx. She had had recurrent attacks of erysipelas. That this was true erysipelas was proved by the fact that the inflammation was very severe, that the nose swelled to a large size and remained thickened for a number of weeks, and that, with the subsidence of the attacks, there appeared a distinct herpetic eruption, as often occurs in erysipelas. In this case no necrosis was present. There was, however, extensive engorgement of the nasal mucous membrane, with some pressure in the neighborhood of the middle turbinated body on both sides. The patient had improved under treatment. About two weeks after her last attack, a younger sister, sleeping in the same room, suffered from the same condition. In the latter case there was also some turgescence of the intranasal mucous membrane.

**Dr. HARRISON ALLEN,** of Philadelphia: I think if Dr. Seiler were present he would tell us of the connection between nasal disease and acne. It has been my experience to see in two cases attacks of furuncles follow treatment of the nose. In a third case these furuncles occurred without surgical treatment of the nasal cavities. In one of the cases there was distinct flushing of the face and nose. I looked upon this as a mild form of cellulitis. I see no difference between a diffuse form of cellulitis of the face arising from intranasal causes and that which follows abscess of a tooth. Under the latter circumstances we frequently see cellulitis of the entire face. I think that Dr. Major meant erysipelas and not cellulitis, so that these remarks refer more to what was said by previous speakers than to the paper itself.

There seem to be several different conditions—first, a distinct erysipelas; second, diffuse cellulitis in various forms; and, third, a chronic determination of blood to the face dependent upon chronic irritation.

**Dr. S. W. LANGMAID,** of Boston: I recently saw a case of erysipelas in Dr. White's clinic in Boston, and he remarked that in such cases we should look for the cause in the nose. The dermatologists have therefore not lost sight of this fact.

**Dr. MAJOR:** In my paper I have avoided theory and confined myself simply to facts. My opinion is based upon clinical observation that led me to look for these cases. I have looked for them and I have found them. These have been cases of erythema and erysipelas under medical treatment by men high in the profession, but without benefit—cases that have been under the care of dermatologists for months without improvement, and they have been cured by simple removal of the pressure. That is about as straight evidence as to cause and effect that any one need want. I do not think that turgescence will produce erysipelas or erythema unless it causes pressure. In regard to necrosis, this is common enough in syphilitic cases. The erythematous condition may continue for months. I have not mixed up erysipelas and cellulitis. One of my patients had fourteen attacks of erysipelas. All commenced in the nose and extended over the body. In regard to the literature, I would say that I consulted a number of books, but saw no reference to this matter. I am sorry that I overlooked Dr. Mackenzie's observations in Wood's "Hand-book."

**Acute Multiple Adenitis (Septic ?); Oedema of the Larynx, with Spontaneous Cure.**—Dr. S. W. LANGMAID, of Boston, read a paper with this title. (See p. 149.)

**Oedematous Disease, or Septic Oedema, of the Upper Air-passages.**—Dr. W. C. GLASGOW, of St. Louis, read a paper on this subject. (See p. 150.)

Dr. T. A. DE BLOIS, of Boston: I have been much interested in Dr. Langmaid's paper, particularly with reference to the possibility of diphtheria being coincident with the condition he describes. Last year I was called in consultation to a case of supposed oedema of the larynx. The epiglottis and the arytenoids were oedematous, not so much at the first examination as subsequently. I punctured the epiglottis and got a slight discharge of blood, and in twenty-four hours the place of puncture was filled by the exudation of diphtheritic membrane. The oedema then progressed, and the arytenoids became so large and obstructed respiration so much that they were punctured, and again extension of the membrane occurred. There was no discharge of pus at all. Sometimes marked oedema will precede a very slight exudation. As Dr. Langmaid has said, there might have been exudation which had passed away when he examined the throat; but I have never seen oedema follow exudation.

Dr. DALY: The condition which Dr. Glasgow has so well described is somewhat new to me. The doctor spoke to me in regard to it a year ago, and asked me if I had seen such conditions. At that time I had not; but last autumn, when the bad weather began, there was in Pittsburgh an endemic of the class of cases to which Dr. Glasgow has referred. A number of them fell to my professional care, but by far the larger number were treated by the general practitioners. I did not regard this swollen condition of the fauces so much as oedema, as we understand that term, as that it was a subacute inflammatory condition of the mucous membrane, with attendant swelling. There was a sufficient number of these cases that had superficial and very thin diphtheroid patches in various parts of the fauces to warrant me in my opinion that they were cases of a diphtheroid disease of the throat. I was confirmed in this opinion by the subsequent occurrence of glandular enlargement, which came on in nearly every case, and was located in the deeper regions at the sides of the throat, sometimes in other parts of the body, and in one or two instances in the axilla. In short, I regarded this endemic as a diphtheroid disease, with exaggerated local symptoms scarcely warranted by the local deposit of false membrane or fibrinous deposit; but, while there were exaggerated glandular symptoms, there was a rather amenable condition of the constitutional symptoms.

The calomel treatment, which I am so fond of employing in cases of true diphtheria, and which has stood me in very valuable service—much more so than any other plan of treatment that I have ever adopted—did not give the results which I am in the habit of observing from it in true diphtheria. These cases were usually manageable, but sometimes slowly so, with a treatment something like this: Three or four times a day, three to four grains of Dover's powder, with two or three grains of quinine upon a full stomach, and then the use, both locally and internally, of a solution of the chlorides—chlorate of potassium, Squibb's preparation—with dilute hydrochloric acid in syrup or, preferably, in glycerin. This was used as a gargle in hot water, and a moderate dose taken every two or three hours.

After the local disease subsided, the glandular enlargement was usually treated with an ointment of veratrine, or simple lauolin, and the use of the iodides. Much handling of these glands was resented by increased pain and swelling. I believe that this is a modified form of diphtheria, with exaggerated local symptoms, but a more amenable condition of the constitutional symptoms, and depending upon a modified form of the germ or

infection. It seems to me that it has sprung up in the Mississippi and Ohio valleys, and has radiated from those regions.

Dr. J. C. MULHALL, of St. Louis: I think that a great deal of credit is due to Dr. Glasgow for being the first to recognize that there is a peculiar type of inflammatory trouble of the upper air-passages sweeping over the country. I can confirm, from experience in St. Louis, the existence of this peculiar class of cases. The last acquaintance that I saw before I left was a gentleman who came to the train to tell me that, for the third time, he had tenderness in the throat. He came to me two weeks ago with what he thought to be the symptoms of ordinary quinsy. I found these white patches of exudation on one tonsil, and a great deal of pain without oedema. I regarded the case as one of ordinary follicular amygdalitis, and treated it in the ordinary way. I gave him aconite and a gargle of tincture of guaiacum. In forty-eight hours he again presented himself with an abscess of one tonsil, but the usual relief did not follow the evacuation of the pus. He again returned in forty-eight hours, and then was present this peculiar type of oedema. It involved the uvula, the anterior and posterior pillars on the right side, and extended down the pharyngeal wall on the right side. He then took my advice and went to bed. The treatment which was then adopted seemed to have a marvelously rapid effect in relieving the trouble. It was the old-fashioned antiphlogistic treatment. The inflammation seemed to be of a rather active type, the temperature being from 100° to 103°. The treatment consisted in the application of very hot poultices to the side of the throat every half-hour, the administration of Norwood's tincture of veratrum viride, and antipyrine. Saline purgatives and scarification were also employed. This treatment had a marvelous effect. He recovered, but subsequently the throat again became sore, and exactly the same thing occurred. The same treatment was pursued, and the symptoms subsided in twenty-four hours. When I left St. Louis he had been well for four days, but, as I have stated, he came to me to say that, for the third time, symptoms of irritation of the throat had appeared. Some time ago I saw another gentleman with the same sort of an attack, which subsided, under the treatment mentioned, in forty-eight hours without any recurrence. I have also observed the glandular implication which is very unusual in ordinary sore throat. I saw one of Dr. Glasgow's patients on Monday. He has been suffering since December 15th, and it is only within the last month that the glandular enlargement has begun to recede. His was one of the cases in which ulceration took place. It is possible that the case described by Dr. Langmaid, and probably the case of Allen Thorndyke Rice, belonged to this class, having involved the larynx and produced acute oedema. I have not seen any of the cases in which there has been laryngeal involvement, although, curiously enough, during the last winter I have seen two cases of acute typical laryngeal oedema from erysipelas. With Dr. Daly, I think that this affection originated in the Mississippi Valley, and has radiated to other parts of the country.

I should like to say a word in regard to the pneumonia which has occurred in connection with these cases. I was recently in the biological laboratory of Dr. Brainer, of St. Louis, and he showed me the results of some cultivation experiments from this form of pneumonia, side by side with the cultures from the ordinary pneumococcus. The growth was entirely different, although the gross examination had shown interstitial pneumonia in both instances.

Dr. S. HARTWELL CHAPMAN, of New Haven: While expressing my admiration for the exhaustive analysis and close observation of the symptoms of this disease which is the subject of Dr. Glasgow's paper, I can not but differ with him as to the character of the disease itself. It is, I am sure, but another and not

unusual development of diphtheria. We are not obliged to seek in the Western States for these peculiar phenomena, for they are quite as common developments of diphtheria in the Eastern, and I feel confident that I am giving the experience of laryngologists in the Middle and Southern States as well.

A case which occurred in my practice during the spring of this year will illustrate the close connection between the ordinary forms of diphtheria and this peculiar form of which we are indebted to Dr. Glasgow for collecting the interesting symptoms. In the first week in March I treated a lad of ten years, in a family consisting of parents and two children—this lad and a boy-baby of about eighteen months. This case was one of mild typical diphtheria with well developed tonsillar and pharyngeal membrane extending to the brim of the larynx, with moderate glandular enlargement, considerable exhaustion, and moderate rise in temperature. The case was treated with quinine, stimulants, and mercurials, and ran an ordinary course of about ten days, with no bad results following. On the fourth or fifth day of this attack my attention was called to the younger child, who was found to have a dense swelling of moderate size directly under the chin, with rise in temperature and the appearance of being very ill. The same treatment was adopted in this case as in the other, with the addition of hot fomentations to the glandular enlargement. No membrane could be observed in the throat, and indeed the mucous membrane seemed to be in a perfectly healthy state. There was no hoarseness and no dyspnoea.

Notwithstanding all preventive efforts, the glandular enlargement continued to increase, extended to other glands, and finally produced a uniform infiltration of all the tissues of the neck. This occurred rapidly, so that by the end of the fifth day the appearance of the little patient was very peculiar. From the ears to the clavicles, and extending almost to the shoulders, the swelling was one uniform smooth mass, into which the face and chin seemed to have sunken. With the gradual increase of this infiltration, dyspnoea appeared and became finally very alarming. The process of deglutition ceased on the second day, and the patient was nourished *per rectum*. It seemed likely that suppuration had taken place, so that I made several deep incisions in the sublingual region. This operation was followed by rather copious haemorrhage, but no pus was found and the symptoms were not at all relieved. An O'Dwyer tube No. 2 was then inserted into the larynx, although with very great difficulty owing to the infiltration. This was left *in situ* four days, during which time the infiltration so rapidly subsided that the conformation of chin and neck again became evident. By the eleventh day the patient was again able to swallow liquids. By the fifteenth day convalescence set in. During the course of the disease there was no membrane to be observed, and the mucous membrane of the pharynx and mouth retained its healthy appearance. The peculiarity of the case was the development of enormous infiltration into all the tissues of the neck, forming a dense, hard, inelastic swelling. During convalescence moderate suppuration of the sublingual gland took place. As far as it is possible to judge, this seemed to be a case of modified diphtheria of the general type of the disease so ably described by Dr. Glasgow.

Dr. CHARLES E. SAJOUS, of Philadelphia: It has been my good fortune to see several of these cases, and the remark made by Dr. Chapman that they are not limited to the West is exemplified by the fact that Dr. Seiler described a number of them before the German Medical Society of Philadelphia a few months ago. The first case that I saw of this affection was in a young man from New Jersey. He had been exposed to the contact of no case of the kind in the neighborhood. I was struck with the amount of pain and the severity of the general symptoms which

accompanied the throat trouble. The appearance of the throat did not resemble the condition seen in diphtheria. Instead of the yellowish, leathery membrane generally present in diphtheria, there were small white patches, probably twenty or thirty in number, covering the pharynx and tonsils. Around these patches was a narrow areola of redness which gradually disappeared to again increase toward a neighboring patch. The vault of the pharynx was slightly involved. There was slight oedema of the soft palate. The temperature was raised throughout the entire course of the attack ( $102.5^{\circ}$ ). The case appeared at first to be one of follicular pharyngitis, but the general symptoms were such that I made up my mind that it was an affection with which I was not acquainted. There was redness of the fauces and slight tinnitus aurium. The patient complained of incessant pain in the back and in both legs. After trying a number of remedies, he was placed on benzoate of sodium, suggested by the remarks of Dr. Seiler, which were reported to me by a member of the German society who was present when the paper was read.

I saw another case in Wilmington to which I was called in consultation. This was in a child about two years and a half of age. The case much resembled that reported by Dr. Chapman. The glands were greatly enlarged—sufficiently so, in fact, to warrant the intention of the attending physician to freely open them, fluctuation being present. The knife was not used, however, but the child was placed under minute doses of the bichloride of mercury. The glandular swelling rapidly disappeared and the child got well. The appearance of the throat and the general symptoms were about those found in the case from New Jersey.

Dr. DELAVAN remarked that this discussion was a timely one, coming as it did in connection with a recent celebrated case. He referred to a patient in this condition whom he had seen suddenly die from heart failure. Other cases, apparently similar, had been occasionally reported. He believed that they were analogous to those described by the older French writers and by Sir Morell Mackenzie as "acute oedematous laryngitis," and more recently by Senator, under the name "acute infectious phlegmon of the pharynx." The speaker thought that the possibility of the disease being diphtheria had not been satisfactorily eliminated. In view of the dangers attending it, he urged that the affection be more carefully studied and explained, and he thanked the reader of the paper for the valuable light which he had thrown upon it.

Dr. LANGMAID: Dr. Glasgow's cases seem to me quite different from the one which I reported, in which the oedema was the result of pressure and not necessarily a symptom of the disease which caused the adenitis. I thought that the case which I have related was of sufficient interest to bring before the society, because it was almost diagrammatic. The neck was swollen even from the jaw to the clavicle. The short history of illness made me expect to find membrane or an ulcerated patch from which membrane had been discharged. I found a perfectly clean throat. I can not conceive of an adenitis as extensive as this in a patient of the age of this one, coming on as suddenly as it did and disappearing so suddenly, that was not septic. I believe that there was diphtheria in this case, but, as the history of the first eight days is not known, I can not speak positively. There was no oedema of the pharynx or fauces when I examined the patient. It also seemed to me that the spontaneous evacuation of pus from some gland, as occurred in this case, must be very unusual.

With regard to the cases spoken of by Dr. Glasgow, it has seemed to me that, with the remains of a general practice clinging to me, if these cases had occurred in Boston, I should have seen some of them. I do not recall any such case, and, so far

as I know, they have not been presented to the societies. For some years we have had conditions in Boston which, with the constant presence of diphtheria in certain sections, would render the occurrence of a general epidemic very probable. It has not occurred, and it has seemed to me that, for some reason, the atmosphere of our city is not suitable for the spread of diphtheria. This is possibly the reason that we have not seen these bastard cases, such as Dr. Glasgow has described.

**Dr. GLASGOW:** There is only one point to which I need refer, and that is in regard to the connection between this form of disease and diphtheria. No one could possibly consider the oedematous form as diphtheritic, and the question could only occur when the exudation is present. In my earlier observations I thought the exudative cases might be diphtheritic. In one case, a young girl of seventeen, the whole palate and tonsil was covered with exudation. I thought that it was a case of diphtheria, and placarded the house as the law exacts. As I watched the case I became convinced that it was not diphtheria. I called in one of our ablest physicians, and at first he said that it was diphtheria, but, after watching the case for a few days, was convinced that it was something else.

The history of the exudation is not that of a diphtheritic patch. It never comes away in a mass, but gradually fades away, growing thinner and thinner day by day. It is not surrounded by the inflammatory zone seen in diphtheria. That diphtheria may be ingrafted on such a condition of the mucous membrane I am fully convinced, since I have met with it in several cases. The oedematous condition of the mucous membrane seems to furnish a fertile culture soil for the development of cocci.

#### NEW YORK SURGICAL SOCIETY.

*Meeting of April 24, 1889.*

The President, Dr. L. A. STIMSON, in the Chair.

**Successive Fractures of the Patella.**—Dr. R. ABBE presented a patient who had first sustained a fracture of the patella in 1871, in that instance by muscular violence, having slipped and suddenly caught himself. His patella had been fractured a second time by a blow from a truck, in the same year. In January of 1888 he had again slipped and fractured the bone, at a different point, however, from either of the previous fractures, and in this case the union had been effected by wiring. On May 4th of the same year he had fractured the bone for the fourth time by muscular violence, and in this case also in a different place from where the bone had recently been wired together. The result had been a wide gap which had, of course, shown no tendency to unite, and made the limb quite useless. The speaker was in some doubt as to whether he should rewire the fragments, as that might only result in a stiff knee. However, previous to the last fracture the patient had been able to bend the knee but little, and the fracture itself had been caused by a forced bending of the limb. The lower fragment, of a crescentic shape, could be brought nearly into apposition with the large upper fragment. A knee-cap could be gained by wiring or circular sutures. The limb had been a good one, practically, from 1871 until January, 1888. If wired, the limb would still be as useful as it now was. Up to May it had been in a splint.

Dr. LANGE thought an operation advisable, because it would improve the usefulness of the limb, and the knee joint might retain the same amount of motion now possessed by it.

The PRESIDENT thought the operation could not do more than give a stiff joint.

**Actinomycosis in the Right Hypogastric Region.**—Dr. F. E. LANGE presented as a case of an exceptional nature that of a man of twenty-five years who, so far as he had understood his

physician to say, had suffered six months ago from an attack, resembling perityphlitis in its symptoms, which had lasted three or four weeks. Three or four weeks before being brought before the society the patient had suffered from pain in the region of the liver, an enlargement had appeared at that point, there had been a high temperature and some chills until two weeks before the present time, when, with the appearance of a swelling in the epigastric region, the pain had become lessened. Two days before he had seen the patient at his office with his physician, Dr. Kerr, but, being still uncertain as to the nature of the disease, had decided to make an exploratory puncture at the house of the patient. At first glance the result of this procedure had seemed to be negative, but by using a syringe a few opaque minute granules had been brought away which had made him suspicious of actinomycosis. The microscope had revealed the true nature of the disease, as the operation done some days later had shown. It had involved the deeper portions of the abdominal wall in the epigastric region, and could be followed to a great depth between the diaphragm and liver. The disease occurred probably not so very rarely in this country. Within the last two years he had seen four cases. In one of these cases it had developed on the neck; in another, in the retro-mediastinal space, involving the ribs and diaphragm; in a third one, on the back. The diffuse dense hardness gave the parts in which this disease occurred a peculiar feeling to the fingers. To the eye the mounted specimen showed small, white-yellowish corpuscles, with fine radiating threads passing out from scattered centers. There had been scarcely any formation of pus, even as viewed under the microscope. The patient had lost in flesh and become run down. The question arose in his mind whether a perityphilitic affection may not have been really caused by a process of the disease. So far as he knew, actinomycosis near the liver was a very rare affection, the intestine itself being more commonly its seat. In this case it might have spread from the œsophagus.

Dr. FRANK HARTLEY instanced a case which had come under his observation in the Roosevelt Hospital Out-patient Department, in which the disease had been connected with the inferior maxilla, there being also a previous history of carious teeth. The disease in this case had involved the inferior maxilla, and the adjacent tissues of the neck.

**Large Ilio-femoral Aneurysm; Ligation of the External Iliac through the Peritoneal Cavity.**—The PRESIDENT presented a patient upon whom he had operated successfully for the cure of an ilio-femoral aneurysm of large size by tying the artery through the peritoneal cavity. The aneurysm had first appeared four months before as a small lump just below Poupart's ligament, and had increased in size at first slowly but of late very rapidly, until it had measured five inches in length and four inches in width. Toward the last, pulsation had been marked, and there had been a large harsh murmur over the central part of the tumor. He had rejected the usual method of operating because of the risk of wounding the sac or exciting its suppuration, and had sought the external iliac artery through the peritoneal cavity. The incision was made along the outer border of the rectus abdominis, and the peritoneum divided for about two inches; then, on pressing aside the intestines, the artery was readily found, exposed by a short incision in the overlying peritonænum, and tied with catgut. Two weeks later, on removal of the dressing, the wound was found entirely healed, and the aneurysm solid and somewhat diminished in size.

**On the Extirpation of Certain Non-pedunculated Pelvic Tumors.**—Dr. F. E. LANGE read a paper with this title. (To be published.)

Dr. ABBE remarked on the immense value of Trendelenburg's posture, as it prevented loss of venous blood which

would otherwise occur by withdrawing it into the upper extremities largely. He had made use of this posture in operations for removing uterine fibromata with the result of greatly decreasing the haemorrhage from the pelvic vessels.

The PRESIDENT asked, in regard to tamponing the cavity with iodoform gauze, how large and long the strips were which Dr. Lange used, and what the length and thickness of the column of gauze formed was.

Dr. LANGE answered that these varied with the surface to be covered. Ordinarily he used six or eight strips two feet long and three fingers wide. The end of each was left outside. He usually arranged it so that there were two lateral strips packed in on each side, and two more in the center. He had found that traction made on large areas of a surface packed with iodoform gauze which formed a continuous mass, when it became desirable to remove this, was painful, and that the procedure of removing it was tedious, and one requiring some force. On the other hand, small strips resulted in limiting the traction necessary to get them away from any one point. He wished opinions as to the occurrence of iodoform poisoning after intraperitoneal operations.

Dr. ABBE said he had had many cases where he had employed iodoform tamponade, and had afterward found iodine in the urine, but never with toxic development of mania.

The PRESIDENT spoke of the danger that ligatures *en masse* might slip when they included much peritonæum. In such ligatures the peritonæum was sometimes drawn in from all sides under considerable tension, and this tension, especially when aided by movements of the patient, created an evertting strain which favored the escape of the included artery. He recalled an autopsy in which such a ligature had slipped, leaving a circular gap in the peritonæum three inches in diameter, and in its center the vessel from which the fatal haemorrhage had come. In connection with Dr. Lange's remarks on removal of the uterus, he showed a uterus and ovaries removed by abdominal section by the method described by the speaker in the "New York Medical Journal" for March 9, 1889 (p. 277), in which he exposed and tied the uterine arteries in continuity. He also secured the ovarian arteries without including the peritonæum in the ligature; he divided the broad ligament after placing a clamp on its outer border, and then easily found the arteries on the surface of section, stripped back the peritonæum, and tied them.

Dr. ABBE thought there was a principle of some importance involved in the history of the wound of the intestine occurring in the operation just described by Dr. Lange in his paper. The speaker had once done an operation on a torn intestine, and applied sutures and a tampon of iodoform gauze on top of these, but after two days the wound had evidently opened, as a faecal fistula had formed. If no tampon had been applied to the sutured peritoneal surface which might have slipped in among the other intestinal coils, he was inclined to think that more lymph would have been exuded to spread over and cement the sutured wound.

Dr. LANGE replied that he had considered that question, but had not dared to act as Dr. Abbe proposed, because he had not been able to make a thorough closure of the opening in the intestine in the instance referred to. He had been able to make only one row of sutures, lest he should narrow the lumen of the gut too much. The iodoform tampon was safe even where we expected loosening of the sutures and escape of the feces, for it furnished a channel along which the extruded matters could come out. Around such a tampon a plastic exudation formed a wall which shut off the peritoneal cavity. The patient so operated on was already much weakened, and, as there was no certainty of a union taking place, it was better to be prepared for the worst.

Dr. A. G. GERSTER said he had listened to Dr. Lange's paper with a pleasure chiefly due to its clear enunciation of the principle of always making an incision of a length sufficient to permit of an easy inspection of the viscera to be handled. We saw some records published telling of such and such a tumor removed through a small incision. He thought all such operations were done at great risk, as being done without the guidance of the eye. The finger, sometimes called the surgeon's third eye, could never, in his opinion, be safely substituted for direct inspection, especially where the latter could be had by the prolonging of the incision to an extent which was relatively without importance as affecting the recovery of the patient. Some writers had dwelt upon the fact that as a matter of statistics it could be shown that the mortality had been greater in proportion as the incisions made at the beginning of operations had been longer. The point here was that the large incision was, in the great majority of cases, not to be blamed for the bad result so much as the serious nature of the operation which the larger incisions preceded. The incisions, necessarily, had only been made of a length more or less adequate to the operation needed, and he believed even more serious results would have followed had smaller incisions been made. When the parts being dealt with lay directly under the eye, not only could bleeding points be seen and ligated promptly, but a variety of other accidents and injuries of the parts could be avoided. The advantages were almost entirely on the side of the ample incisions.

**Bony Union of the Patella.**—Dr. ABBE presented the patellæ which he had removed at an autopsy from the body of a man, sixty years of age, who a number of years ago had sustained a transverse fracture of each patella, and had come under the care of Dr. Markoe at the New York Hospital some time after the accident, who, finding the union that had occurred in each not sufficient to enable the man to walk, had wired both together, putting an interval of three months between the two operations. As proved by the autopsy three years later, this patient had possessed very little kidney structure at that time, as only a shell of kidney tissue had been found at the autopsy. Consequently the tendency to suppuration had been very marked, and both wounds had suppurated some time after the operation. Nevertheless, both patellæ had firmly united by bony union. Both joints had become ankylosed. The wire had been removed from one, but was still present in the other patella.

Dr. T. M. MARKOE said that when the patient had first come under his care there had been a separation of about an inch between the fragments of each patella. In both the operations there had been great difficulty in approximating the fragments, owing to the rigid contracture of the quadriceps. This had been divided at several points in each operation, and even then the approximation had not been satisfactory until the wires were pulled home. In the first operation the wound had healed under one dressing. In the second some suppuration had occurred owing to the opening of the synovial cavity in making the division of the quadriceps. The wound had finally healed, however, with the exception of a small sinus which had still existed when he was discharged. The recovery in the use of the limb had not been satisfactory, because the patient, a heavy, fat, and flabby man, would not take any exercise, and had persisted in stamping about the ward on crutches. The indications for operation in this case had been enforced by the fact that the man had practically no use of his limbs, since, both patellæ having been broken, he had been unable to bear any weight on either limb when it was flexed in the slightest degree, and had not the other one to keep him from falling.

The PRESIDENT thought the inference ought not to be drawn from such cases that bony union would follow wiring in all

cases; autopsies in cases where this method had been followed had too often shown that the union which had been obtained was not complete.

Dr. ABBE suggested a partial explanation for the successful result in this instance in the fact that the patient had a tendency to a rapid bone formation, and had once been operated on for the removal of an exostosis of the orbit.

#### An Intraligamentous Cyst of the Broad Ligament.—

Dr. FRED. KAMMERER presented such a cyst which he had removed from a patient, twenty-five years of age, who had given the physical signs of an abdominal tumor. The cyst had lain very near the uterus, and, as the latter was placed very high in the pelvis, the operation was one of some difficulty. He had not been able to enucleate the cyst until he had tied off the arteries, severed the connections with the uterus, and had worked down for some distance along the side of the cyst, nearly to the floor of the pelvis. During the operation he had tapped the cyst and let out a clear watery fluid; sections made after it had been removed had shown that it was in the beginning of malignant degeneration. There had been slight ascites. The case had ended fatally. He had not seen the patient after the operation until the fourth day. Persistent vomiting had set in after the operation, and on the fourth day had increased in violence. There had been no rise of temperature, no tympanites, or tenderness of the abdomen. On removing the dressing, a loop of intestine was found protruding at the upper angle of the wound, where one of the catgut stitches with which he had closed the peritonæum had probably given way. He replaced the gut, but this made no change in the symptoms of obstruction. Laparotomy on the following day gave no clew to the persistence of ileus. Enemata had not even resulted in a passage of gas. The patient died on the eighth day. The autopsy showed that no peritonitis was present, and no mechanical cause for the obstruction was discovered. The case seemed clinically to correspond with Verchère's description of *septicémie intestino-peritonéale*, the main feature of which was absolute constipation. The only rise of temperature had occurred shortly before death.

**Operation for Pyosalpinx.**—Dr. KAMMERER also presented two specimens, consisting of the tubes and ovaries, which he had removed. The patients were twenty-five and twenty-eight years of age, respectively, and both had recovered. The diseased organs had been matted down on the floor of the pelvis. In both instances the sacs had burst, and their contents had poured freely into the peritoneal cavity, but, after sponging out the latter well, it had been closed. The temperature had not afterward risen above 101° F. In thirty-nine cases in which Gusserow had operated for pyosalpinx, rupture of the tubes and escape of their contents into the peritoneal cavity had occurred in nineteen, and all the patients had recovered. The speaker had never seen any other method of operation used in these cases, or any drainage of the peritoneal cavity, and there had been no bad results. Microscopical examinations and experimental cultivations made with the fluid from tubes distended with pus had in no instance shown the presence of micro-organisms. It was a remarkable thing that, after a spontaneous rupture of the tubes, septic peritonitis often occurred. He thought this might be explained on the basis of a mixed infection, the primary pyosalpinx being due to an invasion of the gonococcus. A secondary infection of the sac with one of the pyogenic cocci might perhaps precipitate a rupture, allowing pyogenic material to enter the peritoneal cavity. Bunn had first called attention to mixed infection in pyosalpinx.

**A Case of Cerebral Surgery.**—The PRESIDENT also presented a small piece of wood and a button of bone removed by trephining from a patient, of whom he gave the following his-

tory: A man of fifty had fallen backward while blacking his shoes, and had hit his head upon the pointed end of a paint-brush, receiving a small scalp wound on the right side of the back of his head. Two days later he began to feel badly, and, after two more days, passed into a dazed condition, with paresis of the left limbs and considerable fever. Six days after the injury he was brought to the Chambers Street Hospital, unable to speak or understand directions given him, but able to feel pain. He was etherized and the wound enlarged. A small foreign body was found driven through the skull; in the efforts made to seize it, it slipped farther in, and a little pus escaped beside it. A trephine was applied over the opening, and a button of rather thin, soft bone removed. The foreign body, which had penetrated the dura, was then picked out, and proved to be the end of the paint-brush, five eighths of an inch long and a quarter of an inch thick, tapering slightly to the point. An ounce of pus escaped from beneath the dura after the opening in the latter was enlarged.

Within two hours after the operation the patient became conscious and intelligent, and the temperature had slowly fallen. Three days after, he was able to sit up in bed and the paresis had diminished, but the aphasia still continued; he was able to understand what was said to him, and recognize the names of things so as to be able to point out anything mentioned which lay within his view. The aphasia was also aggraphic. By the next day he had become able to write his name with partial accuracy, and set down numerals called out to him, with slight confusion of the numerals required. Hemianopsia was also present, the right side of each eye being blind. The wound was situated on the back of the head, an inch and a half to the right of the median line and an inch and a quarter above the occipital protuberance, almost diametrically opposite the position habitually assigned to the speech center. The patient was not left-handed. On the other hand, as regarded the hemianopsia, the position of the wound coincided with the results of other observations and of experimentation. The paresis was to be explained as a pressure effect, or as due to a spreading surface inflammation. The wound was three inches behind the most posterior part of the motor area.

**A New Urethrotome.**—Dr. GERSTER presented a new instrument for the division of urethral strictures. (See vol. xlix, page 683.)

**Dorsal Dislocation of the Hip.**—The PRESIDENT presented a portion of the structures of the hip joint taken from the body of a man who had died ten days after receiving a dorsal dislocation of the right hip. The rent in the capsule was situated in its posterior portion, close to the labrum cartilagineum, beginning at the cotoyloid notch and running upward about two inches. From its upper part a prolongation ran parallel to the axis of the neck along the posterior part of the capsule, in close relations with the tendon of the obturator internus. The labrum cartilagineum was detached, but not separated, from the margin of the acetabulum for an inch and a quarter at its posterior part, beginning at the notch. A piece of bone of new formation, which was attached to the outer surface of this part of the labrum and in close relations with, but not a growth from, the margin of the acetabulum, an inch long and from a quarter to half an inch wide, had been pushed back, and its upper quarter of an inch broken off. The ligamentum teres was completely divided. On the anterior surface of the head of the femur was a groove or contusion parallel with and close to the edge of the articular cartilage, an inch long, half an inch wide, and an eighth of an inch deep, along which the cancellous structure of the bone was exposed. When the dislocation was reproduced, this groove rested on the piece of new bone above described, and had evidently been caused by

pressure against it. The ilio-femoral ligament and the anterior portion of the capsule were un torn. When the dislocation was reproduced, the tendon of the obturator internus was stretched over the upper part of the head. The injury had been caused by a fall through a hatchway.

**Fracture of the Patella.**—The PRESIDENT also exhibited a specimen of fracture of the patella taken from the other limb of the same patient, of interest as showing the difference between a fracture produced by direct violence and one caused by muscular action. The bone was broken into five or six large pieces, which were held close together by the un torn fibro-periosteal investment of the anterior surface. Knowing that there was rarely any tendency to separation in such fractures, he had left this for the ten days of the patient's survival without any other dressing than the straight posterior splint, and, as the specimen showed, no separation had taken place.

Meeting of May 8, 1889.

The President, Dr. LEWIS A. STIMSON, in the Chair.

**Fracture of the Patella.**—The PRESIDENT presented a patient who had sustained a fracture of the left patella by muscular action on February 25th, which had been treated by means of the subcutaneous silk suture. The patient's condition two months and a half after the accident was as follows: No independent mobility of the fragments, full active extension, and ability to flex the knee to a right angle. A plaster-of-Paris splint was applied on March 7th, and worn constantly for about three weeks, and thereafter only during the day-time. The patient wore a check-spring. This was not a selected case, but one of fourteen thus treated since the December previous, with an equally good result in almost all. The operation had been performed without ether. The speaker expressed his increasing confidence in this operation, as it had given such excellent results in his hands, but he thought further experience was necessary to determine the measure of risk incurred; however, the avoidance of risk seemed of more importance than the time necessary for recovery.

**Acromegalia.**—Dr. FRANK HARTLEY presented two women exhibiting the characteristic symptoms of this unusual disease, described by Freund, Erb, and Virchow, which consisted in a progressive enlargement of the bones of the face, arms, legs, hands, and feet, together with hypertrophy of the connective tissue and skin in these same regions. Genital difficulty was a usual though not constant symptom. Menstruation had ceased in one of Dr. Hartley's cases, the patient being then thirty-five. Only twelve cases had been recorded. The measurements in one of the two patients presented exceeded those given by Virchow as having been taken in one of his cases. These cases were to be fully reported on by Dr. Vough at a later period. The cause of the disease was unknown. Erb had said it was impossible to tell the exact cause. Freund considered the condition a species of atavism, a return to the negro type first, and then to that of the ape. The condition gave evidence of retrograde changes. In acromegalia the growth was not limited to the proportions normal to the higher types of mankind, but took on the forms common to inferior races. Persons having this condition resembled negroes at first, and later in life developed in a measure the physical structure of apes. At first the condition expressed itself physically only; afterward there was a tendency to melancholia, which resulted from being constantly watched and talked about; sometimes a kyphosis was one of the symptoms presented. Erb had considered this condition due to a tumor of the hypophysis cerebri, but post-mortems had failed to disclose a tumor in this locality, or any enlargement of the thymus or thyroid glands.

## Book Notices.

*A Text-book of Human Physiology.* By AUSTIN FLINT, M. D., LL. D., Professor of Physiology and Physiological Anatomy in the Bellevue Hospital Medical College, New York; Visiting Physician to Bellevue Hospital; Fellow of the New York State Medical Association; Correspondent of the Academy of Natural Sciences of Philadelphia; Member of the American Philosophical Society, etc. With Three Hundred and Sixteen Figures in the Text and Two Plates. Fourth Edition, entirely rewritten. New York: D. Appleton & Co., 1888. Pp. xvii-872.

It is natural that the author of a text-book that has proved acceptable for a considerable period of years should content himself, in preparing a new edition, with a simple revision; and certainly the faults in the old edition of Dr. Flint's work were not so many or so glaring as to call imperatively for more than occasional changes and additions. It is therefore all the more to his credit that he has chosen to rewrite it entirely. The result, of course, is more satisfactory, and it is not to be supposed that his readers will fail to appreciate the service he has done them by going through with the task.

In general plan and scope, the present edition does not differ from its predecessors, and it is not notably different in the arrangement of matter, but it presents the facts of human physiology as they are accepted at the present day, stated in such clear language and in such a natural sequence that it is easy for the student to make himself master of the subject. The author's many years of experience as a teacher of physiology in one of our largest medical schools have taught him to know just what the medical student and the medical practitioner want in a text-book of that science; they have enabled him to solve most judiciously the difficult question of drawing the line between the facts and doctrines necessary to be presented and unnecessary details of methods and means of investigation that would add inconveniently to the bulk of such a book and prove little more than confusing to the reader. As it stands, this text-book, we think, has no superior in its proper field. It is trustworthy in its statements, sufficiently comprehensive, free from irrelevant and cumbersome matter, and easily understood.

The publishers are to be commended for bringing it out in so handsome a form. The excellence of their work shows both in the typography and in the press-work. The pictorial illustrations are numerous, well adapted to their purpose, and exceedingly well made.

## BOOKS AND PAMPHLETS RECEIVED.

*Lectures on Pathological Anatomy.* By Samuel Wilks, M. D., F. R. S., Consulting Physician to, and formerly Lecturer on Medicine and Pathology at, Guy's Hospital, and the late Walter Moxon, M. D., F. R. C. P., Physician to, and some time Lecturer on Pathology at, Guy's Hospital. Third Edition, thoroughly revised by Samuel Wilks, M. D., LL. D., F. R. S. London: Longmans, Green, & Co., 1889. Pp. xx-672. [Price, \$6.]

*The Physician Himself and Things that concern his Reputation and Success.* By D. W. Cathell, M. D., Baltimore, Md. Ninth Edition, revised and enlarged. Philadelphia and London: F. A. Davis, 1889. Pp. 298. [Price, \$2.]

*Zwölf Vorlesungen über den Bau der nervösen Centralorgane.* Für Aerzte und Studirende. Von Dr. Ludwig Edinger, Arzt in Frankfurt am Main. Zweite umgearbeitete Auflage. Mit 133 Abbildungen. Leipzig: F. C. W. Vogel, 1889. Pp. viii-164. [Preis, 6 Mark.]

*First Annual Report of the Methodist Episcopal Hospital, located in the City of Brooklyn, N. Y., covering a Period of Ten and One Half Months, and ending October 31, 1888.*

The Washington Life Insurance Company. Historical, Actuarial, and Medical Statistics. New York: Published by the Company, 1889.

## Reports on the Progress of Medicine.

### SURGERY.

By MATTHIAS L. FOSTER, M. D.

**Focal Epilepsy cured by Trephining and Excision of the Motor Centers.**—Lloyd and Deaver ("Am. Jour. of the Med. Sci." Nov., 1888) report the case of a man thirty-five years of age who had suffered from epileptic seizures for fourteen years. Six years before the first fit he was struck on the head with a ball bat, from which blow he became unconscious and was confined to bed one week. The seizures became more and more frequent until he was admitted to the hospital. The fits commenced in the left arm, the fingers were flexed over the thumb, the hand flexed at the wrist, and the forearm flexed on the arm. The head was drawn over to the right side and the right arm and leg became rigid. The head soon began to rotate to the left, the fingers of the left hand relaxed, the mouth opened and was drawn to the left side with the right angle depressed. Clonic spasms occurred in the left arm and in the left side of the face. The pupils were widely dilated and fixed. Consciousness was preserved, at least partially, throughout the fit, which was of short duration. Paresis of the left arm and of the left side of the face followed the fit. At length the fits occurred very frequently, twenty-eight being recorded in a single day. The paresis became very noticeable. The face was relaxed, the angle of the mouth depressed, and the right side drawn over perceptibly. The orbicularis palpebrarum was not involved. The tongue was not paralyzed. The pupils were equal and responded to light and accommodation. The flexor muscles, particularly of the arm, were weakened, but did not present any reactions of degeneration. There was no change in tactile sensibility. Nothing indicative of organic cerebral changes could be found in the fundus oculi. From these symptoms it was inferred that there was an irritative lesion in the region of the junction of the middle and lower thirds of the ascending frontal convolutions on the right side, possibly involving the contiguous portions of the ascending parietal convolutions. The nature of the lesion was not clear. There was no history of syphilis, and treatment with the iodides resulted in no benefit.

A button of bone an inch and a half in diameter was removed, exposing an area on both sides of the fissure of Rolando in the region of the lower and middle thirds of the ascending convolutions. This opening was enlarged with a rongeur forceps, but nothing abnormal could be found in the bone, membranes, or cortex by gross inspection. By means of exploration with the faradaic current a point was discovered back of the fissure of Rolando where faradization produced exactly the same action of the flexors of the left arm which took place at the onset of the fits, and at a point farther in front and below, faradaic stimulation caused marked contraction of the facial muscles of the affected side. At no time during the application of the faradism did contractions of the leg muscles occur. There was no evidence of a subcortical tumor.

Three pieces of brain tissue three fourths of an inch in depth were removed—one, half an inch square, from the point back of the fissure of Rolando, and two smaller pieces anterior to it. After the operation the left arm and the left side of the face were paretic, with occasional twitches of the muscles. These ceased after six days. On the third day there was some stiffness of the fingers, which may perhaps be explained by irritation of white fasciculi during the process of healing. The temperature of the left axilla was at this time one to one and a half degree higher than that of the right. From the sixth to the eighteenth day the patient was not in a normal mental state. He became dull, then lacrymose and incoherent, and a part of the time had maniacal delirium. At times there seemed to be headache. There was much œdema of the scalp, the pupils were dilated, the left side of his face was the more flushed, and when at the worst there was some ptism. Then he began to improve, and by the end of the fifth week was practically well and had recovered some muscular power. Three

months afterward the sensory condition was excellent and the motor was much improved.

Dr. Deaver prefers the lines given by Reid and Horsley to locate the fissures of the brain to Broca's, Lucas-Championnière's, Harss's or Wilson's method, because he considers them simpler and more comprehensible and quite as correct. He thus describes the lines: "First draw a line which runs from the lower border of the orbit through the center of the bony meatus of the ear. To find the fissure of Sylvius, draw a line from a point one quarter of an inch behind the external angular process of the frontal bone to a point three quarters of an inch below the most prominent part of the parietal eminence. Measuring from before backward, the first three fourths of this line will represent the main fissure, and the rest of the line the horizontal limb. The ascending limb starts at the point indicating the termination of the main fissure—*i. e.*, two inches behind the external angular process—and runs from this vertically upward for about an inch. The fissure of Rolando is found by drawing two lines from and perpendicular to the base line to the top of the head, one passing through the depression in front of the ear and the other through the posterior border of the mastoid process. The fissure of Rolando is now represented by a line drawn from the point of intersection of the posterior vertical line with the line connecting the nasal eminence with the external occipital protuberance, indicating the great longitudinal fissure, to the point of intersection of the anterior vertical line with the line representing the fissure of Sylvius, upon either side of which are the ascending frontal and parietal convolutions."

**Cerebral Abscess.**—Dr. Thomson ("Med. Chron.", December, 1888) reports a case of cerebral abscess cured by trephining. The patient was a boy eleven years of age who had received a blow from a cricket bat a year before, and had since then often complained of frontal pain, especially on stooping. On one occasion the headache lasted a week, and was accompanied by vomiting after every meal. When brought to the consulting-room headache and sleeplessness had persisted for two days, but the pupils, pulse, and temperature gave no indication. Three days later the pulse was 62 and the temperature 99° F. The next day the pulse was 56, the temperature 99·8°, and the patient was unable to articulate. He showed irritability on being touched. The pupils were normal. The skull was trephined over the site of the injury, and a director was passed an inch into the brain substance, but no pus was found. Sixty hours after the operation he returned to consciousness and the cerebral symptoms abated. There was a slight bulging at the wound, which increased so that two days later the wound was reopened and a considerable amount of flaky pus was evacuated. The wound had to be reopened twice subsequently, at intervals of one and two weeks. Eventually the patient made a complete recovery.

**Antesternal Dislocation of the Clavicle.**—Ducket reports a case of this rare form of dislocation ("Lancet," Oct. 6, 1888). The patient was swimming on his left side and attempted to turn upon his back when he "felt something give way in his neck." When seen there was a marked projection of the sternal extremity of the left clavicle forward, inward, and somewhat downward upon the anterior surface of the sternum, over which the skin was tightly stretched. The dislocation was very easily reduced and the parts were easily retained in position.

**Hernia into the Foramen of Winslow.**—Treves ("Lancet," Oct. 13, 1888) makes a very valuable contribution to our knowledge of this form of internal hernia by an excellent description of the clinical history, operation, and post-mortem discoveries in a case which came under his care. The clinical history indicated a complete intestinal obstruction involving the colon not far from its commencement, and some peritonitis in the epigastric region. An exploratory laparotomy was performed, hernia through the foramen of Winslow was diagnosed, and two or three feet of small intestine was reduced, but another coil could not be reduced, as it was impossible to enlarge the opening through which the bowel had passed. On autopsy, it was found that the cæcum, the ascending colon, and part of the transverse colon had passed through the foramen of Winslow and had become strangulated. The cæcum lay at the extreme left of the abdominal cavity, had forced its way through the anterior layer of the gastro-hepatic omentum, so that the vermiform appendix was lying on the anterior aspect of the lesser

curvature of the stomach close to the œsophagus. The strangulated colon was gangrenous in two places and had ruptured. Outside or beyond the foramen of Winslow the colon bent very sharply to the left and was again sharply bent at the splenie flexure. A few inches of the ileum were found in the hernial cavity, and lay at the seat of stricture behind the colon. Reduction of the strangulated colon could not be accomplished until the hepatic artery, portal vein, and bile duct had been divided. The foramen of Winslow admitted four fingers. It was evident that the cæcum was undescended and had led the way through the foramen. All the other viscera were normal. Only four other cases of this condition appear to be on record.

**Amputation of the entire Upper Extremity.**—May ("Ann. of Surgery," December, 1888) reports two cases of amputation in the continuity of the trunk according to the mode of Paul Berger. Each case was for malignant tumor of the upper end of the humerus, in which exarticulation would have been evidently insufficient to eradicate the disease. He divides the operation into three stages. In the first he resects the portion of the clavicle between the attachments of the rhomboid and coraco-clavicular ligaments through an incision extending from one inch outside the sterno-clavicular joint along the clavicle to its external end. In the second stage the large vessels are secured. To do this, he cuts across the subclavius, defines the upper border of the pectoralis minor, and ligatures the cephalic vein and any branches of the acromio-thoracic artery which may interfere. The external anterior thoracic nerve appears prominently and serves as a guide to the subclavian artery. If it is followed upward it leads between the artery and the vein. The artery is tied with two silk ligatures a little more than half an inch apart and divided, and the vein is then treated in a similar manner, but with more care and delicacy, after holding the arm vertically for a couple of minutes to empty it of blood. The supra-scapular vessels which cross the upper part of the wound are similarly divided. In the third stage the flaps are formed and the limb removed. An incision is made from the middle of the first incision down the front of the shoulder, across the inner side of the arm in a backward direction to the tip of the scapula. The pectorales are divided, then the brachial plexus; the arm, which hitherto has been kept down to the side, is drawn away and the latissimus dorsi and teres major are cut. The patient is then rolled on to the sound side, the limb drawn across the chest, and an incision carried from the outer end of the first straight down the back of the shoulder to the angle of the scapula, where it joins the preceding. The integument is dissected up as far as the vertebral border of the scapula, and the limb is severed from the body by dividing close to the bone the muscles attached to it. The flaps so formed he found to fit admirably.

The necessity for so extensive an amputation seldom occurs. Berger collected fifty cases of the operation done by all methods. It is indicated in tumors of the scapula necessitating removal of the greater portion of that bone; in tumors of the upper end of the humerus—if benign, of such size as to render exarticulation impracticable—if malignant, englobing the articulation, invading the scapula or its muscles, the skin over the deltoid, or, above all, the lymphatic glands in the axilla; and in traumatic cases with extensive shredding and laceration of the integument and tearing away of the limb. The causes of death range as haemorrhage, entrance of air into the veins, shock of operation or injury, purulent infection, secondary haemorrhage, exhaustion, and sloughing. Pure operative shock is not a marked feature—much less so than at the hip.

**Club-foot.**—At the meeting of the British Medical Association ("Brit. Med. Jour.," Oct. 27, 1888) a very interesting discussion took place on this subject. Mr. Parker considers the cause to be the environment *in utero*. When the cause begins to act early the deformity will be a very fundamental one, but when it begins to act at a later period the deformity will be less severe. Paralytic talipes is a secondary and accidental condition, differing entirely from the congenital condition. The only constant anatomical condition is the ligamentous hindrance to rectification, which is more or less pronounced. The chief ligamentous combination consists of the astragalo-scaphoid ligament blended with more or less of the anterior portion of the internal lateral ligament of the ankle joint and the capsular ligament between the scaphoid and internal cuneiform.

Operations, when necessary, should be performed at the earliest possible moment, and all of the requisite cutting should be done at once. The chief guide in the treatment is the amount of rigidity present, which is greater in proportion as the ligaments are implicated. With the exception of the tendo Achillis, it is seldom if ever necessary to divide tendons unless together with the ligaments associated with them at their insertions. The deformity should be rectified at once as much as possible.

Dr. Ogston recommends rectifying the deformity as much as possible by means of manual pressure, and then applying a plaster bandage made of the best quality of plaster rubbed into fine bandages, next to the skin, without intervening flannel or muslin. This is removed at the end of six weeks and the process repeated. If the bandage be not pulled tight during its application, but be laid loosely around, no constriction results, but merely accurate adaptation. The adducted or varus position should be entirely corrected before the equinus is meddled with, and then the tendo Achillis should be divided. Three to eight sittings are necessary to cure the adducted position and one to three for the plantar flexion.

In very bad cases he seems to prefer Lund's operation of excision of the astragalus. Linear osteotomy of the tarsus he does not consider a good method. Cuneiform excision gives a result pretty to the eye, but after it is done the anterior part of the foot is of no assistance in walking. He has also obtained good results in some cases by osteotomy of the tibia and fibula just above the ankle joint.

Dr. Whitson maintains that the only method which holds out any hope of permanent benefit in talipes varus after the second or third year is the extraction of a portion of the tarsus. The soft structures might be stretched if they alone were at fault, but the resistance of the osseous deformity is much too formidable to be overcome by mechanical means. After operation, mechanical treatment must be diligently pursued for from twelve to eighteen months. For this purpose he recommends incasing the foot in paraffin boots which should be renewed every month.

Dr. Buchanan divides cases of talipes varus into three classes: First, those of minor degree in which the deformity depends on shortening and rigidity of the tendons, fasciae, and ligaments, which can be remedied by manipulation and fixation; second, cases in which the abnormal position of the bones is maintained by such a degree of tension and rigidity of the soft parts as to render tenotomy necessary of the tendo Achillis, or of the plantar fascia and the muscular substance attached to it. To divide the latter he introduces a tenotomy knife at the inner edge of the foot opposite the tuberosity of the scaphoid, passes it superficial to the plantar fascia till the point reaches the middle of the sole of the foot, turns the edge of the knife vertically, elevates the handle to depress the point, and cuts through the plantar fascia and the muscles beneath it till the point is over the articulation between the head of the astragalus and the scaphoid. Here he cuts the tendon of the tibialis posticus and the deep ligamentous fibers, thus freeing the astragalo-scaphoid joint, which is the one upon which the incurvation of the foot hinges. In his experience no bad results have attended this somewhat heroic incision. Third, cases in which the bones have been so altered by pressure from walking on the distorted foot as to require excision of a portion of the tarsus for their correction. The form of operation should be chosen to suit the individual case.

Mr. Symonds employs the chain saw passed around the tarsus at its greatest convexity for the purpose of tarsotomy, and says that it is a method superior to any other because it is more simple and more easily executed, because practically no deformity is left, and because it is almost a subcutaneous operation.

**Dislocation of the Metatarsus.**—Atkinson ("Lancet," Dec. 1, 1888) reports a case of this rare dislocation which resulted from a fall. A prominence was found corresponding with the line of the tarso-metatarsal joint. Posterior to the prominence there was a hollow where the articular surfaces of the four outer metatarsal bones could be felt. The base of the first metatarsal was raised a quarter of an inch above the level of the internal cuneiform. The front of the foot was everted, forming a distinct angle with the tarsus. The extensor tendons on the dorsum were prominent. The length of the foot from the heel to the tip of the hallux was half an inch less than that of the other foot; from

the external malleolus to the tip of the fifth toe it was a quarter of an inch less. The dislocation was easily reduced under chloroform.

**Unilateral Adductor Paralysis of the Larynx due to Reflex Nasal Irritation.**—Stewart ("Lancet," Oct. 13, 1888) reports two cases which tend to confirm the view that laryngeal paresis may be due to nasal irritation. In both of the cases given the paresis was unilateral on the right side, and the adductors were at fault; in both, the right middle turbinate bone was much enlarged and was pressing on the septum; and in both the laryngeal symptoms disappeared on removal of the nasal trouble.

**Congenital Cyst of the Urachus.**—Lawson Tait ("Lancet," Oct. 6, 1888) reports a case in which a cyst of the urachus projected into the pelvis of a woman, aged twenty-eight, completely filling it. It was filled with fetid, thick, flaky pus, and was attached to the abdominal wall by a short sessile pedicle more than two inches in diameter. It was easily removed.

**Cholecystotomy.**—Torrance ("Brit. Med. Jour.," Dec., 1888) reports a case in which he removed forty-three small calculi from the gall-bladder. They were round and closely packed together. The patient made a good recovery from the operation.

**Danger of operating upon Persons with Splenic Enlargement.**—A reminder of conditions not surgical under which it is dangerous for him to operate is occasionally useful to the surgeon. So an article by Mr. Williams ("Lancet," Nov. 24, 1888) on a fatal case of litholapaxy is very instructive. This patient was suffering from splenic leucæmia, a condition which militated greatly against the success of any operation. But that persons with simply enlargement of the spleen are liable to serious risks if operated on is shown by two cases furnished by Mr. Cadge. It is also the opinion of Sir Joseph Fayrer that it is best to avoid, if possible, any operation not absolutely necessary to save life in cases of splenic enlargement, even though there may be no leucæmia or apparent anaemia present.

**An Antiseptic Solution.**—Rotter ("Ctrlbl. f. Chir.," No. 40, 1888) advocates the following solution as effectively antiseptic while not likely to produce such toxic symptoms as occasionally follow the use of the generally employed solutions of carbolic acid and bichloride of mercury. He considers these points to be of major importance to an antiseptic solution, and claims that these are met by the one which he proposes. 1. The antiseptics must be cheap and easily kept. 2. The solution should remain perfectly clear without color or odor. 3. The materials should be always readily soluble in common spring water; and 4, should be dry and easily carried about. The formula he gives, for a solution in one litre of water, is:

R Hydrargyri bichloridi .....	0·05 grm.;
Sodii chloridi .....	0·25 "
Acidi carbonici .....	2·00 "
Zinci chlorid, } .....	5·00 "
Zinci sulphocarbonatis, } .....	5·00 "
Acidi borici .....	3·00 "
Acidi salicylici .....	0·60 "
Thymolis .....	0·10 "
Acidi citrici .....	0·10 " M.

He arrived at the formula theoretically and professes to have proved its value practically.

## Miscellany.

The Philadelphia "Times and Register" thus states its position with regard to the matters concerning which we quoted from the "Druggists' Circular and Chemical Gazette" in our last issue:

"The 'Druggists' Circular' continues the attack upon us which was opened by its manager at Newport. We desire to say at once that every statement and insinuation therein made concerning the 'Times and Register' is utterly and unqualifiedly untrue. Neither manufacturers nor patent-medicine houses own or control our company. It is not a trust and has no designs upon its contemporaries. The absorption policy

suggested only exists in Lillard's imagination. This, and the impudent attempt to represent the 'Times and Register' as favoring substitution, are simply intended to create a little prejudice against our enterprise in the minds of publishers and advertisers."

"By one of those mistakes which, we are assured, occasionally happen in even the best regulated families, an annotation slipped into one of our late issues which was worded in such a manner as to give rise to misapprehension. It scarcely seems necessary to say that neither the 'Times and Register' nor any member of its editorial staff favors or desires in any manner to condone the wrong of substitution. Our record in that matter is certainly clear, and there is scarcely a medical journal in the country which has not quoted approvingly our editorial condemnation of this practice, and defense of the physician's right to prescribe whatever he considers best, and the pharmacist's duty to give exactly what is ordered, no matter what his individual opinion thereupon may happen to be. We have even gone to the trouble and expense of having special examinations made of the various pepsins and fluid extracts in the market, and demonstrated the necessity under which the prescriber rests of designating the manufacturer upon whose fluid extract he is basing his dosage; as, in the case of belladonna, we found a diversity ranging from 0·18 to 0·58 between the samples tested. The writer of the annotation headed 'A New View of Substitution' had no thought of defending the manufacturers of febrilines, whoever they may be (we do not know the parties, and have no advertising or other interest in them), in what was an undoubted wrong—the selling of one thing under the name of another. Even if commercial quinine does contain, as is claimed, a portion of quinidine, this is also a wrong, and does not constitute a valid reason for their action. The writer of the paragraph labored under the hallucination that his item was ironical, and that he was making a very passable poke at himself and his brother physicians when he suggested that they were themselves doing the very thing they so strongly objected to in the case of the druggists. Like Mark Twain's celebrated joke about the Indian statue, however, this one seems to have been so far fetched that nobody saw it."

**An Exanthem following the Subcutaneous Use of Antipyrine.**—Mazzotti ("Giorn. ital. del. mal. ven.," etc., 1888, xxiii, 210) employed subcutaneous injections of antipyrine over the sciatic nerve, seven grains and a half once a day, for the relief of sciatica, and on the third day of the medication an exanthem appeared in the region of the injections. It consisted of raised round or oval papules of the size of a lentil or a bean, of deep brick-red color, and grouped, sometimes forming irregularly shaped figures. The eruption reached its height in twenty-four hours, and then began to fade slowly. On the fifth day of the eruption an unexpected change took place in the exanthem. Some of the papules were much paler and more flattened; others had assumed a bright-red color, and upon them had arisen small, pinhead-sized vesicles containing nearly clear serum, which were confluent. There were also groups of vesicles along the outer side of the leg and on the dorsal and plantar surfaces of the foot. A zoster had developed, extending beyond the site of the original eruption. It was noticeable that upon the original site of the eruption the zoster showed itself exclusively upon the original papules. The zoster ran its regular course.

**The late Dr. Isaac O. Lea.**—At the last meeting of the Medical Society of the County of Richmond the following preamble and resolutions were adopted:

Whereas, The announcement through the public journals of recent date has informally brought the sudden and untimely death of our late esteemed associate, Dr. Isaac O. Lea, to the attention of this society; therefore,

*Resolved*, That the Medical Society of the County of Richmond recognized in the late Dr. Lea one of its oldest, ablest, and most experienced members; a physician who, for the past thirty-four years, had held a position in the medical profession of this county second to that of none of his conpeers; a genial, warm-hearted, and clear-headed man, who, when questions of vital interest to the profession were under discussion before this society, never failed to take a prominent part in its deliberations and a conservative position in regard to its action thereupon; a gentleman always in all his relations to his associates,

and a physician whose place among us it will be difficult to fill. Peace to his memory.

*Resolved*, That this society tender its profound sympathy in their bereavement to the several members of our deceased associate's family, and that the secretary be ordered to forward a copy of these resolutions, properly engrossed, to the son of the deceased, as the family representative, and provide that the same be published in the county papers and in the New York "Medical Record" and the "New York Medical Journal."

Committee: { F. E. MARTENDALE, *Chairman*,  
F. U. JOHNSTON,  
J. WALTER WOOD,  
MAY R. OWEN, *Secretary*.

**The City Board of Health.**—The office of Sanitary Superintendent having been resigned by Dr. Walter De F. Day, the secretary of the board has sent him the following letter, dated July 30th:

"The Board of Health directs me to inform you that it has this day, with great reluctance, accepted your resignation of the office of Sanitary Superintendent, which you have long filled to the entire satisfaction of the public and of this department, and with great honor to yourself. The board desires me to officially express to you its high appreciation of your valuable services as the chief executive officer of this department, of your ability and integrity, and of your uniform kindness and courtesy in all your official relations. The board regrets that your health obliges you to dissolve your connection with this department, and thereby deprive it of the services of an officer who has its entire confidence."

We are informed that the appointment of Dr. W. A. Ewing as Dr. Day's successor was favored by the president of the board as being for the best interests of the department and the public service. Dr. Ewing served the board in various capacities from 1870 to 1886, and is considered thoroughly familiar with all the work of the office to which he has now been appointed.

**The Walden California Brandy.**—The "Merchant and Viticulturist," of San Francisco, publishes a translation of an article in the "Destillateur-Zeitung," in which Mr. Edward Walden, of the firm of Walden & Co., of California, is represented as having said to its representative:

"The manufacture of cognac out of California wines is not at all new. A number of growers have tried it for years, generally, however, without success. The conditions for manufacturing brandy in California are identical to those of Europe; only few districts producing wines suitable for it. It was a sore mistake of many a grower to believe that any good sound wine, distilled anywhere, would produce a cognac like the French, the only kind in demand; like those who have tried the same thing in Hungary, Spain, Portugal, and other countries, they have met with sad disappointment. It is only after a number of experiments and close observation that I have been able to determine which are the most suitable wines and where to find them. My distilleries are now north of San Francisco in the Napa and Sonoma valleys. To manufacture cognac I use but very young wines from grapes of my own vineyards or those of my neighbors, pressed on my own premises. Early in September the fresh-cut grapes are brought to the pressing-house and the work begins at once. Immediately after the first fermentation we begin to distill, and the work continues until the middle of February. Buying older wines at the vineyards for distillation I have abandoned entirely. I can only guarantee the quality of my product and its subsequent aging when the pressing has been controlled by me. For the manufacture of cognac in California I consider this of the utmost importance. We have great difficulty in keeping light wines of good quality. The temperature is evenly warm. We lack the cold of winter, the freshness of spring, and the coolness of fall. A winter like that in Germany we do not know. Wines pressed in the fall often become spoiled the following summer, and this for the simple reason that, with but few exceptions, the wine growers have not sufficient room in their cellars or proper places to keep the wine. It is of frequent occurrence that wines more or less gone are used, to save them from entire destruction, for the manufacture of so-called cognac, a poor and miserable product, not worth a third of the cognac manufactured from sound, fresh wines. Cognacs made of spoiled wines have a very

peculiar ethereal taste, which becomes stronger as it gets older, and which after a while does not even remind you of anything like cognac. In my distillery cognacs are brought from the still at 14° above proof (equal to 75° Tralle), and as they come from the still they are delivered to the trade. For this reason no sugar is added to my cognacs, as is the case with most of the French cognacs, and this is not without value to the German consumer. The import duty on cognacs to which sugar has been added is, I understand, 180 marks per 100 kilogrammes, while the duty on my production is only 125 marks."

#### ANSWERS TO CORRESPONDENTS.

**No. 278.**—We do not call to mind any recent articles on the subject. One form of the affection, the *entérite glaireuse* of the French, is well treated of in Nonat's "Traité pratique des maladies de l'utérus," etc.

**No. 279.**—A weak lotion of corrosive sublimate has been recommended.

**No. 280.**—1. It is an excellent work. 2. Letheby, "On Food, its Varieties, Chemical Composition," etc. New York, 1872.

**No. 281.**—Try Labarraqe's solution.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

## Original Communications.

### OPERATIONS UPON STRUMA.\*

By FRANK HARTLEY, M. D.

My interest in this subject is due not only to the privilege which I have enjoyed of seeing a goodly number of cases operated upon by others, but especially to six cases in which I have operated for enlargement of the thyreoid gland myself. These cases comprise one for struma fibrosa—total thyroideectomy; two cases of partial thyroideectomy—one for simple adenoma (struma hypertrophica simplex), the other for substernal vascular adenoma; one case of enucleation for struma cystica, one case of Kocher's resection for struma hypertrophica simplex involving only a portion of one lobe, and one case of partial thyroideectomy involving one lobe, in which the sarcoma had extended beyond the capsule on its external surface. This operation was done not with the intention of a radical cure, as it was too advanced to expect any such result, but only for relief from the impending asphyxia. The patient is now free from her difficulty in respiration, although there is a return of the tumor beneath the sterno-mastoid muscle. The length of time elapsing from the operation is now nearly two months. I take the liberty of reporting to the society my experience in these cases for the purpose of obtaining an expression of opinion on the part of those who have met with this class of cases.

Although we must admit that the good results of to-day (0·8 per cent.) for simple goitre are largely due to the care which we bestow upon the treatment of the wound, we must not overlook the fact that the technique of this operation as practiced by Kocher, Miculicz, Liebrecht, and others is important, and is dependent upon two principles—the one, the management of the haemorrhage; the other, the avoidance of the recurrent laryngeal nerve.

Of the arteries and veins, by far the more important are the veins. The thyreoidea ima artery, existing only once in ten cases, is the only artery for which we are to be especially careful, since the other arteries are less liable to anomalies, and can be easily found. The veins are, however, more numerous, larger, and more important than the arteries, and an exact knowledge of them is necessary for a bloodless operation. Of these veins, the venae subcutaneæ colli have always been prominent and quite important, on account of their relation to the external incision. The external jugular vein has only been seen in one case, in which there was an exceedingly large development of the lateral lobe. The oblique jugular vein has been present in three of the cases, but in only one did it require ligature. In all cases the anterior jugular veins were present and required ligature. Of those veins lying upon and within the external capsule of the gland, the communicating branch between the superior thyreoid veins, when present, has seemed of more importance than the vein itself, probably from the fact that one is more liable to overlook it than the main trunk.

Its ligature is important, for it receives often a communicating branch from the anterior jugular veins above their point of usual ligature.

The superior accessory thyreoid vein was present in three in five cases, and in two was as large as the superior thyreoid vein itself. Of the veins about the lower border of the gland, the venæ thyreoideæ imæ have been marked, and in each case the right has been larger than the left. The inferior accessory thyreoid vein has been present in two cases, and in the remaining three cases the inferior thyreoid vein was present without an accessory. As to the position of the recurrent laryngeal nerve to the inferior thyreoid artery, the nerve has been found in all these cases where it was exposed (5) in front of the artery, and crossing it while its course was transverse; but when the artery divides into its branches its relation is altered so that its position is on a plane posterior to the artery and parallel to it. I have examined in all about twenty cadavers for this purpose, and have found the same relation to exist, except in three cases, where the nerve passed between branches of the artery. This seems to be the case only when the artery divides early in its course into its several branches.

Wölfler first drew attention to this matter, and Kocher has shown that the relation of the artery to the nerve is important, and is a constant one in that the artery from the thyreoid axis passes transversely, slightly ascending, lying at first upon its outer side, and then behind it. When the artery meets the trachea it ascends upon its inner side, and, dividing into its branches, supplies the posterior surface of the lateral lobes. For this reason, the only safe points at which we may ligate the artery are either at its origin close to the carotid artery, or its branches must be tied close to the capsule of the gland.

Of the various incisions used, I have, in partial or complete extirpations, preferred that of Kocher's to the median or that along the anterior border of the sterno-mastoid muscle. It gives the most perfect and complete survey of the whole field of the operation, and an excellent chance to ligate the veins and arteries without difficulty. So perfect is the field offered by this incision that the operation can be done with quite as much ease as in a dissection upon the cadaver. The veins and muscles are recognized in their respective relations to one another, and are undisturbed by the line of incision or the slight traction given to the margins of the wound by the retractors. Moreover, the exposure of the trachea where the gland is attached and of the inner surface of the inferior horns of the lateral lobes where the thyreoideæ imæ veins are present, and which in struma substernalis must be rendered free for ligation, seems to be perfect. The upper oblique portion of the incision, besides dividing the skin and the platysma muscle, crosses the anterior, oblique, and external jugular veins transversely, or at least obliquely, so that they may be secured by double ligatures before proceeding further with the operation.

The median and oblique incisions seem to me to be best fitted to those cases in which we are to remove strumous nodules either by enucleation (Socin) or *évidement* (Koch-

\* Read before the New York Surgical Society, May 22, 1889.

er), but not for partial or complete thyroidectomies or resections (Kocher).

As to the treatment of that portion attached to the trachea, the isthmus, I have made use of Miculicz's method in two cases, which consists in fastening the struma in the neighborhood of the isthmus and trachea and by squeezing out the glandular portion to leave a pedicle consisting only of the connective tissue representing the tunica propria of the gland. This pedicle, which is made at a point where the gland is not attached to the trachea, may be treated as in ovarian tumors. It seems to me that this method is preferable to the usual one of dissecting the gland from the trachea on account of the safety one feels in respect to the nerve without any increased concern as to the conduct of the pedicle in the wound. It is true, however, that in Kocher's resection one is perfectly safe so far as the nerve is concerned, but I can not see that, as Kocher states, the danger is so much greater in this method that we are to prefer his resection in most cases of enlargements of the thyroid on this account alone.

Tracheotomy has been carefully avoided in these cases in which thyroidectomy was performed, and would only have been performed in case of immediate danger of suffocation, such as is generally the result of stenosis of the trachea from the pressure of substernal strumæ or severe tracheitis or a double recurrent paralysis. In all other cases it appears to me best to avoid it as long as possible, allowing, as Kocher suggests, an assistant to press upon the trachea from before backward, maintaining an oval or rounded lumen and giving a free ingress of air until the operation is finished, when, unless the rings are softened to the last degree, if the head is fixed, the danger will not recur.

The perfect success of this method was shown to me in one case in which the danger of immediate suffocation seemed impending until the pressure of the finger upon the deformed trachea restored it to its proper shape. It was maintained in this shape by the use of sutures passing through the tracheal walls, as suggested by Kocher.

This method consists in passing one suture through the lateral wall of the trachea without injuring the mucous membrane, over the anterior surface of the trachea, and through the lateral wall of the opposite side. The ends of the suture are then drawn tightly and tied over the anterior surface. In this way the lateral walls are drawn away from one another, the sharp anterior angle is pushed backward, and the rounded form of the trachea is more or less completely established.

It has been suggested to sew the lateral walls to the soft parts upon each side and thus attempt to maintain the size of the lumen by giving support to the lateral walls. With this method I have had no experience. It does not, however, suggest itself to me as so perfect a method as the first one. The sutures in the first method maintain the position of the walls to one another as given them by the pressure of the finger during the operation, and exert their pressure directly upon the trachea itself and not through traction upon movable tissues in the neck. This method is, of course, applicable to the majority of such cases, since the deformity in the trachea is more frequently due to approximation of

the lateral walls than of the antero-posterior walls, or of one wall alone to the other. Should there be a more or less complete absorption of the tracheal rings, so that the trachea becomes practically a membranous tube whose walls will collapse from atmospheric pressure as soon as the support given them by the struma is removed, nothing is left but tracheotomy with the attendant danger of septic bronchopneumonia, cervical and mediastinal cellulitis.

The selection of the mode of operation in these cases has been guided by the fact that as much of the thyroid gland as is not involved in the struma should be left, not only for the avoidance of cachexia strumipriva, but for the prevention of the deformity in the neck as the result of the loss of the gland. Moreover, the variety of the struma, its size, vascularity, the extent of the involvement of the gland, and the character of the pathological condition existing in the gland will decide for us the particular method best suited for its removal.

Dependent upon the observations that a cachexia will not occur if a portion of the gland remains, Miculicz has recommended his so-called "resection" of the thyroid gland in order that not only a portion of the gland may be left, but also that any injury to the nerves or vessels may be avoided. Instead of this mode of operation, but for the same reasons, Wölfler recommended the ligature of the thyroid arteries in order to induce an atrophy of the gland. Such a method might be of advantage in the vascular or aneurysmal variety, but certainly not in the colloid or cystic.

Rydgier has lately reported sixteen cases in which ligature of the arteries has been performed—in fifteen all four arteries, and in one only the two arteries upon one side. These cases have been observed one year and a half after without return of the struma or the development of cachexia strumipriva. He seems to limit the operation to the recent parenchymatous struma. The methods of ligature used have been those of Velpeau, v. Langenbeck, Drobek, and Rydgier. It is alleged for Rydgier's method that the cosmetic result is much better, as the cicatrix is concealed beneath the collar. I have no experience in this method of operation.

The intracapsular or intraglandular enucleation of the struma, as recommended by Julliard and Socin, however, seems to be the most certain and radical of the methods for partial extirpations, with the slightest possible danger from hemorrhage or injury to important nerves.

In cystic strumæ the intracapsular enucleation first recommended by Julliard seems to be the safest and least dangerous of all methods. It requires the shortest time for healing and is easily accomplished. The bleeding is slight, as the vessels of the capsule are already obliterated in large part.

In parenchymatous strumæ the intraglandular enucleation recommended by Socin and Garré is applicable to those cases in which small or moderately large and circumscribed nodules are present and in which the vascular supply is not marked. Kocher's *évidement* or evacuation differs from the enucleation in that, instead of dividing the glandular capsule down to the struma and shelling it out, one incises immedi-

ately through the strumous nodule and removes it with the fingers or sharp spoon. This method Kocher recommends for those cases where the separation of the strumous nodule from its surrounding tissue is too difficult to accomplish and the haemorrhage from the gland is excessive, or where, during an operation, dangerous symptoms of suffocation are present. This condition of affairs is seen especially in those cases consisting of large, soft, and circumscribed nodules with abundant vascular supply.

These two methods are less liable to be followed by tetany or cachexia strumipriva than other methods of partial thyroideectomy. In fifty cases Socin saw no case of tetany or cachexia.

Should the parenchymatous goitre involve the whole of one half of the gland, or be composed of a large number of cysts or nodules not covered by the parenchyma of the gland, a partial thyroideectomy is to be preferred to an intracapsular method, as the bleeding is much less and the time required for the operation shorter.

In just such a case P. Bruns lost his first case in seventy consecutive operations. If we are obliged to select an operation for the removal of one lobe, or if both lobes be so involved and pressure upon the trachea and oesophagus such as to give symptoms of impending suffocation, struma bilobaris or circularis, struma maligna, or the thyreoiditis diffusa, we can do no less than the partial or total thyroideectomy. Such conditions put the life of the individual in immediate danger, and we are forced to use a radical method to overcome the immediate danger, although in so doing we expose the patient to risk of a cachexia strumipriva amounting to thirty-three per cent. in total operations and one per cent. in partial ones. In order to avoid just this possibility, one selects either Miculicz's or Kocher's resection. In the first method we leave behind a certain amount of the gland and avoid to a large extent doing injury to the recurrent nerve; but the vascular supply of this portion left has been more or less interfered with in the operation, and it renders the result somewhat uncertain if we rely upon the portion remaining for any functional action.

The second, Kocher's resection, which has been recommended to supersede Miculicz's simply on account of the possible danger of injury to the nerves in the application of the ligature to the stump, has also the great advantage of leaving behind a portion of the gland normally supplied with blood. This method, which we may consider as applicable to the greater number of cases of struma, except the malignant, diffusely inflamed, and the diffuse hypertrophic goitres, for which extirpation alone is applicable, consists in two principal steps: 1. If we wish to preserve as much of the healthy gland as possible for functional activity, we omit the ligature of the thyreoid arteries; if not, this is done as in the operation of extirpation. 2. Enucleation of the diseased portion according to Kocher's method. This operation may be said to be an enucleation with a circular division of the gland, and with or without ligature of the arteries.

The extirpation of the gland, either partial or complete, is to be reserved for those cases not applicable to some of the above methods, because of the extent of the involve-

ment of the lateral lobe, or for the malignant strumæ, the diffusely inflamed strumæ (thyreoiditis diffusa), or the hypertrophic and diffuse variety with impending symptoms. It appears to me that we must be very careful in our selection of the extirpations, for we are often not certain of the condition of the opposite lobe in the partial operation, nor can we as yet place much reliance upon the accessory thyreoid glands to carry on the loss of function from complete extirpation. Although these glands, together with a processus pyramidalis, have been shown by Streckhusen, Zuckerkandl, and Gruber to be by no means uncommon and to be situated above and below the hyoid bone (twenty-eight per cent. and twenty-one per cent.), below the isthmus and upon the arch of the aorta (Carle), upon the lateral borders of the lobes (Madelung), as well as posterior to the thyreoid gland between the trachea and oesophagus, or oesophagus and vertebral column, and to exist in about one half of the cases, still the development of cachexia strumipriva amounts today to thirty-three per cent. for total extirpation, and for partial extirpation to one per cent. I do not think we can disregard this sequela to this method of operation, and I think that we should, considering the frequency of it, limit the operation as much as possible. So far as we know at the present day, the theories of Kocher, Baumgärtner, Gussenbauer, Reverdin, and Bircher are not substantiated by the results of operations upon man. When we compare these with the experiments upon animals made by Dr. Halsted, now of Baltimore, with the clinical observations as collected by the Clinical Society of London, and the exact physiological investigations of Horsley and Fuhr, we are led to the belief that the symptoms following the loss of the thyreoid gland, either from operation or as the result of disease, should be ascribed, not to any injury to the nerves nor to any general disease existing before the operation, but to the loss of a function which is indispensable to the proper activity of the nervous system (Bruns). Considering these facts to be true, we would assume: 1. For aneurysmal or vascular struma, possibly recent hypertrophic strumæ, ligature of the thyreoid arteries (Wölffer). 2. For cystic strumæ, enucleation (Julliard); when involving the whole of one lobe or both lobes, extirpation, partial or complete. 3. For parenchymatous strumæ, when circumscribed and not vascular, enucleation (Socin); when diffuse, ligature of the thyreoid arteries (Rydygier); when confined to one lobe, or if both lobes are involved and composed of a large number of small cysts and nodules with no parenchyma uninvolved, a partial or complete thyroideectomy is alone admissible, especially if there are present dangerous symptoms of impending suffocation. 4. In by far the greater number of cases of struma a Miculicz's or Kocher's resection is indicated, and the selection is to be made according to the value of the portion remaining in the prevention of the cachexia strumipriva. 5. Extirpations: complete are to be reserved for the cases of struma maligna, thyreoiditis diffusa, struma bilobaris, with impending symptoms of suffocation; partial, to those cases in which the involvement of one lobe is complete, so that no parenchyma is left which can be saved.

In the cases operated upon I have not seen any compli-

cations in wound treatment except in one case,\* nor has there been any case of tetany or cachexia strumipriva. In one case of large substernal struma a left recurrent paralysis has followed, which, however, was not present at the time of the operation, nor in the hospital before his discharge. How to explain this otherwise than as from cicatricial contraction I am at a loss.

## PERIPHERAL PARALYSSES DUE TO CARBONIC-OXIDE POISONING.†

By GEORGE W. JACOBY, M. D.

THE occurrence of poisoning by the inhalation of carbonic-oxide gas is a well-known fact; it is also acknowledged that the cases of poisoning ensuing upon the inhalation of the products of combustion which are developed from glowing charcoal, mineral coal, and turf, or from the incomplete combustion of wood, when burned in a closed room, are dependent upon the deleterious action of this gas. Naturally, the composition of the gas will vary greatly, according to the quality and quantity of the coal burned, as also according to the duration and degree of combustion.

The products of such combustion are, on the average, composed of about five per cent. of carbonic oxide and six per cent. of carbonic acid, in addition to seventy-nine per cent. of nitrogen and ten per cent. of oxygen. Purified illuminating gas, which contains from eight to ten per cent. of carbonic oxide, probably also owes its poisonous qualities to this gas. It is for this reason that I feel myself justified in referring to the two cases which form the incentive to this communication together, although in the one instance the poisoning was due to coal gas and in the other to illuminating gas.

The action of carbonic oxide upon the animal organism is recognized by all writers upon the subject as being a double one—that upon the blood and that upon the central nervous system. A few inhalations of the pure gas produce convulsions, frequently also sudden paralysis, anaesthesia, and long-continued unconsciousness, the gas in this instance acting as a direct poison upon the brain and medulla oblongata. The walls of the vessels also lose their tonus, become dilated, and rupture easily.

Autopsies have revealed large foci of softening in the brain, haemorrhages into the meninges, and capillary apoplexies in the brain substance, but there are as yet no pathological or experimental data showing an action of the gas upon the peripheral nerves. Clinically, where we are not dealing with the pure gas, our knowledge of the action of this poison upon the peripheral nervous system is, as will be shown, also very meager, although *a priori* there does not seem to me to exist any valid reason why the peripheral nerves should in this case be exempt from the same influence which we know is exercised upon them by a variety

of other poisons, infectious as well as chemical. The symptoms, as described in the various reported cases, consist of a burning sensation and reddening of the face; dizziness; tinnitus; headache, particularly in the temporal regions; a feeling of throbbing in the temples; oppression; nausea; vomiting; unconsciousness; tonic and clonic convulsions; involuntary passage of urine, faeces, and semen; complete paralysis; coma and death. In some cases eccentric pains in the extremities, as well as sensory disorders of the skin, have been noted. The objective symptoms referable to the nervous system observed in patients who have recovered are local or generalized anaesthesia of the skin and paralyses of the voluntary muscles. Cases have also been reported in which paralysis of the sphincters of the rectum and bladder has remained for a long time. Psychic symptoms have also been noted, and even cases of dementia paralytica described as occurring after such poisoning. The number of cases reported in which paralyses of voluntary muscles have occurred after poisoning by carbonic oxide is not large, and all of them, with the exception of one or perhaps two, are evidently of central origin. This has been particularly surprising to me, not only because I had seen two cases which were undoubtedly peripheral, but also because Schachmann, in an introduction to the report of a case observed by him, accepts all previously reported cases as peripheral. A reference to the original reports and articles, however, shows that this assumption is entirely unwarranted, and that, if the cases prove anything, they prove just the reverse. Thus, as early as 1775, Portal \* described four cases of paralysis after carbonic-oxide poisoning; they are very insufficiently given, but the descriptions leave no doubt as to the central origin of these paralyses.

The cases briefly are as follows:

CASE I.—Two women were asphyxiated by carbonic oxide; one died; the other "remained for several days without being able to support herself upon her legs, and she experienced a considerable numbness in the lower extremities."

CASE II.—Male; asphyxia by carbonic oxide; recovery. "And it was believed for several days that he could not support himself upon his legs; but, little by little, the extensor muscles regained their action."

CASE III.—Girl, aged twenty-one; asphyxia by carbonic oxide. She was unable to move any one of the extremities: the arms recovered first, and soon thereafter the legs.

CASE IV.—Male, aged twenty-two; asphyxia by carbonic oxide. "The lower extremities could not support him, and the upper ones were very weak. . . . The first day that he went out his legs trembled and could not carry him, but they acquired power in a few days."

Another case was published by Bourdon in 1843. From Leroy D'Étiolles,† who refers to it, as well as to Portal's cases, I have taken the following quotations, as Bourdon's thesis was inaccessible to me. The case was that of a young girl asphyxiated by carbonic oxide. "She noticed that she could hardly keep upon her legs. . . . This weakness lasted about twelve days."

\* "Observations sur les effets des vapeurs mephitiques sur le corps de l'homme," 1775. Sixth edition, 1787.

† "Des paralysies des membres inférieures ou paraplégies," Paris, 1856.

\* Bichloride eczema; did not interfere with the recovery in the usual time.

† Read before the New York Neurological Society, June 4, 1889.

The next writer upon the subject was Leudet.\* His article is probably the best and only extensive one concerning these affections since Portal's. Although the author mentions the occurrence of peripheral paralyses, the chief value of the article undoubtedly lies in the description of the vaso-motor disturbances, as the two cases of paralysis which are there described do not seem to me to be clearly of peripheral origin.

In the first case there was "a feeling of numbness in the three last fingers of the right hand, and they are extended with difficulty." There was also an "eschar over the lower part of the sacrum of the size of the palm of the hand."

The second case commenced with a paralysis of the extensors of the right leg, occurring in a male alcoholic, nineteen days after the poisoning by carbonic oxide. The entire right leg then became paralyzed; thereupon the left leg and thigh, both arms, and finally the face. Death ensued on the sixth day after the onset of the paralysis. The autopsy showed merely inflammation of the right sciatic nerve, the brain and spinal cord being found normal. This case is apparently a case of acute ascending paralysis (Landry), and was probably due to some undiscovered central cause, no mention being made of a microscopical examination of either cord or brain.

Since then but isolated cases of paralysis due to carbonic oxide have been published, and all, with the exception of the two following, are undoubtedly of central origin. The first of these, described by Rendu,† occurred immediately after poisoning by carbonic oxide and showed the hemiplegic form of paralysis. The muscles of the face and the extensors of the forearm and foot of the right side were affected. The skin of the paralyzed parts was anaesthetic; the thighs and upper arms were not implicated. Four weeks after the occurrence of the paralysis, faradaic excitability was entirely absent. Rendu believes the case to have been of peripheral origin, but the data given are not sufficient to establish this positively.

The second case is undoubtedly peripheral and is recorded by Schachmann.‡ Three persons attempted suicide by asphyxiation with carbonic oxide. Two of them died and the other survived. This one was a female aged twenty.

The attempt at suicide was made on May 8th. On the 10th the patient appeared to have entirely recovered from the effects of the gas, but, upon examination, a complete extensor paralysis of the left forearm was found. Sensation was normal. An electrical examination of the muscles was not made.

*May 11th, 12th, and 13th.*—The condition remained unchanged.

*14th.*—Slight movements of extension could be made with the fingers.

*15th and 16th.*—Continued improvement.

*17th.*—Almost complete restoration of function.

*20th.*—Complete cure.

† "Union médicale," 1882, pp. 386, 397.

‡ "France médicale," July 1, 1886.

How little was known about paralyses following carbonic-oxide poisoning, and that the occurrence of a purely peripheral paralysis with reaction of degeneration, etc., from such a cause was even doubted up to the time of this publication of Schachmann's, is shown by the demonstration of a patient and the subsequent discussion which took place at the *Berliner medizinische Gesellschaft* in January, 1885. Herc Remak\* showed a case of partial radial paralysis in consequence of hypodermatic injections of ether. The patient, a female, aged twenty-three, was received into the hospital at Friedrichshain (December 5, 1884) on account of carbonic-oxide poisoning, and was given several injections of ether into both forearms because she was deeply comatose. When she regained consciousness she noted a paralysis of the left hand, which consisted principally in an inability to extend the basal phalanges of the fingers and an inability to abduct the thumb. Examination (eight days before the demonstration) showed a partial paralysis in the territory of the radial nerve. The supinatores longus and brevis and the extensors of the wrist joint were not affected. Electrical examination showed the severe form of reaction of degeneration in the territory supplied by the deep branch of the radial nerve. Sensory disorders were not present. Although Remak was cognizant of the fact that numerous cerebral, spinal, and peripheral disorders might occur after carbonic-oxide poisoning, he nevertheless believed that in this case the paralysis was not due to the action of the carbonic oxide, but that it could only be accounted for by the ether injections.

In the discussion which followed, Bardeleben asked for further proof in support of this supposition, saying that he considered that already given as insufficient, whereupon Remak replied that paralyses occurring after carbonic-oxide poisoning had been but little studied; all that we knew was that they occurred, but that "particularly the increase of galvanic excitability observed here—*i. e.*, the typical course of a severe traumatic paralysis—had not been observed in carbonic-oxide paralysis."

This deficiency, which must be looked upon as the *punctum saliens* of the entire discussion, is not supplied even by Schachmann. The following personal cases cover the ground completely, as particular attention was paid to this point:

**CASE I.**—S. W. H., male, aged thirty-eight, came under observation December 8, 1887. Previous history unimportant. Habits good, and had always been comparatively well, although not very robust. On December 1st he left home in the evening in his usual health, called upon a friend, and entered into conversation with him. The room which they occupied was heated from below by means of a furnace; doors and windows were closed. After a short conversation his face became flushed and hot, then he felt dizzy, and his head began to ache. In addition to this he noticed strong pulsations of the arteries of the head and neck, blackness before the eyes, nausea, and a feeling of deathly sickness. Then complete unconsciousness supervened. The last recollection which he had of that time was seeing his friend sitting in a chair holding his head in his hands and hearing him say "Oh, my God! my God!" During the unconscious period he vomited. He was unconscious for about six hours, but

\* "Berliner klinische Wochenschrift," 1885, p. 76.

had been removed to another room several hours before his return to consciousness. Beyond a feeling of general malaise, he experienced nothing until he attempted to walk, when he noticed that his right leg was weak and that his foot turned in, also that he had no feeling in his right foot. The following day severe pains were felt in the right leg, and these have not abated.

*December 8, 1887.*—Examination showed patient to be normal in every way except as regarded his right foot. Here it was found that the foot and toes hung lax in extension, and that they could not be flexed dorsad; the condition, therefore, representing a paralysis of the muscles supplied by the peroneal nerve. The muscles affected were the tibialis anticus, the extensor longus digitorum communis, the extensor hallucis, the peronei longus et brevis, and the interossei.

Examination of sensation showed complete anesthesia of the front of the foot, extending upward to the middle of the leg; partial anesthesia of the outer side of the leg, extending around the leg to beyond the median line upon its posterior surface. The outer margin of the little toe on the dorsal surface, the inner border of the foot, and the entire plantar surface, including the heel, were not affected. The electrical reactions of all the muscles were normal, and there was no atrophy. Patient complained of severe pain in the leg and foot.

*12th.*—Lowered response of muscles to faradaic current.

*22d.*—Motor paralysis present to about the same extent as at the first examination. The anesthesia has disappeared, except in patches, located in the above-described territories, varying in size from that of a pea to a twenty-five-cent piece. Marked atrophy of the interossei. Pronounced reaction of degeneration is present in all the muscles supplied by the external popliteal nerve.

The course was that of a typical severe degenerative paralysis. The patient improved slowly, so that in April, 1888, when he discontinued treatment, he had complete control over all the muscles, although they still presented some weakness and reduced excitability to both currents. The anaesthetic spots also had not entirely disappeared.

**CASE H.**—A girl, E. D., aged eighteen, of French nationality, on account of domestic affliction determined to commit suicide. She locked the door of her room—a small hall room—turned on the gas, and went to bed. Some time afterward people in the house, noticing the smell of gas, traced its origin, broke into the room, and found the patient moaning and dazed; but not unconscious, upon the bed. She was removed to the fresh air, where she in a short time regained the full use of her senses; she then noticed that she could not use her right hand, while all her other extremities, with the exception of a feeling of weakness, were normal. I saw her two days after this occurrence.

*January 6, 1889.*—Examination showed the patient to be normal in every way except as regards her right hand. Here we found a paralysis of the extensor digitorum communis. Extension of the basal phalanges of the fingers was not possible, whereas extension of the end phalanges (interossei) was normal. There was also paralysis of the extensores pollicis longus and brevis and of the abductor pollicis, and paresis of the extensors of the wrist. The supinator longus and the triceps were normal. Slight sensory disturbance in the radial territory of the hand was present. The patient was seen regularly at intervals of three or four days, and the development of reaction of degeneration in the affected muscles, together with some atrophy of the muscles of the forearm and thumb, was plainly observed. Improvement began to take place in the beginning of February, and by the 1st of March the patient was considered sufficiently recovered to discontinue treatment.

It does not seem to me that in either of these cases there can be any reasonable doubt as to the connection existing between the paralysis and the carbonic-oxide poisoning. The paralysis occurring immediately after such poisoning must place the idea of a connection between the two uppermost in our mind. The possibility of a pressure paralysis must certainly be thought of, but it seems to me that this is an entirely gratuitous supposition, as the first patient was found sitting in an arm-chair, and was thence removed to a bed, so that pressure upon the external popliteal nerve could hardly have taken place; in the second case there is, in addition to the improbability of pressure having taken place, the fact that the paralysis did not implicate the supinator longus or the triceps. This partial localization of the paralysis makes it highly improbable that pressure should have been the cause. As regards the peripheral nature of the paralysis, I think there can be no doubt in either case. The localization of the paralysis, the strict confinement to a single nerve territory, the sensory disturbance, and the occurrence of reaction of degeneration and atrophy, together with the further typical course—all make it safe to assume that we are dealing with a neuritis.

The lesson which directly results from these cases is that peripheral paralysis affecting the radial or peroneal nerves may be due to the action of carbonic oxide; that we are once more taught that it is not safe to draw positive lines of demarkation between the possible central or peripheral action of certain toxic agencies. It has furthermore seemed to me (but this is only an impression in support of which I have no facts) that both radial and peroneal paralyses occur most frequently in winter among the poor occupying small and unventilated rooms, generally heated by a stove in the room itself; that, as my second case shows, complete unconsciousness is not necessary for the production of such paralysis dependent upon carbonic-oxide intoxication; therefore it is possible that these paralyses are, more frequently than we can at present admit, due to this cause. Further observations in this respect might prove of interest.

### A CASE OF COMPOUND FRACTURE OF THE PATELLA TREATED BY WIRING.

BONY UNION.\*

By S. T. ARMSTRONG, M. D.,  
PASSED ASSISTANT SURGEON, UNITED STATES MARINE-HOSPITAL SERVICE.

ALTHOUGH it is now almost a decade since Sir Joseph Lister said, "The risk a patient incurs in having his knee joint opened antisepically is not greater or so great as that attending the removal of an ordinary fatty tumor without antisepic treatment," † still it is the more frequent custom for surgeons to treat fractures of the patella by the old fixative procedures. This is done, notwithstanding the fact that the late Dr. F. H. Hamilton, in his work on "Fractures" (ed. 1884, p. 542), says: "Probably none of the

\* Read, in part, before the Section in Surgery of the New York Academy of Medicine, May 13, 1889.

† "Lancet," 1879, vol. ii, p. 768.

tabulated transverse fractures (106) were united by bone; . . . only a small proportion of the vertical and comminuted fractures were thus united," thus demonstrating the failure of splints to secure bony union.

It is hardly credible that it is an accepted fact that ligamentous union of a fractured patella is as useful as bony union. Mr. W. Adams said: "From an examination of specimens [of fractured patellæ] in London museums, un-united fractures or feeble ligamentous union was the rule, a firm ligamentous union almost the exception."

Whatever may be the difference of opinion regarding the utility of wiring simple fractures of the patella--a procedure that will certainly find no supporters in the authors of our surgical text-books--there can be no question of the justifiability of operative interference in compound fractures of the bone in which the integrity of the knee joint has already been assailed.

In a paper by Mr. A. Poland,\* published in the pre-antiseptic days, he has collected sixty-nine cases of compound fracture of the patella. Of patients with incised wounds, six recovered, two died; bony union took place in one case and ankylosis in one case; four patients had mobile joints. Of those with lacerated wounds, nine died, in one case the result was not stated, and thirty recovered; of the latter, ten had mobile joints, five had partial ankylosis, eleven had complete ankylosis, four had the leg amputated. Of those with gunshot wounds, three died and eighteen recovered; of the latter, two had mobile joints, three had partial ankylosis, eight had complete ankylosis, and in five cases the result was not defined.

The above-given statistics are far from encouraging, but medical literature of recent date contains a creditable number of recoveries following wiring of compound fractured patella, and the following case is reported as a contribution to the subject:

J. B., aged thirty years, a native of the United States, was admitted to the United States Marine Hospital, New York, on the night of March 23, 1889. He stated that he was injured on the 21st instant by a barrel of paint rolling against the left knee, the chine of the barrel striking over the patella, lacerating the skin and fracturing the bone. The wound was made as aseptic as possible by the interne, Dr. George B. Young, and the fracture was temporarily dressed.

On the 24th I examined the knee, finding a transverse fracture of the patella, the fragments moderately separated, and the joint distended by fluid. The necessity of an operation was presented to the patient, and, as he consented to its performance, he was prepared therefor.

On the morning of the 25th he was chloroformed, the incised wound of the skin of the knee was scraped with a sharp spoon, and the wound enlarged by transverse incisions to the bone. A quantity of bloody fluid escaped, and between the bone fragments was a quantity of blood-clot and some shreds of ligamentous tissue. These were removed, and the cavity of the joint was thoroughly cleansed with warm Thiersch's solution. Much trouble was experienced from venous haemorrhage, and time was expended in ligating bleeding points.

A longitudinal incision was made in the skin over the upper fragment, in order to expose the bone, as nailing was intended. But in driving the nail into the upper fragment it was found

that there was a longitudinal fracture through this fragment, so holes were drilled through each portion of the upper fragment, corresponding openings made in the lower fragment, and the bone united by wiring instead of a nail. The wires were inserted so as to be extra-articular. A drainage-tube was placed over the patella and the skin united by a continuous catgut suture. Iodoform gauze was wrapped about the knee and the leg and thigh incased in plaster of Paris. Acetanilide and quinine were given every two hours. On the evening of the 26th his temperature was 38° C., but at no other time did it exceed 37.2° C.

On April 12th the dressing was removed. The wound had healed by first intention, except at entrance and exit of the drainage-tube and at the point of emergence of the silver wire. The patella could be moved over the condyles, showing that there was no ankylosis. The drainage-tube was removed. Leg placed on an inclined long posterior splint.

On April 18th the wire was removed from the patella.

On April 22d and 24th there were fungous granulations at the point from which the wire was removed. A sharp spoon was used to curette them. The patient was allowed to use crutches on the 24th. On May 9th a bone-hook was introduced into the sinus, about which the granulations had formed. The bony surface of the patella was detected, especially at the site of fracture, demonstrating a bony union. The patient was allowed to walk without the aid of crutches.

On May 13th the sinus over the patella had healed, and the patient was discharged on the 22d with a mobile joint, not quite able to flex the leg as in the normal state, but every day the range of motility was increasing and he was able to resume his occupation on shipboard.

The patient used his leg freely after being discharged, but while at work on June 10th he chafed his knee, and during the night the joint was painful. He was treated for this by the ship's surgeon on June 11th, and readmitted to the hospital on June 12th. When he was admitted, the joint was painful and swollen, and in the cicatrix over the patella was a mass of granulation tissue that was necrosed superficially; a temporary dressing was applied the evening of his admission.

The patient was seen by me on the morning of the 13th, and the joint was evacuated with an exploring trocar. As the fluid was slightly cloudy, and a microscopic examination showed pus corpuscles present, the joint was washed out, through the cannula, with a warm Thiersch's solution. The granulation mass was scraped with a sharp spoon, and when the patella was reached a piece of wire was found that had caused all the trouble. It proved to be a suture that was overlooked in removing the wires originally. The wound was dressed aseptically after removing the wire, and the patient given quinine and acetanilide. No fever occurred during the convalescence, and the motion in the joint was excellent.

There are several cases on record that have recovered with wires left in the bone, in which the wire had to be removed at a later date. One of the most interesting is recapitulated:

Mr. G. R. Turner reported ("Lancet," vol. i, 1887, p. 572) a seaman, aged twenty-five, that had fractured the right patella. For twelve days he received no treatment; then the joint was strapped and a plaster-of-Paris splint was applied. He was discharged in a month. Four months later he came under the care of Mr. Robson, of Leeds, who found separation of an inch and a half, and the limb weak and useless. In order to wire the fragments, Mr. Robson had to divide the lateral expansion of the vasti and quadriceps femoris. He discharged the patient in

\* "Medico-chirurgical Transactions," London, 1870, p. 49.

something more than two months. While at sea the patient fell and hurt the knee. On landing he went to Mr. Turner for treatment. A wire protruded from a sinus at the outer side of the joint; a little suppuration around it. As there were signs of septic infection of the joint, it was opened, turbid lymph escaping, and a drainage-tube introduced. Three wires were removed. The patient recovered with a useful joint.

After being discharged the patient fell in an epileptic fit and refractured the same patella at a point below the first fracture. He recovered from this.

In treating fractured patellæ with wires two points seem to be essential: (1) To introduce the wires so that they will not enter the cavity of the joint, and (2) to remove the wires as soon as osseous union has occurred.

As the removal of the wire will always necessitate some disturbance of the granulations, it is suggested that a small bone drill, or gimlet, be employed to keep the fragments in apposition, and this may be left *in situ*, and can be easily removed.

If sufficient confidence could be reposed in the slow absorption of chromatized catgut, as well as in its adequacy to keep the fragments in apposition, it would be the best material to employ, as the wound could be closed and healing take place by first intention.

### SOME DISCURSIVE REMARKS

BASED UPON HAVING OBSERVED INTIMATE RELATIONS BETWEEN  
CHRONIC DISEASES OF THE UPPER AIR-TRACT  
AND NEURASTHENIA.\*

By WILLIAM H. DALY, M. D.,  
PITTSBURGH, PA.

DURING the past five years I have made some observations and noted them with reference to certain symptoms or diseased conditions referable to the intranasal structures or of the pharynx or larynx which have either been the immediate precursors or the concomitants of neurasthenia. In other words, many of the patients that have consulted me for a variety of symptoms referable to the upper air-passages have at the same time given a history of concomitant or early succeeding neurasthenia, and I think I may offer these observations to the profession as being not only new to its literature, but based upon a clinical experience sufficiently extensive to warrant us in taking up a new line of thought as to some of the features expressed in naso-pharyngeal catarrh and functional and inflammatory aphonia as they precede or coexist with neurasthenia in some one of the latter's many forms. It was the teaching of Murchison and others, and quite generally accepted too by the profession, that many of the conditions we know now as neurasthenia were conditions of suppressed or undeveloped gout or lithæmia; but if the thoughtful medical man will carefully read Murchison, eminent and able reasoner and clinician though he was, he will nevertheless be forced to conclude that the data for pronouncing certain forms of nervousness, in men especially,

which are characterized by insomnia, indigestion, mental irritability, etc., conditions of suppressed gout or lithæmia are wholly insufficient to satisfy those of us who like to believe we have found a rational cause, or that we have been taught one that is to our minds reasonable and borne out by future observations of our own upon patients. Unless this can be done, few of the thinking men in the profession can long hold to any dogma, let it emanate from whatever source it may.

I am fonder of noting plain practical observations in pathology and therapeutics than of indulging in abstruse theories as to what causes these certain conditions noted. Why? Because it is much easier for me to do this, and it suits best my practical bent of mind. Yet how much commoner it is among medical men, as among laymen, that at once a cause is sought for an evil and little or no attention paid to the interpretation, meaning, or cure of certain manifestations! As I have said, I confess to being more wrapt in noting the coexistence of symptoms, and, if possible, getting a remedy for their alleviation and cure, than of diving into their mysterious workings and explaining their manifestations by mere theories. The abler heads may weave theories to their hearts' content. But one page of practical experience, with careful and intelligent observation honestly reported, will redound more to our instruction than whole tomes of dry and baseless theory or dogma. What I have to say will, I trust, at least seem worthy of inspiring further observation in this direction. In these days of hard going and pushing for place, fame, and fortune, especially in cities, it is appalling indeed to see the early wreck of the physical and mental constitutions of the cultivated and respectable men and women who are neurasthenic either through their own folly or circumstances that are innocent enough of themselves if guarded by common sense and moderation. Now, it will seem strange to you possibly to hear from me that I believe laryngology and its congener, rhinology, have much with which to concern themselves in neurasthenia, as well as in the many reflexes that have been so well studied by the able minds of J. N. Mackenzie, Hack, of Freiburg, Roe, of Rochester, and others. But you will not be altogether surprised either. One of the old masters in medicine spoke of the nose and throat as the gateways of life, and I believe he was quite right. They are more than that; they are also the sentinels at the gateways of life in more ways than one. It is from these regions we are so often warned of the approach of discomfort, danger, and disease.

I need not refer to the fact that all the disease germs enter the system through these gateways. It is in one of these gateways that the half-pleasing sense of titillation causing sneezing warns us that we are catching cold; and, by the way, let me digress and ask, What is "catching cold"? My observation has taught me that the causes of so-called "catching cold" are as often intrinsic as extrinsic. That is to say, a patient without any exposure whatever to draughts of air, either suspected or real, may, by a certain state of the organs and their secretions, be seized with a tickling in the pituitary membrane and sneezing, followed by all the symptoms of "catching cold," and subsequently have pneumonia or other form of pulmonary inflammation

\* Read before the American Laryngological Association at its eleventh annual congress.

with all its worst and most protracted consequences. Now, resuming my subject, permit me to refer to a summary of twenty-five cases of which I have the clinical records bearing specially upon the question I have brought herein to your notice in the title of this imperfect paper. These cases have a clinical history like the following ones selected, with certain features altered, masked, or absent, but the main ones to which I call your attention prominent and leading —viz., the presence of acute or chronic disease of the upper air-tract in some of its extent, and neurasthenia in one of its protean forms.

**CASE I.**—J. G., male, aged thirty, of bilious temperament, good parentage and habits of life, no acquired blood disorder, occupation active and mentally exciting. Subjective symptoms, a sense of intranasal fullness under the bridge of the nose and alternating stenosis in one or the other naris, especially at night when trying to sleep. Has a sense of worry and anxiety constantly present, and his mind is very active when repose is sought at night, precluding sleep, which, when obtained, is light and fitful. Appetite good, and digestion thought to be good. Uses no tobacco or stimulants. Social relations marital and excellent. No vices or excesses. Local objective symptoms, a bony spur upon the left side of the septum narium and a flaccid state of the mucous membrane on both inferior turbinates. Still under treatment, with some improvement going on, although the patient says he fails to discover the latter. This, however, will be discovered to him surely when the local intranasal condition is cured, and a cure in this case is one of the most encouraging and certain of possibilities, with further time and care.

**CASE II.**—Miss W. J., aged twenty-eight, nervo-phlegmatic temperament. A well-rounded, symmetrical, and apparently well-nourished figure. Complexion sallow. Nose flattened and tip deflected to the right. Secretion of mucus from nares posteriorly copious and sometimes offensive; tongue clean. Appetite and digestion always poor; bowels constipated. Cata menia normal. Has lived for over a year on pancreatized milk chiefly. A sense of intranasal fullness even when she is certain the canals are cleansed and freely pervious to air. Always weary and tired, and especially at the latter part of the day she is utterly exhausted. Sleeps badly, and always wakes with a bad taste in her mouth and a dry tongue.

Objective intranasal examination reveals a contorted condition of all the internal parts throughout that looks as though the nose had been hit with a hammer or caught in the door at some former time and badly twisted in its extrication. All the ordinary anatomical relations are of a cork-screw pattern and quite beyond a brief description. This patient is improving, but nothing short of the highest and most skilled rhinoplastic surgical art will ever make this nose a thing of beauty. The neurasthenic state is improving under alterative, local, and general treatment.

In ten cases, with which I will not burden you in detail, there was obstinate inflammatory aphonia attended with utter prostration, nervousness, and insomnia; seven of these patients had nasal disorder of a chronic character; the remaining cases all had as leading factors naso-pharyngolaryngeal diseases in some form, with neurasthenia in some form also. Although one swallow does not make a summer, a flock of them will cause us to look for a change of weather; and will this little flock of cases not cause us to look out for this too widely prevailing constitutional condi-

tion as one of the unfortunate possibilities or concomitants of disease of the upper air-tract? That they coexist there can be no question.

#### DISPUTED POINTS IN THE PATHOLOGY AND TREATMENT OF PERITYPHLITIS.\*

BY RICHARD J. HALL, M. D.,  
SURGEON TO BELLEVUE AND ST. LUKE'S HOSPITALS.

THE amount of light thrown on the unsettled questions in regard to the pathology and treatment of perityphlitis by the numerous papers and discussions on the subject during the last year might seem to render a revival of the subject at present unnecessary. Undoubtedly the weight of surgical opinion was in favor of the intraperitoneal situation of the abscess, and a tendency to recommend operation a little earlier than has been customary.

Yet surgeons were not wanting to maintain the old views and methods, and when we find the name of the late Professor Sands at the head of this list, and consider the confidence which the profession has justly placed for many years in the accuracy of his observations and judgment, it seems to me important to publish every case whose symptoms, treatment, and course furnish evidence for the one side or the other.

In June, 1886, I published a case of suppurative peritonitis due to perforation of the vermiform appendix—laparotomy; resection of the appendix; recovery. A distended hernial sac on the right side naturally led to the supposition of a strangulated hernia before operation, and in reference to the operation various writers have seemed inclined to regard it as a case of strangulation of the appendix. It may be well to state, therefore, that the perforation was due to tubercular ulceration, and that there was no constriction at any point.

Since that time I have had occasion to open the abdomen for existing or threatened perforative peritonitis three times. My second case, which ended fatally, has already been reported to the Clinical Society, so I will merely state here that I was called out of town to see a married lady, about thirty-five, who had suffered for several months from pain in the right iliac fossa. Three days before I saw her, the pain being much worse, her husband proposed a drive to distract her attention. While driving, the pain became intense, and, on returning, her physician recognized general peritonitis. She was treated with opium and the cold-water eel. When I saw her, I at once made a diagnosis of perforation of the appendix, with suppurative peritonitis.

I at once performed median laparotomy, found a gangrenous and perforated appendix, a small suppurating cyst of each ovary, and the lower portion of the abdomen filled with faeces and pus.

The appendix was resected and the stump sutured; both ovarian tumors were removed; hot-water irrigation and toilet of peritoneum were performed, with drainage through the incision. The delay necessary for the double ovariotomy and the miserable condition of the patient doubtless made the death from septicæmia, twelve hours later, inevitable.

\* Read before the New York Surgical Society, April 10, 1889.

My third case was as follows:

CASE III. *Perityphlitic Abscess*.—J. M., married, aged fifty, Ireland, farmer, admitted to Ward 8, October 14, 1886.

Previous history: Patient says that, five days previous to his admission to Bellevue Hospital, he ate a hearty meal of fried sausage, and a few hours afterward he was taken with vomiting, purging, and cramps in his bowels. The symptoms abated somewhat, but the pain continued, and during the last three days the pain has been referred to the right iliac fossa. Patient has had diarrhoea until thirty-six hours before admission, when it ceased. Nothing characteristic about patient's stools. About two days before admission he noticed a hard, tender swelling, of about the size of a man's fist, situated in the right iliac region and extending toward the umbilicus, which has increased in size and become more and more tender and painful till now. Patient says also that he has had great pain and stiffness of the thigh in walking, that during the past twenty-four hours he has had chilly sensations and a feeling of heat alternating therewith, and that now he feels prostrated.

On admission, patient has a rapid, feeble pulse, a considerable elevation of temperature, fetid breath, and muscular weakness.

Case seen by Dr. R. J. Hall. Patient placed at once upon operating table and abdomen examined. There is a large, tense mass lying low down in the right side of the abdomen and chiefly occupying the iliac region. The tumor causes a considerable swelling of the abdomen. On pressure, it is sensitive, and at its lower part and toward the right border deep fluctuation seems to be obscurely felt. There is no redness of the skin.

Operation performed by Dr. Hall. Patient etherized and the abdomen and parts shaved, scrubbed, and thoroughly disinfected in the usual manner. A hypodermatic needle was inserted deeply over the supposed site of fluctuation. After several punctures, about fifteen minimis of a brownish-yellow, turbid, and odorless fluid were withdrawn, which, on microscopical examination, was found to consist largely of pus. An

incision three inches long was then made through the skin, beginning about two inches above the right anterior superior spine of the ilium, and thence running downward and inward. The superficial fascia and the three muscles of the abdomen were divided, until the fascia transversalis was reached. This structure was found much thickened and slightly edematous. It was divided on a director, and, the loose tissue beneath having been torn through, the caput coli was exposed. After some further exploration with the hypodermatic needle, pus was found lying behind the gut. It was readily reached with the finger by tearing some slight adhesions between the intestine and the fascia transversalis. The quantity of pus evacuated may have amounted to two drachms. The cavity was then gently irrigated with a solution of mercuric bichloride (1 to 2,000), two drainage-tubes were inserted into the wound, and a dressing of iodoform gauze and bichloride gauze was applied. Patient recovered readily from the effects of the ether and was transferred to the Sturgis Pavilion, where he was put to bed, covered warmly, and surrounded by hot bottles. He received liquid morphinæ, Magendie, &c., and was ordered milk diet.

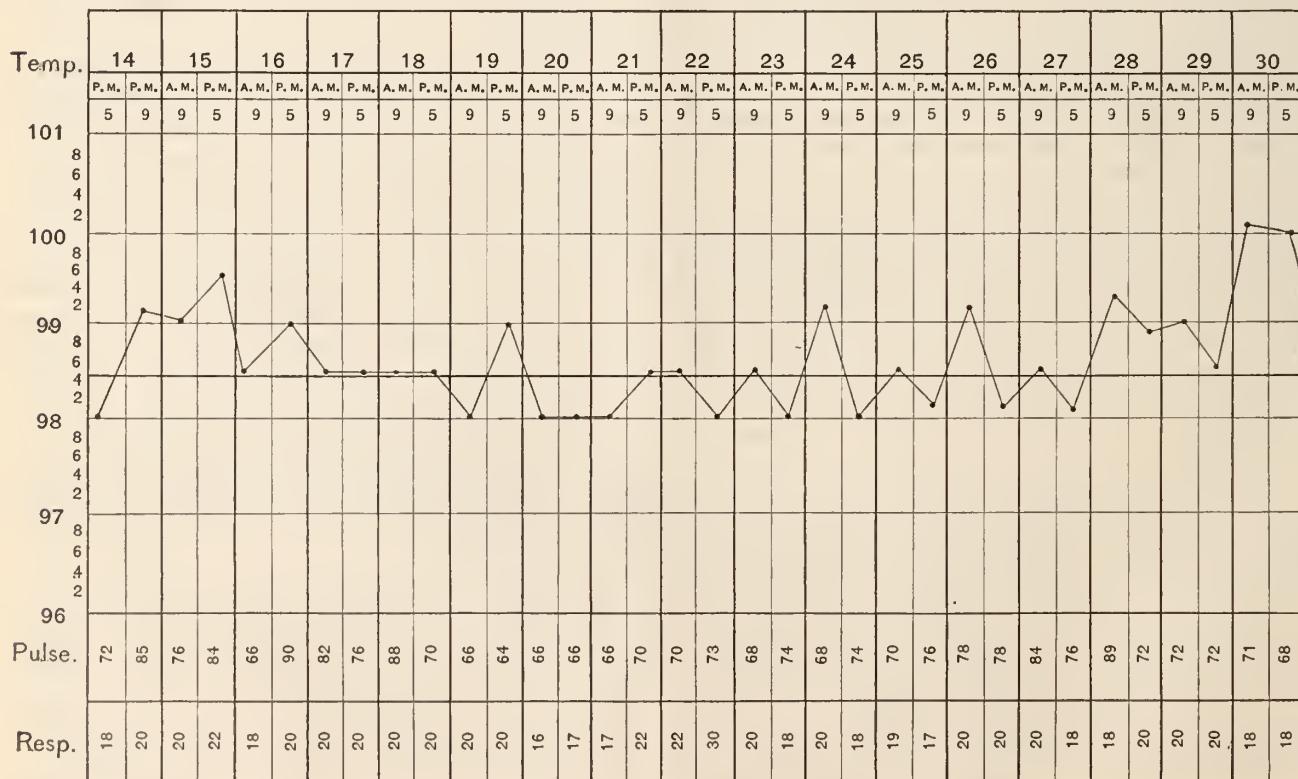

October 15th.—Patient passed a good night. His temperature since the operation has been about 99° F., and he has but little pain. Dressing removed this afternoon. Wound found to be healthy and very little pus in the drainage-tubes.

Tubes cleansed and dressing reapplied.

16th.—Temperature remains low. Patient comfortable.

18th.—Wound redressed; small quantity of pus in it. Patient had a movement from the bowels which was natural in character.

20th.—Redressed. One drainage-tube removed; there is no inflammatory redness about the wound; the amount of discharge is small. Patient free from pain and fever.

ing. Small amount of pus in the wound. Raw edges touched with argenti nitras and the wound then strapped.

27th.—Patient continues to do well. Wound granulating; strapped.

November 8th.—This a. m. patient had several large movements, following salts, one dose.

12 M.—He complains of chilly sensations and a rigor. The wound appears as usual.

9 P. M.—Temperature rose to 102°. Pulse 102. Patient suffered from pretty severe pain, described as colicky and referred to lower part of abdomen. He slept but little during the night.

9th.—Pains continue this forenoon.

9 A. M.—Temperature 100°, pulse 96, respiration 20.

5 P. M.—Temperature 100°, pulse 107, respiration 20.

Patient continues to have abdominal pain. Wound redressed; presents no evidences of retained pus, but rather more tenderness about it than usual.

29th.—Since last note the wound has entirely healed. Patient has had no further abdominal symptoms. Slight increase of fullness on right side of abdomen. Discharged cured.

The confusion in our anatomical text-books as to the real relations of the caput coli to the peritoneum led to an animated discussion, among the Bellevue interns who witnessed the operation, as to whether I had opened the peritoneal cavity or not, and the writer of the history reported it in accordance with the, at that time, current views. The real state of affairs was as follows: The tumor in the iliac fossa extended well toward the umbilicus, the patient was profoundly prostrated, in a condition of acute septicæmia, and there was much tenderness and moderate pain over the whole abdomen. The patient stated, moreover, that the pain had been constantly increasing during the last few hours. This determined me to open the peritoneal cavity if I found no adhesion between the tumor and the parietal peritoneum. Having done so and come directly on a distended cæcum, I was able to raise the abdominal wall, to palpate and inspect the whole iliac fossa, the cæcum and adjacent coils of small intestine, and ascertain that they were intensely congested, but not suppurating. I sought also for the appendix, but did not find it. The upper portion of the wound was then packed with iodoform gauze, the cæcum raised, separating adhesions so slight as to offer no sense of resistance to the fingers, and an abscess between the posterior surface of the cæcum and the parietal peritoneum evacuated. I searched for the appendix again, but did not find it.

Had the abscess been situated behind the iliac fascia, it is evident that I must have cut a second time through the iliac (transversalis) fascia, and found myself in a cavity bounded posteriorly by the iliocostalis muscle, which was not the case.

I narrate this case as affording evidence in favor of the following propositions:

1. That an abscess, which would until recently have been regarded as typically extraperitoneal, is shown by anatomical considerations and inspection to have been intraperitoneal.

2. That the preliminary incision of the peritoneum is no barrier to the subsequent evacuation of the abscess. We are apt to forget that the abdomen is completely filled by

the intestines, and offers no encouragement to the entrance of pus so long as a free exit exists in another direction.

3. That we can not divide cases into two classes, readily recognizable from the beginning—one a circumscribed inflammation, in which it is safe or even imperative to delay operation; the other, a spreading peritonitis, usually rapidly fatal, immediate laparotomy offering the only chance.

Further, the fact that my needle must have repeatedly passed through the peritoneal cavity and both walls of the cæcum, and been withdrawn infected with both feces and pus, went far to determine me to abandon a procedure sometimes dangerous and almost always useless. Certainly the failure to find pus would never prevent my operating where other indications pointed to an acute inflammation. My fourth case was as follows:

CASE IV. *Perityphilitic Abscess*.—J. N., aged twenty-one, married, United States, bricklayer, admitted to Ward 8, August 11, 1888. Patient said he had fallen off the platform of a horse-car, twisting his right ankle and knee. He also complained of abdominal pain in the right iliac region.

On admission, examination showed a sprain of the right ankle, a sprain of the right knee, and contusions of both eyes. The abdomen was tense, and the right iliac region was very tender to the touch. Patient said he had some diarrhea.

*Treatment*.—The patient was put to bed, and Magendie's solution of morphine in seven-minim doses was administered.

August 14th.—For the past forty-eight hours the patient has had twenty-one minims of Magendie's solution of morphine in twenty-four hours, and has rested quietly in bed. The patient lies on his back with the right thigh flexed. In the right iliac region there is a large tumor, which is very tender on manipulation, and the abdomen is markedly tympanitic. At eight o'clock p. m. the operation was performed by Dr. Hall. The patient was placed upon the operating table and anaesthetized with ether. The parts about the tumor were shaved, senneted, and thoroughly disinfected in the usual manner. Then an incision, about six inches long, was made parallel with and one inch above Poupart's ligament in the right iliac region, and, by means of a director and curved scissors, the subcutaneous layers were successively divided down to the peritoneum. The peritoneum was opened, and about three ounces of pus were liberated from behind the cæcum, being shut off from the peritoneal cavity by adhesions. The cavity was washed out thoroughly with Thiersch's solution.

The hand of the operating surgeon was introduced into the cavity, and all adhesions were broken up. There occurred some parenchymatous hemorrhage. A few deep and superficial catgut sutures were inserted, and then a large-sized rubber drainage-tube was placed in the cavity.

The cavity was packed with iodoform gauze; this was covered with bichloride gauze, and the dressing was retained in place by a sublimated gauze bandage. The patient was put to bed, where he was warmly covered and surrounded with hot-water bottles, and he soon reacted well from the effects of the ether and received hypodermically eight minims of Magendie's solution of morphine.

15th.—The condition of the patient is much improved.

20th.—The operation wound has been dressed every other day, and it is healing well by granulation. It is now dressed with balsam of Peru and iodoform gauze.

September 15th.—The wound is healed, except a small fistula an inch and a half in depth, and this is packed with iodoform gauze and balsam of Peru every other day.

October 24th.—For some time past the wound has been com-

pletely healed. The patient is fully restored to good health. Discharged cured.

This case is of special interest because of its apparently traumatic origin; no doubt an already ulcerated appendix gave way, though rupture of a healthy distended caecum can not be excluded. The invasion of the pus had been so rapid that the abscess walls retained in places the shining peritoneal surface.

The symptoms of threatened general peritonitis were much more marked than the history would indicate, tenderness rapidly extending over the abdomen, with pain and symptoms of acute septicæmia.

I may add that I did not see the patient until immediately before the operation or I should have interfered sooner; that the tumor determined the line of incision, and its length was such as to enable me to introduce the hand and inspect and palpate all the surrounding parts before evacuating the abscess. As before, the peritoneal adhesions were so slight as to offer no sense of resistance on separating them. The upper portion of the wound was packed with iodoform gauze before opening the abscess.

Although the cavity could be freely examined and explored, no trace of an appendix or of a rupture of the caecum could be found.

I offer the case as confirming the previous propositions, and to support Dr. Weir's plea for early operation in such cases. I am confident, so threatening were the symptoms, that a delay of twelve hours would have resulted in general suppurative peritonitis.

## A SUCCESSFUL CASE OF INTUBATION, WITH SOME REMARKS UPON AFTER-TREATMENT.\*

REPORTED BY F. H. BARTLETT, M. D., AND  
J. C. CLARK, M. D.,  
OLEAN, N. Y.

INTUBATION of the larynx, since operators can report their cases by hundreds, has become an operation of such common occurrence that the report of an isolated case can not be a matter of particular interest to the profession unless there are circumstances attending the case—in the way of clinical history, after-treatment, or some other facts in relation to it—which impress the operator with its peculiar importance. The object, therefore, in reporting the following successful case of intubation is more particularly to call attention to the after-treatment and some of the difficulties which are frequently encountered after the introduction of the tube, and regarding which the literature on the subject furnishes comparatively little information.

F. J. C., female, aged seven years, on Monday, April 8th, complained of sore throat, which developed into what was supposed to be follicular amygdalitis. This yielded readily to the usual treatment, so that she was considered well and allowed to go out of doors on the following Saturday and Sunday. On Monday, April 15th, she again complained of sore throat. This was accompanied by slight fever and slight hoarseness. She was then given tinctura ferri chloridi. This condition remained unchanged until Tuesday night, when her symptoms became worse,

the hoarseness increasing, accompanied by dyspnœa and restlessness. On Wednesday diphtheritic exudation appeared on the tonsils, her temperature then being 101.5° F., and pulse 130. She was then given bichloride of mercury,  $\frac{1}{2}$  of a grain every hour, with apparently some beneficial effect, as her condition on Thursday and Friday was somewhat improved. Her pulse and temperature were nearly normal, and the exudation in the throat had commenced to disappear; the hoarseness was also less marked. Saturday morning her condition became worse. There was an increase of the stenosis of the larynx, with considerable dyspnœa, and she coughed constantly. Saturday afternoon the dyspnœa increased rapidly; she became cyanotic, and preparations were made for intubating the larynx. About 5 p. m., however, during a violent paroxysm of coughing, a bit of membrane was coughed up, which greatly relieved her breathing. She immediately fell asleep and rested quietly three hours. Sunday morning the dyspnœa again increased. She from that time coughed constantly, the stenosis rapidly increased, and the general condition became grave, she showing evidences of extreme exhaustion.

Dr. M. C. Follett, Dr. C. H. Bartlett, and Dr. W. H. Sage were called in consultation, and all hope of recovery, except by means of an operation, was abandoned. Intubation was decided upon, and was successfully performed by Dr. F. H. Bartlett, with immediate relief of the dyspnœa, the patient falling asleep and resting two hours.

As has already been said, the literature on the subject gives unsatisfactory information as regards the details of the after-treatment of intubation. This being the fact, the operator of limited experience is somewhat uncertain as to the best mode of procedure. Such proved to be our experience in this case. O'Dwyer recommends giving semisolid food, like custards, etc., to avoid irritation caused by fluids entering the trachea through the tube. This plan was tried, but there was such a loathing by the patient of anything that approached solid foods that very little was taken. Milk and brandy in small repeated doses were given, but this excited a cough, which was so distressing that it was with great difficulty that she could be induced to take any nourishment by the mouth. Enemata of beef juice and brandy were given; but the morning following the operation found our patient in no better, and perhaps a worse condition, so far as the symptoms of exhaustion were concerned, than immediately after the operation, her pulse being then over 160.

At the suggestion of Dr. J. C. Clark, who was in attendance after the operation, the patient was kept in a recumbent position when taking nourishment, with her face turned to one side, and, instead of giving her nourishment by teaspoonful doses, she was induced to drink from a feeding cup, taking as large swallows as possible and swallowing rapidly. By adopting this method we were delighted to find that she could take two ounces of milk with two drachms of brandy at each feeding with little or no difficulty and no coughing, very little of the fluid entering the tube. As soon as the effects of the increase of nourishment and stimulants began to be felt there began a steady improvement in her condition, which continued until she had fully recovered. The dyspnœa did not return after the introduction of the tube, which kept free from mucus while it was retained, it being coughed up eighty-four hours after its introduction, there being no return of the dyspnœa after its expulsion. The expectoration became muco-purulent on the second day after the operation, and on the third day bits of membrane were coughed up. During the first week after the operation she took thirty-two ounces of milk, two ounces of Cibyl's beef juice, and two ounces of brandy every twenty-four hours. Minim doses of fluid extract of digitalis were given, more especially for its diuretic effect, and on the third day,

\* Read before the Medical and Surgical Club of Olean, N. Y.

when the expectoration became scanty and tenacious, two grains of chloride of ammonium were given every hour with satisfactory results.

The patient's improvement, although slow, was satisfactory, and at this writing, although her nervous system is considerably shattered, she is slowly recovering her usual health.

## Clinical Reports.

### NEW YORK POLYCLINIC.

SERVICE OF DR. LANDON CARTER GRAY.

ERB'S TYPE OF PROGRESSIVE MUSCULAR ATROPHY.\*

(Reported by R. S. Newton, M. D.)

H. S., aged thirty-five, married, Englishman, parents Jewish Poles, came to the Polyclinic on January 7, 1889. His mother and uncle have some difficulty in walking, of unknown nature. Patient's health has always been good. He was a strong and athletic boy, seldom defeated in running, swimming, wrestling, turning hand-springs, or any rough play. When twelve years old he was apprenticed at sea, being a deck boy for three years, and his strength was unimpaired during this period. The first symptom noticed was an inability to start on a foot-race when fifteen years old; yet for several years following he carried a heavily laden basket daily as a match peddler. He married when twenty-one. At this time he walked with "a flopping-down of his feet." Eight or nine years ago he found that he had to pull himself up stairs with his hands, though he could run down stairs without difficulty and walk on the level as well as before. Two years subsequently both his arms were equally and insidiously affected, and, in attempting to lift anything heavy, he could not carry his arms beyond the horizontal—as in putting a load on his shoulder or head. He soon became awkward even in combing his hair. The main trouble appears to have been in his arms and shoulders, as his fine movements of adjustment remained intact. He continued to walk about, although his back grew very weak. For the past seven years his disease has gradually but positively progressed. One year ago he walked without assistance, though slowly and imperfectly, but he now needs a man to aid him. No history or any evidences of syphilis. Several of his children were seen, and presented nothing abnormal. He has never, at any time in the course of the disease, had any pains or paræsthesiæ; no disturbances of the sensory, sexual, rectal, or vesical functions.

*Present Condition.*—He is a short, heavily-built man, with enormously bulky shoulders, scapulæ that fall far away from the ribs, ridiculously thin arms and well-developed forearms, and perfectly normal hands. As he stands, his abdomen is greatly protuberant from the great lordosis present. A plumb-line from the shoulders falls away from the buttocks, and the concavity of the spine is fully five inches away from the line. The buttocks are small, and there is great waste of the thigh muscles. The calves are hypertrophied; the feet normal.

*Measurements.*—Chest, 96 centimetres; right biceps, 19½ centimetres; left biceps, 20 centimetres; right forearm, 25½ centimetres; left forearm, 24½ centimetres; right shoulder girdle, 58 centimetres; left shoulder girdle, 57 centimetres; right thigh, 35½ centimetres; left thigh, 34½ centimetres; right calf,

34 centimetres; left calf, 36 centimetres; circumference of shoulder, 113 centimetres.

The patient can inflate his chest slightly, and retain air but a short time. Diaphragm not affected. Movements of the head natural; forward and lateral movements of the head natural, but backward movement is limited from the hypertrophied muscles over the cervical prominence. The arms can not be raised above the horizontal; can only be brought forward to bow out; touch the finger-tips and palms with the greatest difficulty. Backward movement impaired. When he sits, the lordosis almost disappears, proving that the extensor muscles of the hips are seriously affected. In attempting to sit down, he falls like a rocket into the chair as soon as he bends past his center of gravity, and can not get up unaided. He must be pulled up like a dead weight, when he will stand for hours without fatigue, as he does every day at his stand in Washington Market. He has the exaggerated roll of a sailor in walking, with a loose, flopping movement of the legs. No static or locomotor ataxia, Romberg symptom, involvement of the cranial nerves or of the face, trophic or vaso-motor disturbances, or fibrillary movements. Deep reflexes preserved. Knee-jerks lost. Pupils active to light and accommodation. Optic discs normal.

The faradaic and galvanic reaction are lost in all the affected muscles, whether atrophied or hypertrophied groups. In some muscles which are greatly wasted the anodal closing contraction is equal to the cathodal closing contraction, but there are no other changes electrically.

MUSCLES ATROPHIED.	MUSCLES HYPERSTROPHIED.
Upper extremity.	Upper pectorales.
Pectorales in part.	Trapezi.
Latissimi dorsi.	Supraspinati.
Serrati.	Levatores ang. scapulæ.
Rhomboidei.	Upper deltoid.
Lower portion of the deltoid.	Gastrocnemii.
All the muscles of the arms, with weak supinators.	NORMAL MUSCLES.
The glutæi, quadriceps, abductors, adductors of the thigh.	Sterno-cleido-mastoid.
The erectors and extensors in part of the spine.	All forearm (except supinator longus).
	All wrist and intrinsic hand muscles.
	All muscles of the leg, except gastrocnemii.
	All muscles of ankles and feet.

*Remarks.*—After first calling attention to this variety of atrophy in his work on electricity, Erb reported twenty cases,\* and maintained that they represented a distinct type. The age of the patients ranged from seven to forty-six, but the disease generally began in youth before twenty, frequently in families, and often in the female members. "It is a peculiar form of progressive muscular atrophy, characterized by a definite location, definite course, definite behavior of affected muscles, and definite alterations in them, but without alterations in the spinal cord" (p. 510). There is a remarkable persistency in choice of muscles affected. It begins most frequently in the shoulders and upper extremities, but it may also commence in the back and legs. It is characterized by slow, mostly symmetrical, but intermittent and often stationary, atrophy and weakness of these definite muscle groups. It is an atrophy, says Erb, "which is frequently combined with false or true muscular hypertrophies, a peculiar firmness of the wasted muscles, but without any fibrillary contractions or any traces of reaction of degeneration. . . . All other parts of the body (*i. e.*, excepting the muscular system),

\* The patient was shown to the Section in Neurology of the New York Academy of Medicine, February 7, 1889.

\* "Deutsch. Arch. f. klin. Medizin," Bd. xxxiv, 1884.

be it of the nervous system, organs of sense, vegetative organs, or external cutaneous system, remain healthy." The muscles of the forearms (except supinators) and those of the hands remain usually unaffected throughout the course of the disease." Erb considers this form of atrophy to be interchangeable with muscular pseudo-hypertrophy, except that the lipomatosis may be wanting.

The disease appears to be rare outside of Germany, as only two undisputed cases have appeared in England, and none in this country before this case. Congenital defective predisposition of the muscular system appears to be the only known cause. The prognosis is most uncertain. The disease may slowly progress, or even become stationary, or after many years involve new or many parts. In a considerable number of cases the malady does not appear to have shortened life. So few cases have been under treatment that nothing definite can be urged in the way of therapeutics.

The symptom group, according to Erb, would be : 1. The strong tendency to heredity. 2. The onset in youth or before twenty. 3. The selective and definite location. 4. The definite course. 5. The prominence of the atrophic process. 6. The subordinate degree of the hypertrophic process. 7. The freedom of the hand and wrist muscles from attack. 8. The absence of all pains, paræsthesiae, or sensory phenomena. 9. The absence of fibrillary contractions. 10. The definite behavior of muscles to electrical tests. 11. The strong clinical and pathological data which point to this being a disease of the muscular system, to the exclusion of any implication of the nervous system.

## Correspondence.

### LETTER FROM PARIS.

*Lactose as a Diuretic.—Chloride of Methylene as a Substitute for Chloroform.—The Water-supply of Paris.*

PARIS, June 28, 1889.

PROFESSOR GERMAIN SÉE has startled us again lately with a new idea—that of using lactose in place of milk itself. It is all very well for Eloy to show afterward that Rabuteau and others had said years ago that lactose was a good diuretic, but the fact remains that the merit of demonstrating the therapeutical value of many of the lately introduced drugs, by careful clinical experiments, belongs to Professor Sée.

It would seem that lactose is the most powerful and at the same time the most inoffensive diuretic that we have, one hundred grammes of sugar of milk producing a diuresis that we are not certain to get with five quarts of milk. The polyuria resulting from the ingestion of the above-named quantity of milk-sugar is greater than that from any other form of medication. It produces very rapidly two litres and a half of urine, and this goes on to three and four quarts on the third day. Then it becomes stationary for a few days, and gradually falls again to two quarts and a half. During this time any œdema or dropsy that may exist disappears, while, the blood being dehydrated, there is no longer the same quantity of urine eliminated, but after a few days of repose the same effect can be produced by the same dose of lactose.

The diuretic action of lactose may be prevented by lesions of the kidneys and by diarrhoea; profuse sweating also may diminish its power, but it will certainly be shown at a later period. The sugar of milk is well borne and should be prescribed for

eight or ten days at a time, allowing a few days to elapse between each period. Dr. Germain Sée gives one hundred grammes of lactose to two quarts of water, and this can be made more agreeable by the addition of a small quantity of brandy or mint water. All other drinks are forbidden. Even soup, if given, is measured, so that the quantity of all liquids taken will be known and their diuretic effect observed.

Dr. Sée is studying another group of diuretics, which he calls the "renal diuretics." They consist of caffeine and theobromine. He also insists again that when dyspnoea exists, iodide of potassium is the remedy to add to diuretics in all heart cases. He finds it is useless to change the iodide of potassium for iodide of sodium, under the mistaken notion that the first is toxic. Indeed, Dr. Sée believes that iodide of potassium is the best medicine we have for the heart and the circulation, and that it only lacks a diuretic effect, which he finds in lactose.

M. Dujardin-Beaumetz also has tried lactose in his hospital service and had good results, but he was led to try also glucose. He dissolved the grape-sugar in milk and found that it also had a diuretic effect. He found, in fact, that all the sugars had a diuretic action, if the kidneys were in a state favoring their action, but, fearing glycosuria, he advises the use of lactose only.

The regular administration of chloroform, to the exclusion of ether, is one of the peculiarities of European surgical practice. Several deaths that have taken place lately in the Paris hospitals, under our most skillful surgeons' hands, when every precaution had been taken and when the patients were apparently in a fair state of health, have brought the subject of danger in the use of chloroform up again. It is now proposed to substitute chloride of methylene, or what is more properly called methylic chloroform. Professor Regnault has called the attention of the *Académie de médecine* to this substance, which was formerly spoken of with great favor by Sir Spencer Wells and also by Richardson. M. Regnault has made a series of experiments on this drug with M. Villemain, his assistant professor, and he finds that this pretended chloride of methylene is nothing but a mixture of four parts (or volumes) of chloroform and one volume of methylic alcohol. It has, however, the great advantage of remaining unchanged in air and light. M. Polaillon gives the results of seventeen cases in which he used this product (which was carefully prepared for him by Professor Regnault). Its action was found to be very slow, as it took from twenty to thirty minutes to produce sleep, although some patients were brought under its effects in fifteen minutes. But the great question is whether it is safer than ordinary chloroform or not, and M. Polaillon says that it would require a large number of cases before that question could be answered, but, from the number of times he has tried it, he thinks that it is certainly not so dangerous as chloroform. Under the action of the new mixture the pulse and respiration were regular. In any case the mortality under the use of chloroform is such that any effort to produce a better method of anaesthesia is to be encouraged.

Notwithstanding the enormous increase of the population of Paris owing to the Exposition, the city mortality is very low, and this notwithstanding that, owing to new fountains and the hot weather, there is a scarcity of water—so much so that the usual supply of spring water is not sufficient and the River Seine water has to be used, in certain quarters, although it is said to be teeming with typhoid bacilli. With all this, Paris is remarkably healthy. Dr. Seguin, of New York, has been presented to the Paris Academy of Medicine as corresponding member.

NEW YORK, SATURDAY, AUGUST 17, 1889.

**DISINFECTION WITH SULPHUR COMPOUNDS.**

EXPERIMENTS with sulphurous acid have been made by Dubief and Bruhl, at the laboratory of the Hôpital Cochin, for the purpose of determining the disinfecting powers of the gas in certain localities. A report of their bacteriological researches has been presented to the French Academy of Sciences. A summary of their results is given in the "Lancet" as follows:

1. Gaseous sulphurous acid has an evident destructive action on germs contained in the air.
2. This action is particularly manifest when the atmosphere is saturated with watery vapor.
3. Sulphurous acid acts upon the germs of bacteria.
4. When employed in a pure state this gas may destroy germs even in a dry condition if its action is prolonged.

What the fate of sulphur fumigations in sanitary work will be it is not easy to say. Sulphurous acid has often been declared useless, and yet it continues in use, and commonly the alleged uselessness has been demonstrated to have been but imperfectly made out. It has risen superior to so many attacks that it may do the same yet longer, and continue to be regarded among our boards of health as a favorite agent for disease prevention. The work of the French experimenters mentioned above tallies very closely with the positions taken by Dr. E. R. Squibb, of Brooklyn, in a paper on "Disinfection by Burning Sulphur," in "Gaillard's Medical Journal," wherein he remarks that the chemical changes which result from burning sulphur in dry air do not yield sulphurous acid, but sulphur dioxide, which, he says, is not disinfectant. "There should be moisture," he says, "either with the sulphur dioxide or with the infected matter, or with both." To fumigate with the active sulphurous acid, instead of the inactive dioxide of sulphur, it is only necessary to evaporate water to the extent of three or four times the weight of the sulphur to be burned, or to wet the surfaces to be disinfected, or both, so that plenty of moisture may be present; a shallow pan of water upon a kerosene stove, well started in advance of the lighting of the sulphur, and the floor, ceiling, and walls well sprinkled with water by means of an ordinary dust-brush, will yield the required amount of watery vapor.

The time has not yet come for the discarding of sulphur fumigations for sanitary ends, but it is imperatively required that, if this method is to hold its place as a disinfectant of value, it be practiced in a more scientific and thorough manner. If it becomes manifest from a future study of this agent that it is not destructive of spores or germs of communicable disease, it will, of course, be discarded for some agent like corrosive sublimate, which, while more potent, is at the same time more dangerous to handle on a large scale, as must be done when its

use becomes a routine factor in public health administration. It is one thing to demonstrate the powers of some particular agent in the laboratory, but it is quite another thing and, in some particulars, a more difficult thing to bring that agent into daily use. For all that, let the laboratory work go on; we are grateful for every discovery and advance that it has made.

For the present, our conclusion is that the laboratory testimony against sulphurous acid as a disinfectant is conflicting, and that the agent should not yet be discarded, but be more thoroughly applied, and to this latter end it seems highly important that our boards of health and other authorities should review and revise their codes and circulars of instruction concerning the prevention of diphtheria and other infectious diseases.

**EXECUTION BY ELECTRICITY.**

THE warfare that has been waged between the supporters and the opponents of the electrical execution law of New York State has given rise to the most conflicting kind of testimony regarding the lethal force of the agent required to be used hereafter. Those who oppose the law are, at the same time, in most instances, persons whose interests lie in the more profitable and popular uses of electricity for motor or illuminating purposes; by some strange logic of their own they seem to argue that if the electrical execution law can be, and is, carried into effect, there will be a stigma placed upon the commercial applications of electricity.

In spite of a variety of statements to the contrary, it is probable that a trial of the means provided by the new law must be had in due time; and we have no fear that it will not prove adequate. Professor William H. Howell, of the Johns Hopkins University, says: "Anybody who has been unfortunate enough to have a very strong electric current pass through his system must suffer paralysis of some or all of the nerve-centers. This may be temporary or may be permanent. If the paralysis does not affect the vital parts of the human mechanism, the patient may live. . . . The descriptions of the apparatus in the infliction of the penalty which the New York criminal is to suffer show that there is little possibility of his escaping almost instantaneous death. His head is to be invested in a metallic cap, and the full strength of a very strong current sent directly through the centers controlling the mechanism of life. These must be immediately paralyzed, and the beat of the heart, as well as the breathing, cease. The brain must also be entirely paralyzed at once, and all consciousness be lost."

Such a statement will, to the medical mind at least, carry conviction. Until the test has been made and the facts are found to contradict these scientific propositions, we shall expect to see the new law obeyed. The contracts have been entered into, we are informed, with our State officials for the delivery of a suitable electrical plant to each of the three prisons where the extreme penalty of the law will hereafter be administered—at Sing Sing, Auburn, and Clinton. These prisons already possess the steam-power sufficient to drive the form of

dynamo that is ordered. The dynamo is said to be of the Westinghouse pattern of alternating current, electric-light machine; the pressure of the current will be equal to that used in the system of electrical illumination.

#### THE DISINFECTION OF THE HANDS.

MUCH has been written on this important subject, but we are rather hindered than assisted in our efforts to arrive at practical conclusions by the very excess of literature. Many of the recent articles give such elaborate directions for cleansing the hands that the general practitioner despairs of grasping so many details, the omission of a single one of which, in the opinion of the antiseptic enthusiast, vitiates all the rest and endangers the life of the patient. At least ten minutes must be devoted to washing the hands before making a vaginal examination, if we follow the teachings of a well-known writer on antiseptic midwifery, and some of our most careful and successful surgeons are equally thorough in their preparations for an operation. This is all very well for the gentlemen with whom this practice has become such a matter of daily routine that they are not obliged to stop and think of the various steps of the process, but the general practitioner, whose work is such that he really needs to exercise greater care than the surgeon, must have some shorter and equally reliable rules. It is, therefore, with no little satisfaction that we call attention to a recent article by Panschinger, in the "Münchener medicinische Wochenschrift," in which he reconciles his practical experience with the experiments of Fürbringer, who arrived at the conclusion that the thorough scrubbing of the hands with soap and warm water was more important than the use of any particular antiseptic solution. The latter's directions are briefly as follows: Clean the nails, scrub the hands for one minute with soap and warm water, immerse them for one minute in alcohol (ninety per cent.), and wash them for another minute in a solution of bichloride of mercury, one to two thousand, or in a solution of carbolic acid, one to thirty.

#### MINOR PARAGRAPHS.

##### VOLATILE OIL OF CORIANDER.

This substance has been made the subject of experiments by M. Cadéac and M. Meunier, who have reported upon them before the *Société nationale de médecine*, of Lyons, at a meeting the proceedings of which are reported in "*Lyon médical*." According to these investigations, the action of coriander is more like that of fennel than like that of anise. Unlike fennel, however, it does not cause convulsions, and the authors do not feel warranted in calling it a carminative. It causes a brief stage of excitement—all the briefer as the dose is larger—followed by blunting of the sensibility, muscular relaxation and inco-ordination, and the stupor of ordinary drunkenness. Its local action is only slightly irritant, and its effects are not materially different whether it is given by the mouth, by inhalation, or by intravenous or subcutaneous injection. It is said to kill the germ of *typhus* in three days and that of typhoid fever in seventy hours. Meat impregnated with it becomes mummified.

#### RECIPROCAL TRANSFUSION.

A CORRESPONDENT of the "*British Medical Journal*," taking for his text Dr. Lauder Brunton's suggestion of washing leucomaines out of the blood of fever patients by injecting saline solutions, asks what the effect would be of mutual transfusion, one of the parties being a fever patient and the other a person proof against the fever by virtue of having had it. The blood of such a person, he thinks, would be better than mere blood from a healthy person who had not had the disease, on the hypothesis of its containing some element destructive to the micro-organism. The formation of such an element he considers a more probable cause of immunity from a second attack than consumption of the pabulum on which the micro-organism must subsist.

#### THE BACILLUS OF SENILITY.

SINCE Brown-Séquard's, no new elixir of life has actually been discovered, but Dr. Achille Malinconico feels confident that he is on the trail of one. In a brochure entitled "*Trattato sulla possibilità della prolongazione illimitata della vita umana*," mention of which we find in the "*Deutsche Medizinal-Zeitung*," he unfolds his plan of operations. It rests upon the assumption that decay and death are not necessary phases of development, but the work of a specific micro-organism. On the principle of "first catch your hare," this organism must be identified, and Dr. Malinconico has no doubt that this will soon be accomplished, and that its destruction will then sink to the level of a mere detail. Until then, however, death still hath its sting and the grave its victory.

#### THE OPIUM HABIT IN BEASTS.

A WRITER in the "*Annales de médecine vétérinaire*," M. Jammes, a summary of whose article is given in the "*Fortschritte der Medicin*," states that in countries where opium smoking is customary it is not uncommon to see cats, dogs, and monkeys that are much in the presence of men acquire a taste for opium in consequence of inhaling the fumes given out by the smokers. He cites three examples, one in a cat and two in monkeys.

#### ITEMS, ETC.

**The Medical Microscopical Society of Brooklyn** will hold its next meeting at the Hoagland Laboratory at 8.30 P. M., Wednesday, September 4th. Papers on the following subjects are announced for the meeting: "Intimate Structure of the Derma of the Skin"; "Silver Images in Inflamed Cornea."

**Back Numbers Wanted.**—If any of our subscribers or advertisers have numbers of the Journal for January 12 or May 4, 1889, which they do not care to retain and will send them to the publishers, they will confer a great favor.

**The Metropolitan Throat Hospital.**—During the past year the work of the Throat Hospital at No. 351 West Thirty-fourth Street has included attendance upon 10,036 patients.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 4 to August 10, 1889:*

SMITH, ANDREW K., Colonel and Surgeon. By direction of the Acting Secretary of War, leave of absence for seven days is granted. Par. 12, S. O. 178, A. G. O., August 3, 1889.

WOODHULL, ALFRED A., Major and Surgeon. By direction of the Acting Secretary of War, leave of absence for two months on account of sickness, with permission to leave the Division

of the Missouri, is granted. Par. 5, S. O. 178, A. G. O., August 3, 1889.

JANEWAY, JOHN H., Major and Surgeon. Leave of absence for two months is hereby granted, with permission to apply for an extension of two months. Par. 3, S. O. 52, Headquarters Division of the Pacific, July 29, 1889.

COCHRAN, JOHN J., Captain and Assistant Surgeon, now on duty at Fort Adams, Rhode Island, by direction of the Secretary of War, will report in person to the commanding general, Department of the Platte, for temporary duty with troops *en route* to and at the summer camp at Fort Robinson, Nebraska. Upon the completion of this duty, will return to his proper station. Par. 10, S. O. 180, A. G. O., August 6, 1889.

GORGAS, WILLIAM C., Captain and Assistant Surgeon. By direction of the Secretary of War, the leave of absence granted in S. O. 84, July 3, 1889, Department of the Missouri, is extended two months. Par. 2, S. O. 182, A. G. O., Washington, August 8, 1889.

BANISTER, WILLIAM B., First Lieutenant and Assistant Surgeon, by direction of the Acting Secretary of War, is relieved from further duty at Fort Wingate, New Mexico, and will report in person to the commanding officer, Fort Grant, Arizona, for duty at that station, relieving Captain ARTHUR H. TAYLOR, Assistant Surgeon, who, upon being so relieved, will proceed to Fort Wingate, New Mexico, and report in person to the commanding officer thereof for duty at that post. Par. 4, S. O. 178, A. G. O., August 3, 1889.

## Proceedings of Societies.

### NEW YORK ACADEMY OF MEDICINE.

#### SECTION IN SURGERY.

*Meeting of May 13, 1889.*

Dr. CHARLES A. POWERS in the Chair.

**A Case of Double Empyema.**—Dr. F. HUBER presented a patient, a boy fourteen years old, of whom he related the following history: On January 14th he had fallen to the ground, from a height of eighteen feet, and had been rendered unconscious for a short time by the blow. Those who happened to be near had drenched him with water. There had been no fracture of the ribs or the skull. A few hours subsequently the boy had been seized with a severe chill, followed by fever and sweating, and within a day or two it had become evident that he had a severe attack of double pneumonia. On the fifth day he had been found in a very precarious state, unable to sit up so as to allow of an examination, and for a week following life had been sustained by digitalis and camphor. After the third week the chest had given signs of the presence of fluid in large amount. On the twenty-seventh day a pint of pus had been removed by the aspirator. Nearly six weeks after the accident it had been found necessary to make openings for permanent drainage, and at that time shreds and also masses of lymph, besides pus, had been removed. At the third month the patient had been able to walk about, and the drainage-tubes had been dispensed with. The patient was in sound condition on the evening of the meeting, five months after the fall. The speaker believed the attack had been caused by the drenching the patient had received when in the unconscious state produced by the shock of his fall. He had delayed so long in establishing permanent drainage because the heart action had been so feeble. The case illustrated the fact that simple incision, drainage, and

washings out with hot water were an efficient means of dealing with even so severe a case of empyema as this had been. He would finally call attention to the tubes he had used for drainage and irrigation, which, by having a simple flange, had been made so that it would have been impossible for one of them to slip into the chest cavity.

Dr. R. T. MORRIS called attention to a form of drainage-tube devised by Dr. Phelps which had a flange to prevent its entering too far, and also a rubber valve which closed as soon as an inspiration began, but opened with each expiration. Any masses of lymph formed late in the course of an empyema were expelled with certainty.

Dr. A. M. PHELPS thought patients having empyema should be divided into three classes: 1. Those having simple empyema; that is, a purulent effusion, or, in other words, an effusion of serum afterward becoming purulent. Such cases should be regarded in a very favorable light; they did not present the granulating surfaces of the severer forms of the disease. The lung would expand when pus of this sort was removed, and this, together with a certain amount of falling in of the chest wall, would rapidly close up the space left. 2. Those presenting the complicated form of the disease, in which large flakes of fibrin were formed and the serous surfaces had patches covered with granulation tissue. Here the more serious surgical measures would probably be needed. 3. Those patients in whom a tuberculous pulmonary abscess had broken into the pleural cavity and set up pyemia. All such died.

As regarded treatment, all abscesses required the same sort of treatment; the pus must be removed and the pus cavity must be obliterated by making its walls fall in on each other. If to effect the latter object we cut away two or more ribs, so as to allow the chest-wall to fall in, we gained the point desired. Some doubt had been raised in many minds as to the expediency of cutting open the chest cavity, on account of a danger of causing sudden collapse of the lung. In an experiment on a dog, exposure of the lung had been followed by collapse, and this had continued until a piece of glass had been fitted over the opening, when the collapsed portion had presently expanded again as respiration went on. In opening the chest for empyema, therefore, the aim should be not to destroy the expansion of the lung; and whenever, to aspirate the chest cavity, a drainage-tube without a valve was inserted the principle was violated. He believed that, as a rule, the chest should never be washed out in empyema unless decomposition had set in, and then Condy's fluid, and not bichloride of mercury, should be used to impregnate the water.

Dr. S. T. ARMSTRONG asked of Dr. Phelps the results he had got by operation in non-tubercular cases.

Dr. PHELPS answered that his success had varied with the causes to which the empyema had been due, and had also depended upon his getting the chest wall to fall in. In his four last cases all the patients had recovered. A number of cases had been recorded by Dr. Gerster where he had removed large portions of the ribs, with recovery in all.

Dr. ARMSTRONG remarked that in his own experience the results following resection had been disastrous, and had led him to feel that the principle on which the operation was based was not wholly correct. He agreed that air should be excluded from the chest. At the same time, the very fact that suppuration was going on in a given case indicated that micro-organisms were present, and these we should have some means of reaching and destroying; it was not necessarily attained by getting approximation of the inner surfaces of the cavity. In all his own cases where he had performed resection a sinus and a discharge of pus had persisted. He considered the case presented by Dr. Huber as one where drainage and washings had

had a successful result. In one of his cases where the patient had recovered (without resection) the same conditions had been present, and his treatment had likewise consisted of drainage of the cavity and thorough irrigation of the cavity with an antiseptic solution strong enough to destroy micro-organisms. The valved drainage-tube, excluding air as it did and allowing the lung to expand by its own tendency, seemed to him the best means of getting a return to normal conditions.

Dr. H. KOPLIK thought that when empyema occurred in children the prognosis was regularly more favorable than in adults; the latter were much more likely to recover with a crippled lung—*i. e.*, granulations followed by adhesions between the serous surfaces, or the beginning of tuberculous disease. In children the process was commonly a serous effusion which became purulent after a time.

Dr. HUBER said that he had sometimes diagnosed empyema as early as the fourth day of the illness, and he had often found the fluid in the thorax purulent from the first. His experience had been quite extensive, embracing thirty cases where he had operated in children. Early diagnosis was the important point in the management of these cases. If the incision was made before the lymph had become organized, the chances of a recovery were good. He had lost only one case, and there the drainage tube had slipped inside the chest. Weeks or months had sometimes been needed for complete recovery, but in none of his cases had a permanent sinus remained. As soon as the chest cavity was emptied of an effused fluid the ascent of the diaphragm and the returning mass of intestines went far toward effecting a closure of the recent space.

**Excised Cancer of the Rectum.**—Dr. PARKER SYMS presented a specimen of an excised rectal carcinoma, and the patient, a colored woman forty-four years of age, from whom the growth had been removed. Her health had been good until eleven months before the operations, when she had begun to suffer from piles, protrusion of the bowel, pains in the affected region, and bleeding. When she was first seen by the speaker a mass of scirrhouss growth protruded from the sphincter, and the general health of the patient was impaired by the loss of blood and the obstruction to defecation. The diseased tissue had been found to extend upward for three inches, but the lymphatics of the region had not been involved perceptibly. The patient's condition had been so poor that he had not done the major operation until the fourth week after doing inguinal colotomy, by which her health had been much improved. He had then determined on the operation devised by Allingham, Jr., in which a circular incision was to be made at the sphincter and carried up around the diseased bowel to a point to which the process had not extended; then, having cut the bowel square off and removed the diseased lower segment, the operator was to draw down the healthy gut and stitch it to the sphincter. In the present case, in carrying out these procedures, it had been necessary to remove the entire posterior vaginal wall and to open the *cul-de-sac*, which had been left to granulate, after establishing drainage. His experience in this case, although the result had been excellent, was that the method was best suited to cases where the growth was low down, or just adjoining the anal outlet. The wound made in the present instance had been large and the exposed surface large. He had been compelled to open the peritoneum, and had exposed the patient to more danger than the case warranted.

**Demonstration of the Mechanism and Anatomical Features of Subluxation of the Head of the Radius.**—Dr. R. T. MORRIS read a paper with this title, with the presentation of a specimen. (See p. 684, vol. xlix.)

Dr. J. H. GIRDNER, while he considered the demonstration

good in its way, thought an element of doubt remained. A joint in a dead body must be a very different thing to deal with from the same joint during life. When the displacement was produced in a living body we had to take into account the swelling and pain commonly present; the traction of the muscles about the joint was not entirely overcome, either, by the anaesthetic. We could not make every deduction from a consideration of the position of the parts, etc., as seen in the dead body, therefore. The speaker had once made a series of experiments on dead bodies relative to the breaking of bones, and the results so obtained he had never been able to check by what he saw taking place in living subjects accidentally.

Dr. VAN ARSDALE, having examined the specimen prepared by Dr. Morris, remarked that the explanation proposed by the latter had been given by other investigators in times past, and had been specially considered in his own paper on the subject, recently read before the Section. It had first been advanced by Hugernet, but had been reviewed and discarded by Schroeble. It had also been considered as the most probable one by Dr. Stimson. The objections to the theory were that the action of the muscles in the living subject kept the capsule of the joint well out; and that it did not explain how the condition should be retained for three days and upward, as it often was.

**A Hip-Splint for Tubercular Arthritis.**—Dr. PHELPS presented a boy who was wearing an apparatus of this sort, consisting of a steel bar running along the inner side of the leg, and of attachments for securing abduction and extension of the limb and at the same time absolute immobilization of the joint. The great object to be secured was to enable the surgeon to control the effects of the reflex spasm in the muscles about the joint. Wearing this apparatus, no patient could recover with an angular deformity, and meanwhile walked about freely.

Dr. L. H. SAYRE thought that in many cases Dr. Phelps's device would be a very admirable solution of the difficulties presented by holding the joint in the position needed, and giving the physician good control of spasm, which Thomas's splint did not do. At the same time he considered that in many cases no upright piece was needed to prevent bending of the limb, and that in many cases a limited amount of motion might be allowed. It was not always necessary to make traction in the line of the axis of the neck of the femur, and relief from pain could be obtained by simple straight traction. The apparatus was excellently adapted to making lateral traction where that was needed, and the shoulder-piece was decidedly preferable to Thomas's shoulder-splint.

Dr. PHELPS insisted that it must be a mistake to allow motion in a joint in tubercular inflammation, for any motion favored the development of reflex spasm, and also broke up the new tissue being thrown out, set up fresh inflammatory action, and directly led to ankylosis. He never had a splint worn in bed. The long traction splint often used was certain to produce angular deformity, or else shortening and ankylosis. Traction, to be of real service, must be made in the line of the origin and insertion of the muscles affected with spasm, whether flexors, abductors, or adductors.

**Compound Fracture of the Patella.**—Dr. ARMSTRONG presented a patient upon whom he had operated for an injury of this sort with entire success. (See p. 174.)

Dr. MORRIS said he wished to speak of two matters in connection with these operations—the chances and conditions of obtaining bony union, and the sort of drainage best adapted to a perfect result. Any one who had cut down on a fractured patella could see how it was that the old tradition that no bony union occurred in the patella had held sway so long. When we considered the blood-clots which formed between the bony frag-

ments and the fibrous shreds from the torn capsule that were turned inward between the underlying pieces of bone, we might well question if bony union had ever taken place under the old methods of treatment. It was difficult enough to obtain bony union, even when we made an ample opening and dissected up the inverted ligamentous fibers. He had had three cases, and had obtained bony union in one; in the two others it had been impossible to bring the fragments into apposition. In a compound and especially in a complicated fracture of the patella it was always in order to lay open and wash out the parts, and to trim away the introverted fragments of the capsular ligament. For draining the wound he could recommend the absorbable bone drainage-tubes. They were needed to let out any excessive serous secretion that might occur; otherwise there should be no need of draining the joint. However, with the permanent dressing a tube should always be included to provide for a possible secondary infection of the joint while dressing it.

Dr. T. H. MANLEY asked for opinions as to whether the surgeon should make it a rule to reremove the wires used to unite a fractured patella, or to leave them buried in the parts. He had had one case of compound complicated fracture of the patella. It had been received in a railroad accident, and the joint had been badly infected by sand, bits of paper and clothing, etc. Every precaution had been taken to get the parts into an aseptic condition. However, surgical fever had set in, and the patient had died in a few days.

The speaker had employed the wiring method in about eight cases, and had met with no unfavorable results, unless there should prove to be such in his most recent case, then under his care, in which for some unknown reason a purulent infiltration into the muscles of the thigh had been set up, and he had been compelled to make a number of incisions for drainage; however, the patient's condition was improving. While there were many things to encourage the surgeon in undertaking these operations, he still believed that complete bony union of the patella must always be an exceptional result. The patella was only a sesamoid bone and had no periosteum. Moreover, whether a fibrous or a bony union was secured, the fracture recurred very easily, as compared with the likelihood of recurrence when the shaft of a bone had been fractured. The speaker then related several instances of successive fractures of the patella. In a case under Dr. McBurney's care the patella had been re-fractured while he was making gradual and cautious movements of the limb to break up the stiffness in the joint, after the union of the recent fracture was thought to be complete and firm. Union was less likely to be lasting in proportion as the seat of the fracture was near to the junction of the ligamentum patellae with the patella. But it was always a defective union, and an operation to bring about that union must always involve some additional dangers, unless, indeed, the joint had already been exposed by the trauma.

Dr. ARMSTRONG replied that while a number of instances were on record in which refracture had occurred, it must not be taken for granted that they occurred in the exact seat of the primary fracture. He had met with one case, and was certain the new fracture had run through a different part of the bone. He should expect after union had occurred that a refracture would be more likely to occur in any other part than the line of union. As regarded leaving in the wires, he could only say he had met with some instances where, on account of the irritation set up by them, a second operation had been required for their removal.

**Demonstration of a New Medical and Surgical Battery.**—Dr. J. H. GIRDNER exhibited a new battery designed to furnish with certainty any sort of current which might be de-

sired, and at the same time be readily carried about. That such a battery was needed, all who had endured the incessant vexations and disappointments connected with the management of even the best chemical batteries would probably testify. His device consisted simply of a battery of one, two, or more secondary storage cells (according to the amount of work required) which could be charged from a dynamo, or, if used in country practice, from the ordinary gravity cells. Once charged, such a battery supplied electricity of large amount, sealed up and portable, not liable to leakage, always instantly available, and convertible into any sort or strength of current desired. The speaker then attached the battery successively to a motor, a canter, an electric arc light, and a faradaic vibrator, and decomposed water with the direct current. The expense was slight in view of the work done, a double-celled battery complete costing about fifty dollars. The battery improved with age. It was made and sold by Ford, of New York.

#### A Mechanical Device for making Roller Bandages.—

Dr. HUBER presented such an instrument. It was so arranged that a bandage was evenly spread or sprinkled with plaster of Paris at the same time that it was wound on a revolving cylinder.

Objections were made by Dr. PHELPS and others that any mechanical bandage roller was apt to wind too tight a roll, so that it did not wet through easily; and, secondly, that a machine-made bandage did not have the lightness requisite in a bandage used to make a plaster jacket. A bandage could be rolled by hand and impregnated with plaster from which a corset might be made weighing but three pounds. A corset made from the machine-made roller weighed not less than eight pounds, and this difference in weight was a serious objection to the latter.

#### NEW YORK SURGICAL SOCIETY.

*Meeting of May 22, 1889.*

The President, Dr. LEWIS A. STIMSON, in the Chair.

#### Operation for Deformity resulting from an Unreduced

**Pott's Fracture.**—The PRESIDENT presented a patient upon whom he had operated for the relief of a deformity due to faulty repair after Pott's fracture—a woman, aged thirty-one, who had been injured sixteen months previously. The fracture had involved the bones of the right ankle. The woman had remained in a hospital for two months. For some time after her dismissal she had walked about, and her use of the limb had somewhat improved for a year following, and still the result had been far from satisfactory. The foot had been markedly displaced outward and backward. He had operated on this patient on April 1st of the present year. He had begun by making two incisions—one beginning three or four inches above the tip of the external malleolus and carried downward and forward upon the dorsum of the foot; the other had been made on the inner side of the foot, beginning about two inches above the malleolus and ending on the inner side of the foot in front of the malleolus. It had then appeared that the foot was so far displaced backward as well as outward that it lay entirely behind the tibia. A large nodule of bone had formed in the torn internal lateral ligament, which completely prevented a reduction of the displaced bones. After its removal and division of the callus that united the broken fibula, he had found himself still unable to restore the astragalus to its true position, and on further dissection he had found a large bony growth forming a buttress or spur on the back of the tibia, against which the body of the astragalus was supported. After removal of this spur, reduction had still been prevented by the contraction of the muscles, and, as the articular cartilage of the tibia had in great

part disappeared, he had cut away enough of the upper part of the body of the astragalus to make reduction possible. The incisions were then closed, two drainage tubes were inserted, and a creolin dressing was applied. The course had been uneventful. The dressing had been changed once, and now, in the seventh week, there remained only a small superficial granulating surface over the internal malleolus. The foot, although still somewhat deviated to the outer side, was entirely serviceable, and there was some motion at the ankle joint—enough, he thought, to enable the patient ultimately to walk without a limp. He had not ascertained how this deformity had failed of being reduced at the time of the accident, but he thought it was not unreasonable to assume that it had been overlooked. The displacement backward, although evident, had not been so marked clinically as one would perhaps suppose. The heel had been prominent, and the foot shortened between the toe and ankle, but until the operation was done he himself had not recognized its full extent. The case exemplified the importance of great care in making and maintaining reduction after such fractures.

Dr. WILLY MEYER remarked that two cases of deformity, following a badly treated Pott's fracture and very similar to the one just described, had recently come under his observation. The deformity had existed for two months in one case and four in the other. Both patients had been markedly flat-footed and utterly unable to walk. The speaker had seemed to get the same good results as those obtained by the president by performing linear osteotomy just above the ankles and then reducing the foot. He had chiseled through the bones at the usual seat of Pott's fracture, and first overcorrected the deformity, the intention having been to put the foot into its normal position definitely at the time of the first change of dressing, twelve days after the operation. Both patients had recovered without fever or any other reaction, and now walked without difficulty. The speaker intended to present both patients before the society after the summer vacation.

Dr. FRANK HARTLEY asked whether it was possible to reduce the deformity in this way without taking out a wedge-shaped piece of bone, and whether Dr. Meyer had cut the bone with the osteotome transversely or obliquely.

Dr. MEYER replied in the affirmative; in both cases he had made the chisel pass through the tibia obliquely from the inner side below to the outer side above. There had been an abundance of callus, still quite soft, which had been readily passed by the chisel.

The PRESIDENT said that, strictly speaking, Dr. Meyer's operation was a correction of the functional disability, not of the deformity of the bones—that is, it brought the foot back directly under the shaft of the tibia and thus enabled it to bear the weight of the body without undue strain upon the internal lateral ligament, but it did this by shifting the lower end of the tibia also to the inner side. It left the abnormal relation between the astragalus and the lower end of the tibia and the fibula uncorrected. His own operation was designed not only to relieve the functional disability, but also to correct the displacement of the astragalus and to restore the malleolar mortise.

Dr. MEYER thought that the main result to be gained was to make the patient walk, and this in the easiest way; when the patient could step on the outer side of the foot he could walk.

Dr. C. K. BRIDDON thought Dr. Meyer's case quite exceptional and that the lesion had been one of minor degree. The very fact that the president had found it difficult to reduce the deformity after he had exposed the lesions of the bony parts would prove that it was difficult and quite exceptional to reduce such a deformity by osteotomy alone; and it also showed that

the operation of exposing the bony parts by adequate incisions was the safer of the two methods. He would be understood that he deemed it quite proper for Dr. Meyer to have used osteotomy in the way that he had, but he believed it would fail to accomplish the result desired in many cases, in which event an operation by open wound would be necessary.

**The Surgical Treatment of Struma.**—Dr. HARTLEY read a paper on this subject. (See p. 169.)

Dr. F. E. LANGE inquired of the author what plan he had for dealing with haemorrhage when performing partial extirpations, either that occurring during the operation or secondary to it; also whether he had met with any severe cases of a cystic or adenomatous character.

Dr. HARTLEY replied that he had seen one case in which severe haemorrhage occurred during operation, but never haemorrhage of a secondary sort. In this instance the tumor was a vascular and partly substernal adenoma. The veins were irregular, large, and thin-walled. The haemorrhage had occurred from the inferior thyroid and thyroideæ imæ veins. They had been isolated, but during ligation were torn. They were rapidly caught, however, and ligated again.

Dr. LANGE had seen two cases in which secondary haemorrhage occurred, following severe vomiting as the patients recovered from the anaesthetic. It had been mostly venous in origin, and not attended by serious consequences.

Dr. BRIDDON referred to a case which had come under his treatment in the Presbyterian Hospital, which had been seen by a number of surgeons of New York, and in which there had been considerable doubt as to diagnosis. It occurred in a female about thirty years old, and she had been suffering some time from dyspnoea. There was a tense elastic swelling occupying the middle and left side of the neck. It rose and fell with the movements of respiration, and when prominent during inspiration it was resonant. On one occasion Dr. Lange had detected fluid by introducing a fine needle. The trachea was displaced to the right and compressed. The only diagnosis that could be arrived at had been that it was thyroid, solid, and cystic, situated in the mediastinal space, and complicated with a pneumocele. The tumor was exposed by a large V-shaped incision, and was found to be exceedingly vascular—so much so that the most careful manipulation was followed by copious haemorrhage, requiring the application of a number of ligatures. A cyst was exposed and emptied and its edges were sutured to the integuments, and it was not deemed prudent to continue the operation. The patient was not benefited; the apnoea continued until her death two or three days afterward. The autopsy revealed the presence of a large vascular tumor involving the thyroid and situated deep down behind the sternum. The trachea had been displaced to the right, and its walls had been approximated by the pressure of the tumor.

It had appeared to the speaker that this condition would have been temporarily relieved by section of the isthmus between two ligatures, and he had thought that after such section a more radical operation could have been made by turning the tumor to either side, until the supplying vessels had been reached and ligatured. This would have endangered the laryngeal nerves, but he thought the operation could have been accomplished. It would have been impossible to accomplish anything in the ordinary manner, so thin were the walls of the innumerable vessels exposed in the wound. The speaker believed that in vascular hypertrophy or struma it was better not to open the capsule; the walls of the blood-vessels were so thin that when unsupported by the capsule they gave way at all points.

Dr. MEYER asked if Dr. Hartley had ever had the opportunity, in his operations, to follow the advice to apply an Es-march's bandage to the pedicle of the goitre. It was thus pos-

sible to perform the intraglandular shelling out of the diseased portions of the thyreoid gland without the loss of a drop of blood. The plan seemed to present but little difficulty, as it was easy to raise the lobe out of its bed as soon as it had appeared in the wound, and apply the bandage.

Dr. HARTLEY replied that he did not remember ever having met with much haemorrhage, but he thought a clamp placed on the isthmus of the gland would render an equivalent service.

Dr. BRIDDON asked what was meant by the pedicle.

Dr. MEYER replied that the term might be used to signify the portion of the lobe beyond the largest diameter and attached to the larynx and trachea. Of course there was no real pedicle of the goitre. A species of pedicle was formed merely by the application of the elastic ligature, especially after the shelling-out of the node or nodes by means of a blunt instrument. He had not yet tried the method himself, but should certainly do so in his next cases.

Dr. BRIDDON repeated the statement that in the case just detailed by him a large portion of the mass had been below the clavicle and beneath the sternum, upon which Dr. Hartley remarked that he had had a case of this kind where an operation for extirpation of the gland was performed. A portion of one lobe had extended an inch and a half below the sternum. The patient had suffered from marked asphyxia, and this had been at once relieved when the process of the tumor had been lifted out of the mediastinum.

Dr. LANGE asked if Dr. Hartley had seen any cases of malignant goitre.

Dr. HARTLEY replied that he had seen one in a girl. The cyst had opened like an abscess; the growth coming out of the opening three weeks afterward, when she entered the hospital, had suggested sarcoma. The lobe was removed and the mass cut down upon and removed as far as the upper border of the left lung. The patient now breathed well, but the disease would soon involve the trachea.

Dr. LANGE then cited two cases in which he had operated for the relief of the intense dyspnoea. In one case the tumor had projected into the trachea; at least, by the laryngoscopic mirror it had been possible to make out a mass protruding into the trachea below the vocal cords. It had been necessary to perform tracheotomy, which was done without an anaesthetic. The patient survived several weeks, and died of septic pneumonia, caused by the breaking down of the tumor and the inhalation of particles of purulent matter. The second patient had died on the table from either shock or asphyxia during an attempt to perform tracheotomy. Before the operation began the patient had been so cyanotic and so nearly asphyxiated by carbonic-acid poisoning that he had not dared to still further increase the dyspnoea by giving an anaesthetic. So the operation had been begun with the patient in a sitting posture, as lying down so increased the dyspnoea. It had been very difficult to find the deeply imbedded trachea. At last he found it displaced over to the right side, but before he could make an opening the patient had died. He opened the trachea when this had happened, and tried to restore life by artificial respiration, but without success. He had never yet performed a total extirpation of the thyreoid body, but he had operated upon many cystic and adenomatous growths in this organ, and had never had to complain of ill-success. Most of his patients had recovered easily.

Some very practical advice had been given by Burkhardt, of Stuttgart, with reference to cystic tumors, that we should distinguish between the capsule of the thyreoid and that of the tumor. Sometimes the two lay close together, and here it was necessary to watch very carefully, for, unless the incision went through the capsule of the thyreoid on to that of the

tumor, there would be much haemorrhage, and difficulties would be met with at every step. Sometimes it might be necessary to cut through a layer of glandular tissue of more or less thickness to get to the surface of the tumor. In such cases considerable haemorrhage sometimes took place. The same thing applied to adenomata.

The PRESIDENT instanced a case of malignant disease of the thyreoid in which the dyspnoea had been so severe that he had feared to place the patient in a recumbent posture, or to give an anaesthetic. The operation was done under cocaine. The trachea was found displaced to the left and deeply imbedded in a mass of calcareous degeneration which existed at that portion of the diseased growth, but he had succeeded in giving the patient a respite which had lasted for some weeks.

Dr. B. F. CURTIS, speaking of the difficulty of recognizing the different layers of tissue which existed about the thyreoid cysts, remarked that he had once removed from a woman a cyst of the size of a base-ball. At the outset of the operation he had made several false beginnings, getting between the wrong layers of the capsule, as the difficulties of dissection soon convinced him, and so, after trying several layers, he had come to the true capsule of the cyst, and enucleation had then been accomplished with no difficulty whatever. The combined layers which in this case inclosed the cyst had been no thicker than a piece of blotting paper. There had been absolutely no haemorrhage during the operation.

Dr. MEYER remarked that a case similar to Dr. Curtis's had occurred in his own practice last summer. He had found it easy, after finding the true capsule, to shell out the cyst. He also wished to put on record a case which had recently appeared at the German Hospital of a Swedish girl having apparently numerous lymphatic swellings along either side of the neck, which were thought to be lymphomata until an operation was done for their removal, when it appeared that they were quite another thing. Eight different masses or swellings had been distinguishable before the operation along the side of the neck between the clavicle and the lower jaw on the left side, and seven on the right side. They had been irregular in shape, and so not identical with the oval swellings proper to lymphomata, but they had been movable. All had proved to be small goitres, each supplied by its own artery. It had been one of the rare cases of multiple goitre. Microscopical examination had shown them to be encysted parenchymatous degeneration. The patient had made a quick recovery.

Dr. HARTLEY spoke of a case which he had seen in Billroth's clinic at Vienna of a very peculiar goitre situated in the posterior triangle of the neck, behind the sterno-mastoid muscle, which had been found to be a tumor of an accessory thyreoid gland. The speaker here added a list of all the possible situations in which accessory thyreoid glands might be met with, the percentages in the different varieties of cases recorded, the presence of an accessory thyreoid of any sort, etc.

**Abdominal Hysterectomy.**—The PRESIDENT showed a specimen, consisting of a uterus in a state of fibroid degeneration, which he had removed by the method of total hysterectomy described in the "New York Medical Journal" for March 9, 1889, the leading feature in which was the preliminary ligation of the uterine arteries. Some haemorrhage had been encountered in this operation, the fifth that he had done. As before, he had divided the uterus above the cervix after applying the two ligatures, and so had removed the body of the tumor before removing the cervix. He had in this case made one of the incisions for the exposure of the uterine artery through the anterior layers of the broad ligament, instead of the posterior, as heretofore, but the result had been such that he should henceforth return to the previous plan of reaching all

the vessels from the posterior aspect of the broad ligament. In removing the cervix there had been considerable haemorrhage, and five ligatures had been required. However, by this method of operation any bleeding vessel could readily be secured. The patient was now doing well, having had no temperature above 100° F.

**Actinomycosis in the Right Epigastric Region.**—Dr. LANGE reported that in the case of actinomycosis, of which he had given an account and shown the patient, and specimens under the microscope, at the previous meeting, he had since operated for removal, but without success. It had been found that the suppuration extended between the liver and diaphragm in the direction of the vertebral column. He had not been able to make out the bottom of the suppurating cavity. The tissues above the diaphragm were in all probability infected, so far as could be judged by the physical signs over the lower lobe of the left lung. The patient had never yet expectorated, but he had a short, hacking cough. A great mass of the actinomycotic matter had come out from the incised wound during the operation. The patient would probably succumb before long to the exhausting suppurative process that was going on. It was not now possible to remove the infected matter from its deeper ramifications.

#### AMERICAN LARYNGOLOGICAL ASSOCIATION.

*Eleventh Annual Congress, held at Washington on Thursday, Friday, and Saturday, May 30 and 31, and June 1, 1889.*

The President, Dr. ETHELBERT C. MORGAN, of Washington, in the Chair.

(Continued from page 161.)

**The Intimate Relations between Chronic Diseases of the Upper Air-tract and Neurasthenia.**—Dr. W. H. DALY, of Pittsburgh, read a paper on this subject. (See p. 176.)

Dr. JOHN O. ROE, of Rochester: This is a subject which can not fail to interest us, because we all must have met with many such cases, and it simply illustrates the general effect which local irritation may have upon the system. The persistent nagging of a constant irritation will sooner or later produce a depressed condition of the system, and, unless we remove the local cause, we can not hope to relieve the general condition. It is useless to enlarge upon the subject, as most of us are familiar with it, and it should not escape our attention in cases of general debility that we must look for and remove causes of local irritation.

Dr. F. W. HINKEL, of Buffalo: I rise with some hesitation to express my opinion, on account of my limited experience as compared with that of the gentleman who read the paper. I can not concur in the opinion that has been expressed. It seems to me that before we admit that a general neurasthenic condition can be the result of any nasal lesion as the sole cause, or as the main cause, a careful analysis of all the constitutional conditions is required. I should be interested in hearing what the general treatment was to which Dr. Daly alluded. I admit that any local irritant would have its effect upon the neurasthenic condition, but that pharyngeal or naso-pharyngeal lesions can be the main cause of such a condition I am, from my own experience and general observation, hardly able to admit.

Dr. DALY: I hope that the gentleman will do me the justice to admit the caution with which I approached this subject. The title of my paper is "Some Discursive Remarks based upon having observed Intimate Relations between Chronic Disease of the Upper Air-tract and Neurasthenia." The problem I left largely for this body to solve, if it is within its power, as to which is the causative condition.

Dr. LANGMAID: I did not understand Dr. Daly to say that the condition was due to disease of the nose, but that there was

an intimate relation I did understand him to say. I should differ with Dr. Roe, and should consider that much of the trouble in the nose was from the neurasthenia. I am sure that is what Dr. Hinkel means. So often is this the case that operative interference fails to relieve the patient because the neurasthenia is not cured.

Dr. MACKENZIE: I do not like to speak upon this subject, for I am afraid that I should keep the society too long. In my paper, read at the meeting in Philadelphia, I made the statement that very frequently in nasal troubles—as, for instance, in hay-fever—the local symptoms are due in a certain class of cases to the neurasthenia, and, until the general condition is relieved, the local treatment is without avail. It is a curious historical fact that this peculiar dullness and incapacity for vigorous intellectual work, dependent upon chronic affections of the nose, was recognized by the ancients. A number of classical writers—for instance, Cicero—mention this curious fact.

Dr. SAJOUS: I am inclined to support rather vigorously the remarks made by Dr. Daly. It has been my fortune to observe a number of cases in which I noted fluctuations in the nervous condition, and these corresponded with fluctuations in the conditions within the nasal fossa. I have now under treatment a gentleman who, some months ago, had an operation for deviated septum performed by a fellow-specialist. The operation was done because all treatment directed to the general systemic condition had been without benefit. After the nasal trouble had been corrected the gentleman immediately began to improve, and the general neurasthenic condition, although it did not quite disappear, was materially improved, and he was able to resume his duties. I am sorry to say that the secondary treatment of the case was not such as to maintain the condition obtained immediately after the operation. The septum, as often happens in these cases, returned to its original position, and at once there was a marked return of the general symptoms. Having undergone a second operation, with a carefully conducted secondary treatment, the neuralgia and other symptoms not only disappeared as they had before, but they did not return. In this case we are able to follow the fluctuations as the case proceeded, and to note the marked benefit brought about by treatment of the nose.

Dr. DALY: The imperfect manner in which I have been compelled to present this subject does not do either myself or the subject justice. I would say that the remarks of my friend, Dr. Roe, have a great deal in them. I believe that he has epitomized a great deal that is valuable—that is, that this local irritation, this local obstruction, which is a source of continual nagging and local irritation year after year, is borne by the patient because he does not know where to get relief, or is in the hands of a practitioner who will not see these conditions or admit that others can see them, and therefore temporizes with the case until some acute disorder comes on, and with it an explosion, so to speak, of one of the forms of neurasthenia.

While the presentation of the subject may seem crude and rather bold, I assure you that it is a modest presentation. I have had sufficient observation, with flattering and lasting results in treatment, to warrant me in re-uttering what I said to you with fourfold force if it were in my power, that local treatment alone, leaving the neurasthenic condition out of the question, is necessary, is advisable, is right, and that such local treatment will be sufficient of itself to cure, and it will be surely followed by relief from the disagreeable and troublesome neurasthenic symptoms. I say *followed*, and I say it advisedly. These symptoms come on late in the history of the case, and they take their departure late. In other words, the physiological and anatomical condition of the intranasal structures can be made as near normal as possible, but still the neurasthenic

symptoms will linger. The patient will not be cognizant of any general improvement, possibly of no local improvement at once, but tell the patient to wait. It will come in one or two months or perhaps a year, but it will surely come, and come to stay.

In regard to the question of general treatment. I do resort to general treatment, which is very simple and rational. In these cases of neurasthenia, while the predisposing cause may be, and I believe that it is, a local condition, there is a condition of deficient nutrition co-existing, and I direct mild remedies, but not frequently given, to act as a fillip to the secretions. I give a mild hepatic stimulant once or twice a week at bed-time, such as a quarter of a grain of calomel with fluid extract of senna, with something to prevent griping. This is simply a stimulant to the liver, and it gains these certain ends, not suddenly, but gradually. Other than that, I do not rely much upon internal remedies. I do not believe in the phosphates, which I regard as a once popular fad now moribund. I depend largely, and would not hesitate to depend entirely, upon restoration of the intranasal structures to what would be considered a normal anatomical and physiological condition.

## Book Notices.

### *Examination of Water for Sanitary and Technical Purposes.*

By HENRY LEFFMANN, M. D., Ph. D., Professor of Chemistry in the Woman's Medical College of Pennsylvania, etc., and WILLIAM BEAM, M. A., Demonstrator of Chemistry in the Pennsylvania College of Dental Surgery. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. vi-9 to 106.

Thus little manual does not purport to be a work on general hygiene or sanitary chemistry, but is devoted to the subject indicated by its title. It treats first of the history of natural waters and then of analytical examinations, both sanitary and technical, with the interpretation of the results. Modern processes are given rather than time-honored ones which have been shown to be inaccurate, so that some which hold a prominent place in most books on the subject are here omitted. The work is sufficiently complete for its purpose, well written, concise, and clear, and will be of good service to the sanitarian.

### BOOKS AND PAMPHLETS RECEIVED.

Retrécissement cicatriciel du larynx d'origine syphilitique. Trahéotomie datant de six ans. Dilatation quotidienne, de haut en bas, du retrécissement, pendant six mois, par les sondes en caoutchouc durci de Sehroetter; guérison. Par le Dr. Gouguenheim, médecin de l'hôpital Lariboisière. [Extrait des "Annales des maladies de l'oreille et du larynx."]

Contribution à l'étude des corps étrangers des voies aériennes. Par le Dr. E. J. Moure, Professeur libre de laryngologie, otologie et rhinologie, etc. (Communication faite à la Société de médecine et de chirurgie de Bordeaux.) Paris: Octave Doin, 1889. Pp. 5-24.

Report of a Case of Stricture of the Rectum, the Probable Result of a Specific Vaginitis. By Lewis H. Adler, Jr., M. D., Philadelphia. [Reprinted from the "Medical and Surgical Reporter."]

Inversio congenita dell' istinto sessuale in due donne. Per Dottor Angelo Zucarrelli, di Napoli.

Transactions of the Southern Surgical and Gynaecological Association. Volume I. Session of 1888. Birmingham, December 4th to 6th.

A Surgical Hand-book: for the Use of Practitioners and Students. By Francis M. Caird, M. B., F. R. C. S. (Ed.), and Charles W. Cathcart, M. B., F. R. C. S. (Eng. and Ed.), Assistant Surgeons, Royal Infirmary, Edinburgh. With very Numerous Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. xv-262. [Price, \$2.50.]

The Urine, the Common Poisons, and the Milk, Memoranda, Chemical and Microscopical, for Laboratory Use. By J. W. Holland, M. D., Professor of Medical Chemistry and Toxicology, Jefferson Medical College of Philadelphia. Illustrated. Third Edition, revised and much enlarged. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. vii, 9 to 84. [Price, \$1.]

Bournemouth as a Health Resort. By A. Kinsey-Morgan, M. R. C. S. Eng., etc., Member of the Sanitary Institute of Great Britain, Medical Officer of Health for Bournemouth, etc. With Illustrations. Bournemouth: F. J. Bright & Son, 1889. Pp. 5 to 98.

Suspension in the Treatment of Affections of the Spinal Cord. By Alexander B. Shaw, M. D. (Read before the St. Louis Medical Society, June 15, 1889.)

Corea in seguito a scarlattina. Nota clinica del dott. Umberto Dieci. [Estratto dalla "Rassegna di scienze mediche."]

The Sixteenth Annual Report of the Metropolitan Throat Hospital for the Treatment of Diseases of the Nose and Throat, 351 W. Thirty-fourth Street, New York.

On Spasmodic Urethral Stricture from Anal Fissure. By L. Bolton Bangs, M. D., Surgeon to St. Luke's and Charity Hospitals, New York. [Reprinted from the "Medical Record."]

Accumulators and their Medical Uses. By Robert Newmann, M. D. [Reprinted from the "Philadelphia Medical Times."]

The Annual Report of the Department for the Insane of the Pennsylvania Hospital. For the Year ending Fourth Month 22d, 1889.

The Natural Rectification of Malpresentations, and its Imitation by Art. By A. F. A. King, M. D., Professor of Obstetrics in the Medical Department of the Columbian University, Washington, D. C. [Reprinted from the "American Journal of Obstetrics and Diseases of Women and Children."]

Pelvic and Abdominal Drainage. By David Prince, M. D., of Jacksonville, Ill. [Reprinted from the "Transactions of the American Surgical Association."]

Two Suggestions for improving the Operation of Excision of the Knee Joint for Strumous Disease. By A. G. Miller, M. D., F. R. C. S. Ed. [Reprinted from the "Edinburgh Medical Journal."]

A Plea for Prompt Interference in Abdominal Diseases. By J. M. Baldy, M. D., Philadelphia, Pa. [Reprinted from the "Medical and Surgical Reporter."]

Thirty Consecutive Cases of Abdominal Section, with One Death. By J. M. Baldy, M. D., of Philadelphia. [Reprinted from the "Medical News."]

## Reports on the Progress of Medicine.

### CUTANEOUS AND VENEREAL DISEASES.

BY GEORGE THOMAS JACKSON, M. D.

**Thiol** is one of the latest additions to the dermatological pharmacopeia ("Monatsheft f. prakt. Derm.", 1889, No. 7). It is allied to ichthylol in its chemical constitution, but is a production of the laboratory and much cheaper than ichthylol. It occurs in two forms—either a liquid or a powder. As it contains sulphur, and is readily miscible with water, a wide use for it is at once suggested. It has been found useful in seborrhœa, rosacea, acne, eczema, combustio, pemphigus, dermatitis herpetiformis, impetigo, zoster, etc. In most of these the powder was used in the proportion of twenty per cent. in tallow, starch, or zinc oxide.

The Treatment of Zoster, according to Unna (*ibid.*), varies with the degree of development of the lesions. To abort the development of the lesions is acknowledged to be exceedingly difficult, and requires very early interference, for, once begun, the vesicles will develop in spite of treatment. In some cases painting the affected spots with ichthylol, or applying equal parts of zinc paste and resorein, will abort the vesicles. Another method is to cover the place with a layer of wadding soaked in a ten-per-cent. ichthylol or resorein solution, and covering this with a piece of adhesive-plaster muslin, a dressing that can be left on many

days. If vesicles have formed, they can be prevented from becoming purulent by applying to them a zinc-sulphur paste, or alcoholic solutions of corrosive sublimate, iodoform, carbolic acid, or resorcin.

**A New Treatment of Acne.**—By this attractive title Startin ("Lancet," May 11, 1889, p. 934) describes a method he has recently employed with success. It consists in steaming the face by means of a steam atomizer. The process should be kept up for some twenty or thirty minutes, and the face then gently rubbed with a soft towel. Tincture of benzoin may be used in the medicine cup.

**Acne Frontalis seu Necrotica** is the name that Boeck, of Christiania ("Archiv f. Derm. u. Syph.," 1889, Heft 1, p. 37), prefers to acne varioliformis (Hebra), acne pilaris (Bazin), and acne atrophica (Bulkley). This form of acne, though well known to dermatologists, is little, if at all, recognized by physicians in general, and is one of the rare forms of skin disease. The case related in this article was remarkable for occurring not only on the face, but also on the breast, neck, and back. The lesions on the back were specially well pronounced in character. All the lesions begin as very small papules originating in the swelling of a hair follicle and its immediate neighborhood. These papules slowly enlarge, and when they reach the size of a hemp-seed and cause a certain amount of tension in the skin, a lot of very small haemorrhagic points will appear in their centers, forming a small, delicately marked, violet-red spot. If the papule grows large enough to include several follicles, it will form a turgid, raised, quite firm and flat patch, of a punctate appearance and a bright violet color. After a time these lesious begin to sink in in the middle, and take on more of a brownish-violet color. These changes are continuous, till at last the whole patch sinks in, and lies in the skin as a sharply defined, circular, hard plane, of brownish-violet color, slowly changing to brown, presenting the appearance of a mummified piece of skin. The sensibility of the patch is preserved. If the surface is removed by emollients, a granulating ulcer is left behind. If left alone, the mummified skin will fall off of itself, leaving a scar. The larger the lesion, the deeper this process of uccrosis goes. The disease may return in the scars, and is prone to relapse. It is a sort of dry gangrene of the skin whose aetiology is unknown.

**Xanthoma Multiplex Planum, Tuberosum, Mollusciforme.**—Dr. Lehzen and Dr. Knauss, of Würzburg ("Archiv f. path. Anat. u. Phys.," etc., 1889, exvi, Heft 1, p. 85), give us a study of this interesting disease as found in two sisters—one eleven and the other nine years old. The parents were healthy, and there was no history of any skin diseases in the family. There were two other children in the family that were free of skin troubles. The older girl was always delicate, having had an attack of jaundice shortly after birth. In the third year of life she had "festers" over her whole body for a long time. In April, 1887, she passed through measles, and entered the hospital in November, 1887. She came into the hospital on account of the xanthoma, which began in her fourth year, on both eyelids, as yellow, slightly raised papules. In about a year afterward the spots appeared on both knees and hands; later on the elbows, the gluteal region, and the left heel. The right heel was attacked about one year later. All the spots increased in size. Subjective symptoms were absent, except a slight amount of itching at the time of the appearance of new lesions. The only other abnormal symptom was insufficiency of the mitral valve. Various tumors were excised under chloroform anaesthesia. The patient died of heart failure about a month after the last operation. At the autopsy the liver was found of a deep bluish-red color, and with its free edge markedly high. On the valves of the pulmonary artery yellowish, xanthomatous papules were found, and a great number of these bodies were scattered about the heart and great vessels. The younger sister showed the same skin disease, but of less pronounced grade, and there was no heart trouble. Her trouble began in the third year, after a vesicular or bullous skin affection of uncertain nature. The peculiarity of the first case was the affection of the intima of the blood-vessels; and the practical lesson is that we should examine patients for heart symptoms in order to qualify our prognosis.

**The Anatomy and Histology of Verruca Vulgaris.**—After describing in detail his methods of preparation and study, Kühnemann ("Monatsheft f. prakt. Dermat.," 1889, No. 8, p. 341) gives the following as the result of his study: The pathological process of wart formation is one of

anomaly of growth, the type of which is purely epithelial, the cutis as such taking no part in their formation, and the papillary character of the wart resulting from the hypertrophied prickle-cell layer sinking down into the cutis. The warty growth begins in the prickle-cell layer, hypertrophy forcing the layer upward and downward. It is probable that some external source of irritation—perhaps the entrance of micro-organisms into the epithelial layer of the skin—produces proliferation of the cells of the stratum dentatum, and as a secondary effect irritation and dilatation of the papillary blood-vessels and the larger vessels of the cutis, an increased supply of blood, and consequent increased nutrition of the tissues. Hence an alteration in structure of the upper layers of the epidermis takes place, and the process of cornification is essentially modified. The process, then, is not merely one of hyperakanthosis, as Auspitz and Hebra teach—that is, so far as verruca vulgaris is concerned—for the prickle-cells do not change into the usual flattened cells of the corneous layer, but preserve, more or less, their original form, and their kerato-hyalin is present, either in very small amount, though evenly distributed through the layers, or is abundant in the interpapillary portions, and entirely wanting over the papillæ. The nuclei of the cells of the corneous layer are preserved. The corneous layer is less lamellated than usual. Warts are, then, keratoses of the order dyskeratoses, and not elongations of the papillæ of the cutis vera.

**The Cure of a Case of Sclerema Neonatorum by Mercurial Inunctions** is reported by Money ("Lancet," March 16, 1889). There was no history of syphilis in the case, and the cure was nearly complete after about six weeks' treatment.

**Mycosis Fungoides** has again been studied histologically, this time by Dönnitz and Lassar ("Archiv f. path. Anat. u. Phys.," etc., 1889, exvi, Heft 2). They conclude that the disease is not due to a parasite. Though cocci are found in the lymphatics and capillaries, these are results and not causes of the disease. Mycosis fungoides, though resembling sarcoma histologically, differs from it in so many respects that for the present it is best to regard it as a special form of new growth of undetermined classification.

**Nerve Lesions and Hair-fall in Relation to Alopecia Areata.**—Behrend ("Archiv f. path. Anat. u. Phys.," etc., 1889, exvi, Heft 1) declares himself as still satisfied that the characteristic change in the hairs in alopecia areata is an infiltration of the hair with air. This he has never found in any other disease of the hair, and has quite constantly found it in alopecia areata. He believes that the fall of the hair in alopecia areata is probably due to some local disturbance of the circulation. He has repeated Joseph's experiments that seemed to prove that the hair-fall was due to a trophoneurosis, using white cats. The experiment was repeated three times on different cats; each time there was redness of the ear of the side operated on, the auricularis magnus being the nerve cut. In all, the redness did not last very long. Cutting the sympathetic had the same effect, though more pronounced. This showed that vaso-motor fibers ran in the course of the second cervical nerves, but that the disturbance was of too short duration to cause the alopecia. Between different species there exist great differences in the distribution of the vaso-motor nerves. They do not exist in the roots of the cervical nerves of the dog, but are found in those of cats and rabbits. To test Joseph's theory, a series of experiments (nine) were performed. In but one of the cases was there alopecia, and this followed the formation of a crust and was passing. The cats were, all but one, killed and dissected, and it was found that the ganglion had been fully cut in two. By these experiments the theory of Joseph is pronounced not proved. [In the succeeding number of the "Archiv" Joseph replies, and so the controversy is kept going.—ED.]

**Some Hair Recipes.**—Lassar, of Berlin, in 1882 published, in connection with our fellow-countryman, Bishop, an account of some experiments tending to show that alopecia prematura was contagious, and could be cured by antiparasitics. In this article ("Therap. Mouatsheft," 1888, No. 12) he still insists upon the contagiousness of ordinary baldness and its spread through the agency of barbers, and the employment by several persons of one comb in common. Even though as yet no definite parasite has been found in alopecia, Lassar believes that there is one and that it will be found in time. He does not believe that alopecia areata is a neurosis, though he allows the possibility of it in a few

cases, but does believe that most cases are from contagion. In the past few years he has met with many hundreds (?) of cases of alopecia areata, many of which have been in relatives, patrons of the same barber-shop, school-mates, or possessors of dogs or cats having similar bald spots. In the belief of the parasitic origin of alopecia, our author has treated more than a thousand cases by means of an anti-parasitic plan of treatment, and with marked success. His method is the following: For six to eight weeks the hair is washed with a soap rich in tar (Berger's), the suds being rubbed well in for ten minutes each day. Then the suds are washed out with warm, followed by cold, water, the scalp and hair dried, and the former anointed with B. Sol. hydrarg. bichlor. (one third of one-per-cent. strength), glycerin, and cologne water, equal parts; then rubbed dry with absolute alcohol containing one half per cent. of naphthol, and then anointed with B. Salicylic acid, 3 ss.; tincture of benzoin, gr. xlvi; neat's-foot oil, 3 iij. M. After six to eight weeks the process is to be less often repeated. In obstinate cases the sublimate solution should be used many times a day. Or this salve may be used: B. Carbolic acid, 15 grains; sublimed sulphur, 65 grains; horse-neck fat, to 3 ij. M. Another good stimulant is oil of turpentine, either with equal parts of an indifferent oil or with dilute alcohol. Another is pilocarpine hydrochloride, 30 grains; vaseline, 5 drachms; lanolin, 2 ounces; oil of lavender, 25 drops. M. Tar is good; and as a final formula we have: B. Pilocarpin. hydrochlor., 30 grains; quinin. hydrochlor., 1 drachm; sulph. praecipitat., 2½ drachms; balsam. peruv., 5 drachms; medul. bovin., ad 3 iij. M.

**Trichophytosis Dermica.**—Campana, of Genoa, believes that the trichophyton is capable of germinating and growing in the connective tissue of the skin ("Archiv f. Derm. u. Syph.", 1889, Heft 1, p. 51), and, further, that the chief part of such tumors as are formed in connection with ringworm is composed of the fungus itself. He gives a case of diffused ringworm of the body, onychogryphosis of all the toes, and a tumor of egg size (location not stated). Mycelia and spores were found not only in the scaly patches, but also in the nails and in the tumor. The latter consisted of hard fibrous connective tissue, which in places showed signs of beginning necrobiosis.

**The Anatomy of Scabies.**—Török, an assistant of Unna's, has examined seven cuniculi of scabies, and believes ("Monatsheft f. prakt. Dermat.", 1889, No. 8) that most of the previous teachings in regard to their anatomy is wrong. He says that the cuniculi are located, not in the prickle-cell layer of the skin, but in the lowest part of the middle cornaceous layer. The eczema to which scabies gives rise is not excited by the scratching, but is caused, probably, by some irritating substance secreted by the itch-mite. The new and smallest vesicles are usually just below the cuniculus, and grow downward, and therefore are not produced by the scratching. Further, a foreign body in the epidermis does not of itself cause much itching; and the moving about of the mites in the epidermis does not account for the paroxysmal itching so well as a paroxysmal secretion of an irritating substance by them would. Of course the scratching due to the itching aids in the production of the clinical picture that we recognize as scabies.

**Ringworm** is studied by Pellizzari, of Pisa, in the "Giornale ital. del. mal. ven. e del. pelle," March, 1888. He first speaks of *ringworm of the palm*, of which he has seen seven cases. It is usually accompanied by manifestations of the same disease upon the back of the hand, but may occur on the palm alone. Usually only one hand is affected. It generally assumes the appearance of a chronic eczema, with special changes in the nails. Sometimes it looks like a dysidrosis; sometimes like a hyperkeratosis; sometimes like an eczema rhagadiforme. The microscope shows a number of mycelia, but no spores in the epidemic scales. The disease is very chronic, often lasting for years. He next describes the three varieties of *tinea tonsurans*, and speaks especially of one variety that resembles very closely and is often taken for alopecia areata. This occurs in the form of more or less round, bald places, without any eruption upon the scalp, redness, or other sign of dermic reaction; covered with fine, dirty-white, or yellowish scales, often having in their center a black point, the remnant of a hair broken off near the surface of the scalp, and filled with the spores of the fungus. This variety is one of the most difficult to cure, and may last for years, one case having been seen in a patient, forty-four years of age, which had lasted nearly all her life. He then speaks of *ringworm of the beard*, and of

cases which, under his observation, changed in appearance and symptoms to a simple sycosis. This leads him to believe that many cases of sycosis have originated in trichophytosis. He explains this on the theory that the presence of the fungus at one time gives rise to an irritation that continues even after the fungus has disappeared. He has found the trichophyton present not only in the epidermic structures of the skin, but also in the derma itself, where it exists mostly in the form of spores. He believes that in many of the cases of simple sycosis in which no broken hairs are present and no fungus demonstrable in epidermis, hair, or contents of pustules, it is possible that the fungus is still in the derma, and there keeping up the irritation that gives rise to the sycosis.

But the most important part of this study is that which relates to *onychomycosis*. This form of ringworm seems to be much more common in Italy than it is with us, for our author had twenty cases of it out of one hundred and fifty cases of trichophytosis in the course of thirty months. Out of nineteen cases, nine were in males. The youngest was aged twelve years, and the oldest was fifty-seven. In four cases the disease was limited to one finger; in two to several fingers of one hand; in two it was spread over the fingers of both hands. In all of these there was no other evidence of the disease elsewhere on the body. In five cases ringworm of the palms was present, in three the scalp was affected, and in three there was ringworm of other parts of the body. The disease seems to first manifest itself by a change in the color of the nail, which appeared as if dotted over with little white points, distributed without order, or as if striated with white longitudinal lines. These lines have a reflex like that of quartz, as if the nail had split. The nail soon becomes uneven, which is readily apprehended by sight and touch. The nail has become thickened, but the thickening is more manifest in the white lines, as there the normal lines of the nail are exaggerated. Sometimes this may occur on only one side of the nail, and then that side will be raised and curled up, while the nail substance is greatly thickened, and some of the superficial corneous laminae are detached. Generally, however, the whole nail is affected from lunula to free border. At times the nails have their superficial laminae intact and transparent, but they are thickened and of a white color. This condition may last for years. The nail-bed likewise becomes thickened so as to obliterate the anterior or subungual sulcus, and the nail itself often becomes eight to ten times as thick as normal, or even more. The surface of the nail becomes marked by transverse lines, especially on the anterior border of the lunula, which is, as it were, hunched up. Sometimes the thickening takes place along the median line of the nail so as to make it raised in the middle, but usually it is general, and the nail has its normal convexity increased. Sometimes onychogryphosis is present. The superficial laminae are the last to be attacked, and when they are, they become opaque, begin to exfoliate, break, and at last fall off entirely, separating first at the periphery and anteriorly. At times the nail looks worm-eaten, on account of the falling out of the whitish spots above mentioned. When the disease is well developed, the nail is rough, and the upper layers look as if they were torn up and frayed out. Subjective symptoms are wanting, and patients seek relief either on account of the ragged nail being in the way of their work or on account of the manifest deformity. At most there is a little itching of the finger end, or slight pain when the part is exposed to heat, as of the fire or warm water.

The diagnosis of trichophytosis of the nail is difficult when it occurs by itself without disease of the skin elsewhere. It might be mistaken for onychogryphosis. Here the diagnosis would be suggested by finding other nails more or less affected with trichophytosis in its early stages, by the fact that, combined with the hypertrophy of the nail, there is also a retrogressive degeneration, while in onychogryphosis the hypertrophy is progressive, and there is great thickening of the cornaceous layer of the nail. In the latter the nail is dark-yellow, but always bright, and throughout the structures of the nail are uniformly thickened. The diagnosis from favus of the nail is made by the fact that favus attacks primarily the superficial corneous laminae of the nail, producing a number of little, depressed, saucer-shaped points, without special color. At the same time there will usually be found other evidences of a chronic favus on the hands. In favus, as in ringworm, there is an apparent great thickening of the nail, but in the former case it is

due to a soft, yellowish-brown substance interposed between the nail and its bed, pushing the substance proper of the nail upward, while in the latter there is a true thickening of the nail substance. In favus there are also little points of sulphur-yellow color scattered here and there through the nail, which are easily seen. They advance from below, and finally perforate the upper layers.

As the fungus is always deeply seated in the nail and its bed, it is useless to speak of treatment by means of scraping the nail and applying antiparasitics. The treatment, to be efficacious, must be energetic enough to cause an artificial paronychia, produce suppuration of the nail, and in this way kill the parasite. A good plan is to keep green soap upon the nail under a rubber cot for a few days until the nail is softened. Then apply equal parts of olive-oil and pyrogallic acid, endeavoring to cause it to enter beneath the nail and into the suseus. When the nail loosens, it is to be removed, and the finger dressed with iodoform.

**Tubercular Skin Diseases.**—Pick ("Prag. med. Woch.", 1889, No. 19), while believing that we are far from having reached our full knowledge of tubercular skin diseases, says that at present we are justified in applying that term only to the following: Tuberculosis cutis propria of Chiari, lupus, so-called scrofuloderms, the tuberculosi verrucosa of Riehl and Paltauf, and the verruca necrogenica of Karg and the last-named authors. He reports one case of verruca necrogenica, which he cut out, together with an enlarged cubital gland. In the latter was found a cheesy mass. He also reports a case of tuberculosis verrucosa in a tuberculous subject, in which there were multiple lesions, all resulting from self-infection by means of the sputum. Two cases of lupus are reported. One was of the nose and upper lip in a tuberculous subject, lungs and larynx being affected. Many bacilli were found in the secretion of the lupous ulcer. The second case was likewise on the nose, cheek, and eyelids. The patient was of a tubercular family. Many bacilli were found in the secretions of the ulcer. Both cases resembled tuberculosis cutis, the resemblance arising from the vascularization of the parts, their maceration from secretions, and the high temperature of the locality. Another case is reported of papillomatous lupus in a strumous subject, beginning as an ordinary verrucous lupus, and changing after measles into a hypertrophic, inflammatory, papillomatous lupus, with rapid dissemination and tubercular infection of the neighboring glands. As benign lupus may thus become active, and take on the characters of tuberculosis cutis, every lupous patch should be destroyed early, and the neighboring glands extirpated where they are involved.

**Scrofula or Syphilis** is the title of an instructive article by Manzino, of Palermo, in the "Giorn. ital. delle mal. ven. e della pelle," 1888, xxiii. After citing several cases to show how difficult it sometimes is to make a diagnosis between the two diseases, he gives us the following diagnostic marks: The color of the syphilide, either of the elementary lesion or the surrounding areola, is dark red, reminding one of the color of copper or of lean ham; lupus is of a pale rose, or a rosy golden color, with a tendency, especially in the areola, to a bluish tinge. The coexistence of the syphilide is hard and resistant to pressure; that of lupus is soft and elastic. The crusts of ulcerating syphilides are dark, brownish-green, or black; those of the scrofulides are usually white or dirty white; in syphilis they are regularly formed, hard, stratified; in lupus they are but little prone to be homogeneous, and but slightly dense and hard. The ulcers of syphilis are sharply cut, with hard, infiltrated edges, deeply adherent to their bases; those of lupus are less sharply defined, and the edges are flaccid, soft, often separated from the floor of the ulcer. The floor of the syphilitic ulcer is more or less deeply hollowed out, uneven, irregular, covered more or less by a grayish-yellow, yellowish-crimson, or lardaceous plaster-like excretion, resulting from the necrobiosis of the gummatous tissue; in old cases of lupus, the floor is slightly or not at all hollowed out, rather raised above the level of the surrounding parts, of a rosy or pink color, often smooth, as if covered by a kind of transparent, easily detachable varnish. The shape of the syphilide is ordinarily gyrate, representing a complete circle or an arc of a circle, a half moon, or only a serpentine undulation; the scrofulide, although at times round or circinate, is usually less regular and more variable. The course of lupus is very chronic, extending very slowly, and destroying the tissues cell by cell;

syphilis develops rapidly, extending as much in a few months as lupus would in as many years, destroys the tissues in mass, and often becomes serpiginous. The history of the two diseases is different, in one pointing strongly to syphilis, and in the other to lupus, and this not only in the personal history of the patient himself, but also in that of his parents and immediate relatives. At present neither bacteriology nor histology is well enough established to furnish positive evidence in any particular case. In truth, the two diseases may in certain cases resemble each other so closely that a diagnosis can be made only by a most careful comparison of all the symptoms.

**Precocious Manifestations of Congenital Syphilis** is the title of a series of articles in the "Progrès médical" for 1888-'89, by Sevestre. Lenticular erythema is a papular eruption, with erosions at times, which may occur upon a papule or independently of one. The lesions are generally isolated; sometimes they may touch at their edges. They occur upon the buttocks, or on the border of the fold of skin above the buttocks, upon the inner side of the thighs, or upon the posterior surface of the calf; more rarely upon the posterior part of the scrotum, or the external surface of the labia majora, and still more rarely in the neighborhood of the anus. They may appear elsewhere, but exceptionally. Another characteristic is that this eruption spares the natural folds of skin. This eruption has been described as a syphilide, but in reality it is not. It may appear in syphilitic children, but it is only a special form of simple erythema. It occurs from the fourth to the sixth month of a child's life. The diagnosis is to be made by the absence of all other signs of syphilis, by the peculiar localization, by the presence of vesicles, by the rapid evolution of the eruption, and by its cure by simple measures. Syphilis occupies the anal region, runs a slower course, and yields only to specific treatment. Dry onychia is not a positive sign of syphilis. It is due to a disturbance of the nutrition of the child, which syphilis may cause, but not necessarily. Ulcerating paronychia may occur independently of syphilis, and is therefore not to be regarded as a sign of syphilis. Alopecia, when occurring in the form of bands and upon the anterior and lateral portions of the head, is diagnostic of syphilis to a certain extent. Adenopathies are of no value as a sign of infantile syphilis. They are rarely met with, and point rather toward tuberculosis than syphilis. Lesions of the lips, mouth, and pharynx are important. Fissures of the lips are most frequently met with. They may be median, and then usually of the upper lip, not involving the skin, but going deep down to the chorion of the mucous membrane. Unless they are very superficial, they are pretty sure signs of syphilis, and heal slowly under a greenish crust. Median fissures may also exist at the same time or alone, and are of less value than those of the upper lip in diagnosis. Scattered fissures—that is, a number upon the lips—constitute positive evidence of syphilis. Commissural fissures involve both the skin and mucous membrane, and are often deep, long, and covered with crusts. These are often mucous patches, and are positive evidence, as are also erosions. Mucous patches of the mouth and pharynx are rare. They are of two varieties, one being simply a reddening of the pillars of the palate, and this is not positive evidence of syphilis. The other form is superficial ulceration, or simply erosions upon the lips, gums, and the free border of the palatine arch. They are not absolutely characteristic, but suspicious. Of the tongue we have mucous patches and a desquamative lesion. Mucous patches here are rare, and occur most often upon the dorsum of the organ near its point, are seldom more than two in number, and resemble those of acquired syphilis. The desquamative lesion of the tongue is not a sign of syphilis, though it has usually been considered as such. It was found only seven times in one hundred and fifty nurslings. Coryza is one of the most constant and earliest symptoms of hereditary syphilis. The mucous membrane is attacked usually alone, the bones are rarely involved. The depression of the bridge of the nose can hardly be regarded as a sign of syphilis in infants, in whom the nose normally has a depressed bridge. A more frequent phenomenon is a sort of narrowing of the anterior nasal orifice, the skin seeming stretched and drawn in. This occurs after the coryza has lasted some time. The voice and cough are usually altered, being harsh, which depends upon a simple tumefaction of the larynx. More rarely we may find ulcerations of the larynx. The alterations of the organs of sense are so rare as to be of no value in precocious congenital syphilis. Interstitial keratitis is very exceptional before the

age of two years. Iritis, choroiditis, and retinitis are not rare, but are so hard to diagnosticate, for one not specially skilled in eye diseases, as to be of little use for diagnostic purposes. Suppurative otitis media is quite common, with perforation of the drum. It is characterized by sudden appearance without any pain. Sudden deafness without antecedent otitis is a positive symptom. Lesions of the viscera are usually not to be determined except post mortem. They exist, but, unless accompanied with some more positive evidence of the disease, are of small diagnostic value. Enlargement of the spleen and of the testicle are the most diagnostic lesions. There are no positive signs from the central nervous system. The teeth are very rarely affected in early congenital syphilis. They are often retarded in their growth. The bones are often affected, most commonly the humerus, femur, and tibia; then the ulna, radius, fibula, ribs, and lastly the clavicle, the metatarsal and metacarpal bones, and the phalanges. The alteration is most often characterized by a more or less extensive thickening, but sometimes it is difficult to recognize it. A solution of continuity may take place near the epiphyses, but it is rarely complete. The skin over the diseased bone may remain unaltered or become necrosed. Ulceration of the skin is most often seen in connection with dactylitis. The bones of the skull may be affected, giving rise to craniotabes or osteophytes. The general appearance of the child should always be noted. It may seem well nourished or greatly debilitated. We may find well-marked cutaneous or other signs of syphilis on a well-nourished new-born child. The debilitated appearance is due to profound lesions and alterations of the blood. But, unless the disease is successfully treated, debility will sooner or later set in in all cases. In all there will be a marked pallor of special tone most evident upon the forehead and chin. As a rule, when a well-nourished infant suddenly begins to grow pale and flabby without any error in feeding or hygiene, we may suspect syphilis or tuberculosis, sometimes it is hard to say which. [This very interesting and important paper is so long as to be the despair of the abstracter. We have endeavored to select some of the leading points, and now commend its perusal in its original form to all who are specially interested in the subject.]

**Extra-genital Syphilitic Infection.**—In the course of nine years Pospelow, of Moscow ("Arch. f. Dermat. u. Syph.", 1889, Heft 1 and 2), met with one hundred and ninety-eight cases of extra-genital initial lesions, distributed as follows: Lips (20 men and 29 women), 49 cases; gums (1 man), 1 case; tongue (1 man and 2 women), 3 cases; throat (14 men and 32 women), 46 cases; breasts (69 women), 69 cases; chin (1 woman), 1 case; eyelids (3 men), 3 cases; nose (1 man), 1 case; trunk (10 men), 10 cases; anus (5 women), 5 cases; arms (3 men and 3 women), 6 cases; legs (4 women), 4 cases.

These initial lesions presented certain peculiarities that make them worthy of special remark for diagnostic purposes.

1. *Initial Lesions of the Mouth.* a. *Of the Lips.*—Most of them were covered with greenish-brown, more or less thick crusts composed chiefly of the secretions of the lesion itself. Sometimes the crusts may be easily removed, and sometimes they adhere quite closely. When removed they leave exposed either an erosion of little if any hardness, or an ulceration of cartilaginous consistence. When the lesion involves both the skin and mucous membrane it is raised above the level of the latter and resembles a hypertrophic secondary papule. Sometimes when the center of the papule has broken down it presents the appearance of *ulcus cupuliforme*. There was nearly always a firm œdema about the sclerosis, which is a diagnostic mark from secondary papules. The lips were nearly equally affected (twenty-three upper, twenty lower). Usually but one lesion was present; only three times was it multiple. The size of the sclerosis varied greatly; the form was usually round or oval, sometimes extended across the lip, sometimes of zigzag contour. Induration was usually marked; secretion was scanty; pain was usually experienced on pressure and on motion of the lip. The submaxillary glands were usually the ones first affected, and in rare cases they became enormously enlarged, even so much so as to change into abscesses. The first suspicious sign of a lip chancre is the failure of a fissure of the lip to heal. The second symptom is the formation of an increasing crust similar to what is seen in *ecthyma*. The third symptom is the enlargement of the submaxillary glands, most marked on the side of the chancre. The fourth symptom is induration and œdema, sometimes cartilaginous in hardness.

**Treatment:** Application of an ointment of white precipitate (gr. 3 to 6), and carbolic acid (gr. 10 to 15) to the ounce of lard. On the mucous membrane the papule was touched with nitrate of silver. Absorption of the infiltrate was hastened by the use of mercurial plaster. General mercurial treatment was used at the same time.

b. *Of the Gums.*—Only one case. Location, left upper side. A hard, slightly raised, bright-red band, with left-sided swelling of submaxillary glands. Probably derived from the use of a clarionet.

c. *Of the Tongue.*—Three cases. Ulcer round, sharply defined, fleshy-red color, and raised and hard. Adenitis, cervical and submaxillary.

d. *Of the Throat.*—To this the attention of the patient is first attracted by a certain difficulty or even pain in swallowing. The pain is located mostly in the tonsils and increases by pressure. It antedates the first eruption on the skin by from two to five weeks. Then the submaxillary and cervical glands become swollen, especially the former, and that more pronounced on the side of the chancre. The third symptom is an intense redness of the pharynx, which may be limited or diffused, and in unilateral infection is unilateral. The color may be brown-red, dark cherry-red, or even dark-violet. The fourth symptom is enlargement of the tonsils, with hardness, pain on pressure, and redness. To this redness and swelling of the tonsils erosions may be joined, which at times extend upon the adjacent parts of the pharynx, and the whole becomes covered with an ash-colored deposit, a sort of false membrane. The last symptom is the ulcer itself. This presents irregular, gnawed-out edges, which are seldom undermined. Around the ulcer is a sharply defined, variously shaded redness. The edges of the ulcer feel much harder than the floor. The latter is superficial when the pharynx is involved; a crater is formed and covered with a dirty-brown or grayish deposit when the tonsils are attacked. There was almost always induration. When the sclerosis was located upon the palatal arch or roof of the palate, it became markedly pale by lifting the roof or by pressure with the sound, like the whiteness produced by rolling back the prepuce when the chancre is located in that region. Most chancres of the throat were located on the tonsils, and in nine cases both tonsils were affected.

2. *Initial Lesions of the Mamæ in Women.*—These were about two thirds of all the cases of extra-genital chancre, and arose in most cases from suckling infected children. The majority of the patients were wet-nurses in private families. Thirteen were mothers infected by their own children, and in them the syphilis was always more recent than in the child. Some were infected through their own children after birth, but it is not stated that all were. Most all the initial lesions of the breast were multiple, either upon the same breast or upon both. One case is reported of five lesions on one breast and a sixth on the other. The nipple was the part most often infected. The size of the sclerosis varied from that of a lentil up to three inches in diameter. In form they were sometimes linear, sometimes sickle-shaped along one side of the nipple and sometimes completely encircling the nipple, and sometimes of various configuration. In appearance they varied as chancres will. When the nipple was affected it was redder than the one of the other side, sometimes dark-red, enlarged, hardened, and at times flattened. Mastitis, simple or suppurative, was met with, also phlegmonous inflammation of the breast. The chancre ended by cicatrization, and at times by a hyperæmic cicatrix. The submaxillary glands of the same side were swollen and hard, and of both sides if both breasts were affected. If one side was infected before the other, on that side the swelling was most marked. In a few cases there was swelling of the glands over the pectoralis major muscle. The diagnosis of these chancres was usually easy. An important diagnostic sign of syphilitic infection of the breasts, when the chancre has healed and there are none of the usual symptoms to point to syphilis, is a flattening of the enlarged nipple and an asymmetrical leaning of it to one side. This is of importance in choosing a wet-nurse, and is best observed by looking at the breasts from behind the patient. It is not a positive sign, as other diseases of the nipple may give rise to it. Leucoderma colli is another important sign of syphilis in women, and is met with after infection of the breasts.

3. *Initial Lesions of the Face.*—In chancre of the eyelid the preauricular and submaxillary glands of the same side were enlarged. In

chancre of the nose the submaxillary glands were enlarged. In chancre of the chin the submental and submaxillary glands were enlarged.

4. *Initial Lesion of the Upper Extremity.*—In chancre of the arm both the axillary and elbow glands were affected. In four cases of chancre of the finger the axillary glands were enlarged in three, the epitrochlear glands in two, and the ulnar glands in one.

5. *Initial Lesion of the Lower Extremities and Trunk.*—These were located on the inner side of the thigh, on the nates, about the anus, on the pubes, on the lower part of the abdomen, and on the scrotum. The possibility of infection of the buttocks from privy-seats is allowed. Extra-genital chancre was found to be much more common in women than in men—nearly three times as frequent. The most frequent location of extra-genital chancre is the mouth. The next, in women, is the breast.

## Miscellany.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the abstract of sanitary reports received by him during the week ending August 9th:

CITIES.	Week ending—	Estimated population.	Total deaths from all causes.	DEATHS FROM—								
				Cholera.	Yellow fever.	Small-pox.	Varioloid.	Variella.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.

**The Health of Michigan.**—According to the State Board of Health's Report for the four weeks ending August 3, 1889, diphtheria was reported from twenty-six places, scarlet fever from thirty places, typhoid fever from eighteen places, and measles from thirteen places.

**The U. S. Grant University** is the title of an institution situated in Athens and Chattanooga, Tenn., formed by the consolidation of the Grant Memorial University and the Chattanooga University. The medical faculty is constituted as follows: Dr. E. A. Cobleigh, dean, medicine, clinical medicine, and dermatology; Dr. G. A. Baxter, surgery and clinical surgery; Dr. J. R. Rathmell, obstetrics, diseases of children, and clinical medicine; Dr. H. Crumley, anatomy; Dr. G. W. Drake, physiology and psychology; Dr. W. T. Hope, materia medica, therapeutics, and clinical medicine; Dr. L. Y. Green, gynaecology; Dr.

F. T. Smith, ophthalmology; Dr. N. C. Steele, otology, rhinology, and laryngology; Dr. J. E. Reeves, pathology, histology, and microscopy; Dr. W. C. Townes, medical chemistry and toxicology; Dr. J. L. Gaston, minor and operative surgery and bandaging; Dr. E. M. Eaton, diseases of the mind and nervous system; Dr. T. C. V. Barkley, urinary and venereal diseases; Dr. E. B. Wise, diseases of the chest and physical diagnosis; Dr. D. E. Nelson, electro-therapeutics; Mr. Harry Wise, pharmacy; Dr. W. G. Bogart, diseases of women and clinical gynaecology; and Dr. R. L. Vaught, demonstrator of anatomy. Chairs of sanitary science, dental medicine, and medical jurisprudence are to be established. The regular winter course opens at Chattanooga on the 7th of October.

**The French Congress of Surgery** will hold its fourth session in Paris from the 14th to the 20th of October, under the presidency of Baron Larrey. Among the subjects to be discussed are the following: "The Immediate and Remote Results of Operations for Localized Tuberculosis," "The Surgical Treatment of Peritonitis," and "The Treatment of Aneurysms of the Limbs." Business communications should be addressed to M. F. Alean, 108, boulevard Saint-Germain, Paris; those on scientific matters may be addressed to Dr. S. Pozzi, secretary general, 10, place Vendôme, Paris.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

## Original Communications.

### THE "PERFECTED EVACUATOR."

By FESSENDEN N. OTIS, M. D.,

CLINICAL PROFESSOR OF GENITO-URINARY DISEASES IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; CONSULTING SURGEON TO CHARITY HOSPITAL, TO NEW YORK SKIN AND CANCER HOSPITAL, TO ST. ELIZABETH'S HOSPITAL, TO THE MANHATTAN EYE AND EAR HOSPITAL, ETC.

THE credit of conceiving and carrying to ultimate success the operation of removing stone from the bladder by lithotripsy at a single sitting is indisputably due to Professor Henry J. Bigelow, of Boston.

The method of crushing the stone has not materially changed from that pursued in former times, although we are indebted also to Dr. Bigelow for more powerful lithotrites. These at once became a necessity when attacking the large and hard stones, which the field of his brilliant operation quickly embraced. With the heavier instruments now available, it is rare indeed to find a stone which, in skilled hands, is beyond their compass. After the ability to use large evacuating tubes (from 25 mm. to 30 mm. in circumference, and even larger) was demonstrated, the evacuation of the *débris* seemed easy of accomplishment. The first instrument (a modification of Clover's) devised by Professor Bigelow answered the purpose admirably in the main, but was soon found to permit a return to the bladder of a portion of the *débris* after it had been deposited in the receiver, a fault which, however, did not prevent the accomplishment of many notable successes by this method; but Professor Bigelow at once began a series of elaborate and expensive experiments to remove the difficulty. Sir Henry Thompson, of London, who soon adopted Professor Bigelow's operation and contrived instruments of his own for its accomplishment, found the same difficulty to contend with. A sharp rivalry between these distinguished surgeons—to construct an evacuator which should act by the most direct and shortest route, and yet perfectly prevent the return of *débris* to the bladder—began in 1879, and for the several succeeding years furnished to the journals (chiefly the London "Lancet") many interesting illustrations and much animated discussion. After various modifications and expedients had been adopted and discarded during a period of several years, Professor Bigelow, in 1883, presented the instrument which has remained from that time up to the present (1889) without modification.

In presenting this improved instrument to the profession, in the London "Lancet," January 6, 1883, Professor Bigelow says:

"However otherwise arranged, a satisfactory aspirator should have some device near the catheter to act as a trap for *débris* and secure every fragment that has passed it. The chief difference among evacuators now is in the certainty with which they retain the fragments they have aspirated. Any instrument will draw out the fragments, but few hold them securely, for the *débris* does not always fall into the glass receiver, nor does it always remain in it. On the contrary, it is easily carried back into the bladder. This de-

feet in the action of the evacuator has received little attention from surgeons, although it is the only point connected with the instrument which offers any difficulty whatever. Until recently it has been remedied only by sacrificing simplicity in the apparatus."

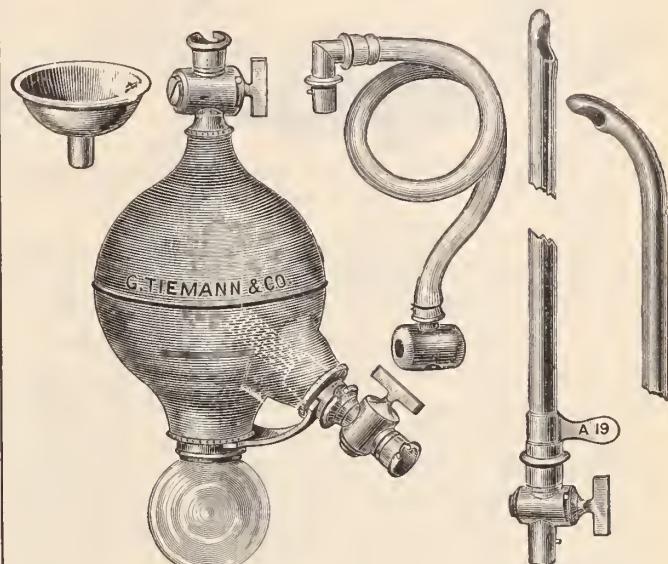

FIG. 1.—Professor Bigelow's latest evacuator. Weighs twenty-four ounces ; filled, weighs thirty-four and a half ounces ; holds ten and a half ounces.

In this latest instrument of Professor Bigelow the route to the bladder has been changed to correspond with that of Sir Henry Thompson, in which the evacuating tube was attached directly to the evacuator, without the intervention of tubing, as in Professor Bigelow's previous instruments, thus apparently giving both surgeons the advantage of the same and the shortest route to the bladder. In place of various contrivances—ball, valves, traps, and strainer of previous modifications—a perforated tube was inserted into the lower side of the rubber bulb and continuous with a stopcock which connected directly with the evacuating catheter. This perforated tube or strainer was alleged to prevent effectually the return of *débris* into the bladder, and, in operation, it was proved to do so; but the strainer, while working perfectly in experiments with crushed coal or coral, when in practical use quickly became so clogged with mucus and coagulated blood that the frequent cleansing of the strainer during operation became necessary. This fact led Sir Henry Thompson to say (London "Lancet," 1883) that "all the perforated tubes and strainers get blocked with *débris* (as I found long since) in the human bladder, not with coal in water, so as to be practically useless there." As Professor Bigelow had, in the "Lancet" of January 6, 1883, presented a large-sized woodcut illustrative of the absolute inability of Sir Henry's then latest instrument to prevent the return of *débris* to the bladder, with ample descriptive text, it might be suggested that his opinions of perforated tubes and strainers had been somewhat modified by personal feeling. The accompanying accurate copy of a photograph of the perforated tube or strainer of Bigelow's improved evacuator, taken at the close of an operation at St. Luke's Hospital not long

sinee, will, however, go far to justify Sir Henry's statement.

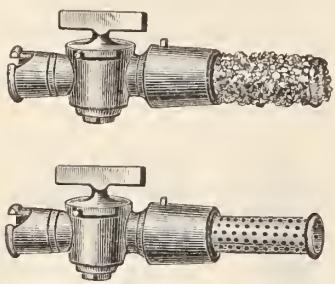

FIG. 2.—Clogging of the tube. The upper figure shows the obstructed tube; the lower one, the same after cleansing.

In cases free from mucus and pus and perfectly free from any admixture of blood with the water during operation, there will not be any noteworthy difficulty; but if there is a trace of blood present in the progress of the procedure the perforated tube will inevitably and promptly become blocked, as in the photographic reproduction above presented. The instrument was a good one for practical purposes before the addition of the perforated tube; but it was open to the objection, as shown, that *débris* was likely to be left in the bladder after operations with it. Save under very favorable conditions or by the frequent cleansing during operation, the objection evidently remains.

Sir Henry Thompson's experiments and modifications finally culminated in an evacuator which, equally in action, prevented the return of *débris*, without being open to the objections made against Professor Bigelow's instrument. This improved aspirator was presented in the London "Lancet" of April 12, 1884.

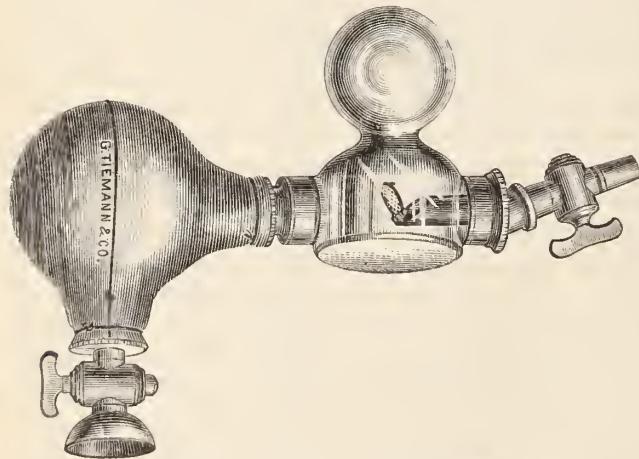

FIG. 3.—Sir Henry Thompson's instrument (improved, 1889).\* Holds 12½ oz.; weighs 27½ oz. (Troy) empty; 40 oz. filled.

"The improvement consists in a light, loosely hanging valve of fine wire attached by a simple hinge to the end of the evacuating tube, which terminates within the glass trap of the instrument. When pressure is made on the India-rubber globe, and the current flows by the evacuating cathe-

ter into the bladder, this light valve is driven close to the aperture and no *débris* can leave the glass trap. When the pressure is removed and the current returns from the bladder, the valve floats widely open and permits the *débris* to enter unchecked. The wire valve is circular in form, and its border, being flat and thin and about the tenth of an inch wide, is delicately sensitive to the movements of the current, and responds to the slightest impulse of the hand on the India-rubber globe." "But," Sir Henry further remarks, "I am quite satisfied that, with my last published aspirator (the one so elaborately criticised by Professor Bigelow in the 'Lancet' of January 6, 1883), as well as with the form now described, no *débris* returns to the bladder if the instrument is properly used, when, of course, the valve is unnecessary. Few persons are aware that very slight but quickly made pressure on the globe, sufficing to transmit only six or eight drachms of fluid into the bladder, generally removes more *débris* than a powerful impulse which transmits, at one act, all the fluid contents of the globe, or nearly so. When employed in the manner last named the valve becomes useful, and only then is it required."

At the commencement of the evacuator contest I was using very satisfactorily the original Bigelow instrument, and was, at the time of the notable discussion in the London International Congress of 1881, under the impression that it was the best then in use. During that discussion Sir Henry Thompson accorded to me a fair share of the honor of contributing something toward the ultimate success of the operation of removal of vesical calculi at a single sitting. My distinguished countryman, Professor Bigelow, however, neglected to give me the credit of the previous discovery of the normal urethral caliber, through which alone the rapid evacuation became possible. Not desiring to assert my claim as a grievance, I determined, if possible, to invent another evacuator and, in describing it, to write the history of evacuators in general; in this I proposed, while acceding honor where honor was due, to take what I believed to be my legitimate place in the preliminary history of litholapaxy.

Two years after—viz., in November, 1883—I presented and demonstrated my first evacuator at a meeting of the New York Academy of Medicine, and read a paper in which "the removal of *débris* from the bladder after lithotomy" \* was fully considered, with representations of previous instruments which had been in use for that purpose, adding those of my own, and in which, while it was distinctly shown that Professor Bigelow did not discover the increased capacity of the urethra, which alone made his operation possible, and also that he did not discover the tolerance of the bladder to prolonged instrumental interference; yet, as I there maintained, "he did much more—he utilized the knowledge which he, in common with other surgeons, possessed. He had the inspiration to conceive of its value as a factor in a great life-saving operation. He seized my de-

\* This cut, which shows the swinging trap of Sir Henry Thompson's instrument, is taken from the latest modification (1889), wherein the general form of the instrument approaches more nearly to that of the author (see Fig. 1).

\* Subsequently published in the "Medical Record," and in a reprint (1883) entitled "The Simplified Evacuator for the Removal of Débris from the Bladder, after Lithotomy." New York: G. P. Putnam's Sons.

onstration of an average urethral caliber of 32 mm. in circumference. He joined it with his knowledge of the tolerance of the bladder to legitimate surgical procedures, and litholapaxy was born. He had the courage, the surgical knowledge, the skill, the inventive mechanical genius, and the perseverance to carry it, *vi et armis*, to a successful maturity, thus finally achieving one of the most brilliant surgical triumphs of modern times."

My own instrument was constructed on an entirely different plan from those of both Professor Bigelow and Sir Henry Thompson. Having appreciated the difficulties of overcoming the alleged faults of both, I endeavored to accomplish evacuation without return of the débris, independently of traps, valves, or strainers. This was effected by a simple breaking of the currents to and from the bladder, so that the débris should be released *in transitu* and drop down into a receiver arranged to be a perfectly dead point.

In its practical working it was found fully equal in its evacuating power to the improved instrument of Bigelow, with the advantage that, without trap or strainer, no débris was returned to the bladder. It was found, however, that, under circumstances where, during the operation, it became desirable to introduce an additional amount of water into the bladder, this could only be effected with considerable inconvenience—much greater than in Bigelow's or Thompson's instruments. In 1885, therefore, a tap and stop-cock were added at the end of the rubber bulb, as shown in Fig. 4, so that, when it was found desirable to introduce addi-

years. The only real embarrassment which was found in the use of this evacuator was from the weight and inconvenience of manipulation of the two stop-cocks, which objection obtained equally in the instruments of Sir Henry

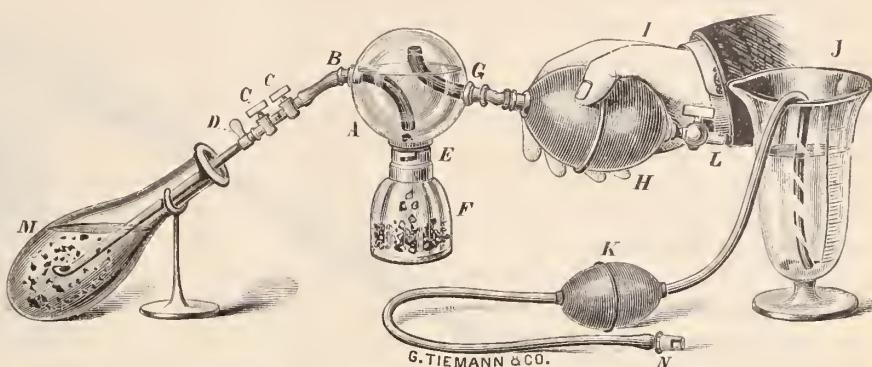

FIG. 5.—The Otis evacuator. With Davidson syringe and graduate.

Thompson and Professor Bigelow. At the suggestion of my son, Dr. William K. Otis, who had noticed the greater lightness of the evacuator of Dr. Ultzmann, of Vienna, I substituted hard-rubber fittings similar to his, and, in the course of experimentation which this change suggested, removal of all intermediate connections between the glass reservoir, the rubber bulb, and the evacuating catheter, was found practicable, decreasing the weight and adding to the ease in handling the instrument. It was then discovered also that a stop-cock was not necessary to prevent the water from flowing from the evacuator, this being effected by atmospheric pressure alone in any position which the handling of the instrument required, and that only when laying it down was any water liable to run out. For use in this event, a simple plug of hard rubber, attached by a string, was alone necessary.

The successful elimination of one stop-cock, previously supposed to be the most important and still absolutely essential in the instruments of both Bigelow and Thompson, directed attention to the possibility of getting rid of the remaining stop-cock on the evacuating tube, which seemed desirable in order to prevent loss of water while attaching the evacuator to it after the crushing. It was ascertained in actual practice that, by changing the routine of operation a little, this stop-cock was also wholly unnecessary. These important changes decreased the weight

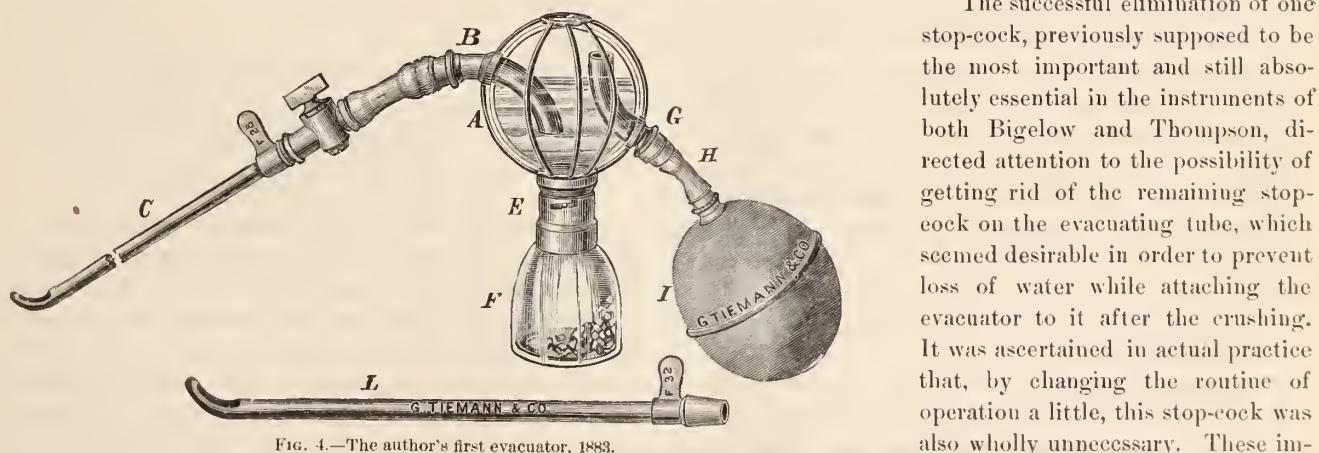

FIG. 4.—The author's first evacuator, 1883.

tional water into the bladder, this was done with great ease by attaching the discharge-pipe of the Davidson syringe to a stop-cock (at L), while the supply end is immersed in a vessel (preferably a large glass graduate) filled with water at a proper temperature. The easy attachment and detachment of the Davidson syringe allow any desired amount of fluid to be introduced into the bladder without delay or inconvenience. With this addition the instrument did most satisfactory service in my hands during the following two

to such an extent that, when filled, my perfected evacuator weighed six ounces less than Professor Bigelow's empty. Now, instead of attaching the evacuator to the evacuating tube immediately upon its introduction into the bladder after crushing, the fluid was allowed to flow out, carrying with it all the fragments that could thus be washed out; then, deliberately attaching the evacuator to the tube, the desired amount of water for working the instrument easily was introduced by means of the Davidson syringe, which

was connected with the rubber bulb. The syringe was then attached, and the evacuation deliberately proceeded with. It was not found necessary to press the end of the evacuating tube to the extent of depressing the bladder floor, so as to make the portion with which it is in contact the lowest point, as advised in using the evacuator of Professor Bigelow; but the current was sufficiently strong to draw out the *débris*, if the tube was simply well introduced into the bladder cavity.

Among the tests which were originally made to prove that the receiver was a perfectly dead point, and that fragments once deposited in it were thus entirely out of the influence of the currents passing to and fro during evacuation, was that of filling my evacuator completely as for ordinary use, then detaching the reservoir, emptying it, refilling it with glycerin, and then reconnecting it with the reservoir. A small quantity of crushed coral (which more nearly resembles vesical calculus than coal) was introduced into an ordinary soda-water bottle, and this half filled with water, to which a little ink had been added. On working the bulb, the fluid thus colored was seen to pass back and forth through the reservoir, but not in the least mixing with the glycerin, while the coral was drawn out of the bladder in the inky current, and, receiving its impulse and direction from the discharge-pipe, was disengaged from the colored medium, and, dropping down through the clear glycerin, was deposited at the bottom of the receiver. This experiment, which proved in a striking manner the perfect retention of the *débris* in the receiver during evacuation, was subsequently found to work admirably in actual practice; and in all operations, for the last two years, where blood was present in sufficient quantity to obscure the fluid, I have used the glycerin with great satisfaction. Without it, it will occasionally be difficult, and sometimes impossible, to tell whether the evacuation of the *débris* is proceeding satisfactorily without disengaging and emptying the receiver.

The changes which have been made in the old instrument are as follows:

1. Removal of all stop-cocks.
2. Removal of tubing between bulb and globe and between globe and evacuating tube, thus making the instrument more compact, and the distance from the bladder to the receiver the shortest possible.
3. Introduction of hard rubber in place of metal wherever possible, giving the utmost lightness.
4. Making the tube apertures in the globe oval instead of round (Dr. W. K. Otis's suggestion), and thus giving the greatest security against their getting loose and leaking.
5. Increasing caliber of evacuating tube where it enters the globe, thus securing a greater rapidity in delivery.

It is now maintained that this latest evacuator presents

the following advantages over all other instruments now in use:

1. Perfect trapping of all fragments without the use of any form of valves, perforated tubes, or strainers.

Fig. 6.—The perfected Otis evacuator. Holds eight ounces; weighs ten ounces empty; eighteen ounces filled.

2. Shortest possible route of fragments from the bladder to the receiver.
3. Absence of all stop-cocks between the bladder and receiver.
4. Ease of filling and perfect control of the amount of water in bladder during evacuation.
5. Lightness, compactness, power, and facility of manipulation.
6. In that the fragments being visible from the moment of leaving the tube until removed from receiver, it can be seen that they do not return to the bladder.

5 WEST FIFTIETH STREET, NEW YORK.

NOTE.—The original Otis evacuator was manufactured by Messrs. George Tiemann & Co., surgical instrument makers of New York, who, with much pains and skill, have aided me in the succeeding changes necessary to bring the instrument finally to its present state of perfection.

F. N. O.

## ANGULAR CURVATURE. INTERDEPENDENCE OF STRUCTURE AND FUNCTION OF THE SPINAL COLUMN.

BY GEORGE H. TAYLOR, M. D.

VERTEBRAL disease, without question, has its source in conditions unfavorable to a sufficiently vigorous vitality. It follows that whatever is adapted to correct these conditions by substituting the more favorable conditions for the less is remedial. True remedies necessarily bear a philosophical relation to the sources of the malady. However urgent and aggressive symptoms may be, if they are effects of a hidden cause, remedies which fail to include these causes are impotent. The stream flows on, while the sources continue the supply. It hence too often happens in vertebral cases that while the physician palliates the pain, fosters the hopes, and opposes the exterior changes of contour of the spine, he has the mortification of noting the almost imperceptible diminution of strength of his patient, and of feeling a deepening consciousness of the inevitable doom.

The medical error is that of blending causes and effects in estimating the nature of the affection, and of practically

restricting his efforts to the latter. Perhaps also he estimates too highly the remedies at his command applicable to the sources of the disease. Vertebral disease exists potentially in its sources rather than in the register of its progress afforded by the shape of the column. But the sources are *functional acts*, and such acts are the only conceivable way in which structure can be either built or repaired.

In vital objects, therefore, structure is indissolubly associated with function, whether health or disease be the product. These two conditions are not opposite or antagonistic to each other, as the sufferer is apt to think, but degrees of the same thing—stages arrived at by function, ranging from perfection down through all forms of imperfection. Depressed and perverted function is disease, or at least its commencement, whatever its mode of expression may be. Such depression portends a corresponding recognizable condition of the structures to which the function belongs.

These statements express a general law of the vital organism. The law is a necessity arising from the nature of vital processes, the unceasing mutation of the *ingredients* serving vital uses. The word *nutrition* includes the sum of these changes of substance in the vital organism. Nutrition implies of necessity the two mutually dependent acts of supply of material to vital structures and expenditure or dismissal of the same. All remedies, therefore, from equal necessity, take effect in one or both departments of nutritive activity.

In all branches and departments of therapeutics the aim is the restoration of functional acts to a due degree of perfection. That such is the legitimate and, in fact, the only practicable way of building and repairing the organic structures is never doubted. Remedies are selected to aid and modify functional acts, not to obstruct, harass, or suspend them. Thus incited and guided, function approaches its normal degree and quality, and structural substance is re-enforced and solidified.

The reasonableness of these statements appears in bold relief when applied to different distinct functional parts of the organism. In disorders of the respiratory, the digestive, the circulatory, the pelvic, the nervous, and other parts of the body having plain functional duties, remedies are employed to assist the processes of which the respective organs are the seat. So far as structure is involved, its reparation is trusted to the consequences of improved and perfected function. The destinies of the two things are naturally and inseparably interlocked. These principles are obvious and probably trite, but are nevertheless invested with a world of meaning in their application to vertebral affections, their causes and consequences. The several tissues of the spinal column afford no exception to the principles above outlined, but, on the contrary, present unequivocal and abundant confirmation of them.

Reparation of diseased vertebrae is therefore to be rationally sought through a judicious adjustment of those activities which are *natural* to its tissues, and which in health maintain the normal state, to their impaired and weakened condition. Indeed, health is but a continuous

reparation; the same effect follows the same causes, adjusted in degree in case of feebleness and impairment.

It is unfortunate for the spinal sufferer and for the therapeutics of the spinal column that the correctness of the above-stated principles has hardly been tested, even for the purpose of refutation. The physiology of the column, its tissues and their functions, has been misunderstood and misinterpreted, and therapeutics has consequently been misdirected. The immediate purpose is to present the neglected elementary facts, which lead to a better selection and use of remedies for spinal affections.

The development of this purpose requires frequent reference to elemental facts in anatomy and physiology. It is important that the reader have an accurate picture in his mind of these facts, including the distinct separate portions of the spinal column, its tissues and muscles, and the purpose these serve in health. In the descriptions of those which follow, all details not useful for advancing the central purpose are omitted.

The spinal column is composed of several distinct anatomical parts, whose functions are associated. It consists of bones, cartilages, ligaments, tendons, canals, and interosseous spaces, filled with fluids. At each side of the column and closely associated with it are large and powerful masses of muscles. These muscles control the position, the shape, and the motions of the column. In doing this they determine the outflow and inflow of its nutritive fluids, and therefore, to a large extent, the conditions for its health. This will be better seen when each anatomical part is examined separately and its intrinsic needs are ascertained.

The *bones* are a series of superimposed blocks or segments, called *vertebrae*, extending from the head to the lowest bone or sacrum. The lower vertebrae are broad, adapted to sustain greater weight; the size gradually diminishes upward. Those opposite the chest articulate with the ribs; those of the neck are narrower in proportion to height. They have very similar external appearance, being broader at the articulating faces, somewhat rough exteriorly, thus increasing the surface for attachments of tendons and muscles which engage the column. All have posterior projections or *spinous processes*. These are long at the neck, the length diminishing with each vertebra downward.

A remarkable peculiarity of the vertebrae is their capacity for fluids. A dried vertebral bone is light compared with other bones, like cork compared with wood. The division of one of these bones shows an interior of spaces or cells, which communicate freely with each other. The divisions are formed of very thin plates or *laminae* of bone which intersect each other, giving an appearance resembling fine sponge. The exterior shell of bone is also very thin.

Although in the dry state the vertebral bones are inelastic, unresisting, and brittle, these qualities are reversed in the vital state and when saturated with moisture. They now have great strength united with elasticity. The thin bony exterior and the thin interior laminae are separately very yielding; united, they acquire resisting power without sacrificing the elasticity of the separate parts. The fluids which the interior cellular spaces contain contribute to both the resisting power and elasticity of the whole, for these fluids

are free to move through all the cells in consequence of their intercommunication. When, therefore, pressure is applied to any point of the exterior, the fluids recede to other parts, and at the same time mechanically diffuse the pressure throughout the interior laminae. The vertebral mass is therefore constructed with a view to elasticity as well as resistance.

The intervertebral cartilages appear to be nearly structureless and devoid of fluid spaces; their function would seem to be mainly that of elasticity. They are susceptible of slight extension by the removal of perpendicular pressure, while vertebrae appear to require a shifting of pressure from one to another part of the transverse diameter in order to develop the elastic property. The one tissue mitigates shocks from arrested motion, the other increases the extent of the lateral motions of the column. The elastic properties of the two classes of tissue supplement each other in the physiological rôle.

The ligaments and tendons which invest and unite the junctures of the vertebrae serve to increase the resisting power of the spinal column and to render it a mechanical unit. These tissues also aid in extending the action and power of the spinal muscles attached to the column.

*Spinal Elasticity.*—The spinal column divested of its muscles and separated from its natural connections would have very little sustaining or resisting power. It would easily yield or bend in obedience to gravitation or whatever force might bear upon it. The spinal column, in other words, is *flexible*, capable of bending in all directions; and it is also *elastic*—that is, possesses the power to return to the initial position.

The elasticity of the spine has been held to reside chiefly if not entirely in the intervertebral cartilages. The evidence is strong that a part of the columnar elasticity, probably a large part of it, in healthy animals and man, is an inherent property of the vertebrae; that it is an indispensable function of vertebrae; that this property may diminish with deterioration of health, and especially with diminished power of spinal muscles; and that it may return with improved health and restoration of the muscles which serve the elastic function. The evidences supporting the proposition that the vertebrae are elastic, a part of which have been mentioned and others to be introduced, are the following:

The structure of the vertebral bones eminently conduces to that function, while a structure resembling that of other bones would forbid it.

The unique combination of fluids with the structure, both uniting while dividing its minutest parts, conduces to the same end.

Cartilaginous elasticity alone is insufficient to account for the *degree* of flexion, and consequently the extent of the elasticity, constantly witnessed in animals and man in health. A part of it, therefore, devolves on other tissues of the column—the vertebrae.

The elasticity of vertebrae is strongly indicated, negatively, by pathology; for whenever they are for a season forcibly deprived of the exercise, the elastic quality, they approach and finally assume a morbid state.

Therapeutics even more strongly indicates, positively,

that vertebrae have elastic properties; for, when suffering unmistakable hyperæmia, the exercise of the elastic quality of the spine in a proper way is the most certain and powerful remedy for the removal of this condition and its consequences. This shows that motions which involve elasticity are a natural function and constant in health. The proofs of the last two statements will appear in the proper place.

*The Spinal Muscles.*—The large, longitudinal masses of flesh which give the rounded form to the back are the spinal muscles and their covering of skin. These muscles fill the V-shaped space or groove each side of the spinous processes, and the outward convexity or bend of the ribs. The visible exterior fails to indicate their thickness; but this is approximately measured by the length of the spinous processes.

The spinal muscles are related to the column in two ways, which together determine the functions and health of the column. A thorough understanding of these relations is imperatively necessary for those whose purpose it is to rectify spinal faults and restore columnar tissues. One of the functions of these muscles is universally understood. It is that of causing the column to bend at will in any chosen direction, and of sustaining it in any chosen position. This purpose is effected by such graduated opposition of muscular action as shall secure the desired result. The action is an interplay of mechanical counter-forces. Whether spinal flexion or a special fixed form of the column is produced, it is equally the result of the tension of some combination of spinal muscles.

It hence appears that flexibility and elasticity of the column impose on its muscles the necessity of *constant work* or function, except only when the body is in a lying position, for, even when apparently motionless, muscular tension is required to maintain the position, and this involves action of the constituent elements of muscular substance. This muscular activity naturally responds to the need of the column of a vigorous collateral circulation promoted by the action of spinal muscles. It also indicates the vast amount of *chemical* function assigned to the same muscles of direct and undoubted advantage to the fluids of the vertebrae.

The other form of relation of spinal muscles and the vertebral column is an extension of that above described. The action of spinal muscles is the potential and effective *instrumentality of columnar nutrition*. Through their agency the physiological state is maintained. The absence of this agency is provocative of disease, liable to become localized in the column.

The details of the process whereby such important results as the nutrition of the column are secured become easily intelligible. In flexion or bending of the column its tissues become compressed at the concave side, and by equal necessity are drawn apart, stretched, or distended at the opposite or convex side. These are inevitable physical consequences of the physical cause operating—they are inevitable and constant. We will next see what occurs in the interior.

A certain portion of the fluids contained by the tissues of the column is unconfined and free to obey motor im-

pulses. These fluids move forward when in the least degree urged, the motion being of course in the direction of least resistance. It follows that the fluids of the compressed side of the column are diminished; those of the stretched side, at the same sectional area, are increased; they become displaced from the compressed portions and admitted into the stretched region. It follows that the nutritive fluids contained by the interspaces of the vertebral tissues which have been subjected to this act of flexion have become renewed and refreshed.

The term "fluids" in this connection includes the two kinds of blood. It further includes all mobile matters borne from arterial sources into the region of mechanical change described, and all similar substances capable of emerging therefrom through venous channels. The term further includes such matters as are rendered fluid and mobile through the chemical changes superinduced by the oxygen introduced from arterial sources, in connection with the coincident motion which facilitates, even enforces, the oxidation of unstable organic matters. It therefore includes the *exclusion* from the columnar region of products of waste, surplus materials, matters whose prolonged retention would threaten the integrity of vital structures; for prolonged retention of unstable organic materials in the extensive spaces afforded by the vertebral cells and canals is a condition which, if not actual disease, is one particularly favorable to its development, and therefore to the degeneration of the columnar structures. The phrase "change of local fluids" is therefore fraught with profound therapeutic as well as physiological significance; it is just what is most earnestly sought by physicians through numberless other channels, yielding only insignificant and temporary effects.

Physiological statements replete with therapeutic interests like the foregoing will necessarily be received with caution, not to say distrust. Except by the few physicians who, under the writer's guidance, have had the temerity to verify these statements by practical and satisfactory tests, their import has been but poorly apprehended. It is therefore proper to multiply analogies, illustrations, and explanatory statements, the better to enable those who desire to push this class of inquiries to do so to the best advantage.

The inability of the spinal column to urge forward, through its own tissues, its sanguineous and other fluids is obvious from the nature of these tissues. Bones contain no muscular or other self-contractile tissue. Such fluids as enter find egress without assistance from the bones. Students of anatomy learn that on entering osseous formations the arterial branches for the supply of nutrition are divested of their muscular coats, and the onward flow is due to other causes. This fact indicates the necessity, and therefore a provision, for such outflow.

The columnar tissues are not alone in requiring muscular power from a distance to aid their sanguineous outflow or venous circulation. There are physiological parallels in many parts of the organism. The *head* is an instance in point. A portion of its venous blood is in large sinuses, and the venous walls in general have feeble if any control of their contents. The brain contains no muscles to indirectly

affect the venous flow. Its blood must remain indefinitely stationary but for exterior assistance. This is supplied in the pump-like action of the chest, which constantly diminishes the pressure in it, and therefore the desired outflow of the cerebral fluids.

The contents of the *pelvic* venous vessels are similarly circumstanced, and have the additional disadvantage of ascending in opposition to gravitation. Yet the same means as before mentioned is effective for the same end, so long as chest-motions operate in the pelvic direction. The therapeutic effects of *increasing* the action referred to, when the contents of the pelvis are in a pathological condition, proves uncontestedly the reality and the efficacy of the force described.

The functions of the spinal column require its tissues to be too dense for an effective penetration of the force which is sufficient for the return of the cerebral and pelvic venous blood and excess of fluids. Nature provides an additional and far more certain and effective means, of which the tissues of the column supply the mechanism while the neighboring muscles supply the force required. The working of the columnar mechanism may be further illustrated.

If a green twig, supple and full of sap, be cautiously and strongly bent, it is evident that the woody fiber of the concave side is compressed, occupies less space; the longitudinal measurement is diminished. The interspaces between the fibers are made smaller and their fluid contents are necessarily in part displaced or *squeezed out*. This mechanical effect extends in diminishing degree to the center.

At the opposite or convex side of the same object a contrary condition of the structure simultaneously appears. The fibers are drawn apart, the dimensions of the interfibrous spaces are increased, and their capacity for fluids enlarged. The removal of pressure produces a condition of the interspaces known by the term *suction*, which is active and efficient in proportion to the rapidity of the motion. It is evident that in the green twig, or any object having similar physical peculiarities, the fluids would be driven from one side and become free to assume other relations, while the opposite side would at the same instant receive such other fluids as come within its sphere of attraction.

The physical changes to which the fluid portions or contents of the spinal column are subjected by its flexible motions are aptly shown in the mechanism and action of a common rubber syringe. The bulb is compressed and water issues from the pipe. The pressure being released, expansion causes inflow in exact measure to the outflow, its direction being controlled by valves.

The steam pump is a mechanism practically similar, and more completely typifies the action of the spinal column, inasmuch as its action is also double. The liquid urged from the *eduction* pipe by the movement of the piston corresponds to the similar consequence produced by flexion. The *induction*, at the other side of the same piston, simultaneously produced, corresponds to the admission of fresh arterial blood into the vertebral spaces by the same acts of flexion. In both cases the reversal of the motion exchanges the work of the two distinct parts, but continues the flow. In both cases, also, the fluids subjected to impulse have

been passed quite through the mechanism, and have emerged therefrom.

The nature of the columnar interspaces may obscure but can not hinder or delay the mechanical effect imputed to the flexile motions of the column. So long as these interspaces are *pervious*, the application of force insures the passage of the animal fluids. The abundance of interstices, all pervaded by fluids, compensates for want of size of the channels. The transfer is physical in its nature and is irrespective of other considerations.

The act of transfer described of the columnar tissues is not an exceptional but an ordinary incident in physiology; a local manifestation of organic law; a step in the grand procession of matter in vital objects. Its analogue exists in every part of the organism. The vital cell exchanges its contents; the muscles change their shape; there is alternation—*rhythm*—of heart, chest, digestive organs, etc. In each case the tissues impel contents. The marked peculiarity of the column is its deficiency of motor energy, and its appropriation of that expended by neighboring muscles, for its special physiological needs.

The fluids supplied to the spinal column in the way described are those whose inflow is insured by arterial pressure, and are necessarily arterial. Those disengaged are venous, and, outside the area of compression, mingle with the venous currents. After the disengagement the columnal fluids are the common property of the vital system; they are subjected to the organized depurating processes of the vital mechanism—to the vital chemistry—and the fate of whatever is derived from the spine, healthy or morbid, is indistinguishable from that common to all parts. All now depends on the completeness attained by this general chemistry, by the further physical act of oxidation, and the working of the physiological mechanism which secures the necessary degree and rate of oxidation.

*Practical Confirmation of the Preceding Statements.*—The practicing physician is usually pressed for time, and loses his disposition for physiological experimenting. He is content to pursue the therapeutic course commended by precedent, and he is but little influenced by unverified physiological statements. He requires practical satisfactory tests of the value of new and strange remedial methods. In the present instance such verification is not wanting. It is even unnecessary at present to cite the direct tests of the author and the physicians who have investigated therapeutic methods based on principles above explained. A more satisfactory evidence is that supplied from another but related branch of therapeutics—viz., that of the spinal cord.

The anatomical position and the physiological relations of the spinal cord largely merge its interests with those of the column. The cord is nearly inclosed by the column, and they have similar sanguineous connections. The cord, like the column, contains no muscular or contractile element; can impart no motor impulses to its fluid contents. Especially it has no direct control of its products of expenditure and semi-expediture.

Even more than the column, the cord is liable, in our civilization, to hyperæmia and its consequences. The cord is conceded to be the central source of sensory power. The

unbalanced exercise of the sensory and emotional faculties may give rise to an excess of arterial supply over the venous outflow from the same part. The vessels of the cord would then suffer from the deterioration within it of stagnant blood, affording symptoms more or less painful and often threatening the integrity of its tissues.

To remove spinal hyperæmia and the concrete and more or less fixed products of hyperæmia is, therefore, the recognized problem of the therapist. Whatever methods and details he pursues aside from temporary relief of pain, his radical design is to empty the cord of its superfluous fluids, and, if possible, to reduce local impediments to an emergent or fluid form. The present writer showed in the "New York Medical Journal," nearly twenty years ago, that *motor impulses*, however communicated, were capable of profound therapeutic effects. Stretching, by hanging and by horizontal tension, was a part of the processes by which impulses were communicated. These processes appeared to reach the *causative* factor. For the removal of hyperæmia and its consequences, under whatever name, is but a temporary advantage unless the physiological mechanism which returns the circulation from the cord and its precincts be also raised to the normal condition. The two objects are effected together by the alternation of pressure which is the natural and indispensable function of the column.

In the May 11th number of the "New York Medical Journal" Dr. William A. Hammond cites Dr. Motchkowsky, of Odessa, as having discovered the same principle as that above described—viz., that certain affections of the cord are relieved by alternations of the column. The word *stretching* is used as descriptive of the process, but continued tension is evidently not meant; only limited periods of suspension at judicious intervals. The process is called *stretching* the cord, but the present writer has found that no amount of tension that can be borne is capable of elongating the spine to a greater extent than occurs spontaneously, follows an hour's quiet sleep—viz., from three eighths to half an inch. If the suspension be by the arms, the practice soon enables the subject to bear the application of a surprising amount of tensile force without in the least increasing the length of the spine.

It is evident that the tensile force applied in these and similar processes falls upon the tissues of the column and its muscles rather than the cord. It would also seem that some term indicating *alternations* of compression, or of the weight sustained by the tissues of the column which actually occurs, would be more appropriate than stretching.

Longitudinal tension of the spine, however produced, necessarily falls upon its *resisting* structures; its physiological as well as mechanical consequences therefore occur in these. It is the vertebrae, the tendons and ligaments, the cartilages, and the longitudinal muscles in which involuntary contraction is incited that are primarily affected. The profound effects secured for the cord are rational consequences of these and are easily understood. In the hanging process the muscular action produced co-operates with mechanical changes in the tissues of the column before described, and the result is powerful revulsion from the cord. Its pent-up fluids, surcharged with matters inimical to vital-

ity, are drained away, and arterial blood charged with renovating power is introduced. Another coincident should not escape notice. The amount of air contained by the lungs in the position described is increased to the utmost just at the instant that both the spinal and chest muscles are at their highest possible activity. These acts co-operate to increase the oxygen actually employed, and therefore to diminish the unstable contingent of the organism—the disease.

The discriminating reader can not fail to perceive that *flexion* of the column and *stretching* by hanging or other means are processes potentially identical. They differ in appearance, not in substance, for flexion or bending causes the convex side to *stretch* or become extended to the greatest possible degree—far more than when the processes include both sides or the whole. The coincident compression of the other half or side of the column corresponds to discontinuance of suspension when the column again receives its normal pressure of weight. The flexion process has the apparent advantage of increasing at will this compression, an important element of alternation. Both acts may be simultaneously repeated so long as may be advantageous. Both forms of the process insure thorough diffusion of the blood, filling the capillaries of the whole system at the expense of hyperæmic parts, and act specifically upon the venous contents of the spine, and are equally advantageous for cord and column.

The considerations above presented appear to show in several distinct and conclusive ways that the flexible and elastic functions of the spinal column are not only natural but indispensable; that such acts are necessary for carrying forward the two branches of nutrition of its tissues, including the osseous, nervous, tendinous, cartilaginous, and muscular; that the location of its structures and their dense nature renders the influence of both the collateral circulation and of the forces which act elsewhere in the system insufficient, at least in weakly constitutions and under unhygienic conditions; and that the flexible and elastic functions are in these cases an all sufficient supplementary force.

**Syphilitic Disease of the Eyelids.**—J. Hutchinson, Jr. ("Roy. Lon. Ophth. Hosp. Rep." xii, 2), draws the following conclusions from his study of reported cases: 1. Late secondary and tertiary affections of the eyelids are met with most commonly in those who have suffered severely from their syphilis, especially those who have had rupial or tubercular skin eruptions or ulcers of the palate. 2. The upper lid is more liable than the lower one to be affected, though both are not infrequently involved. 3. The tertiary ulceration (gummatus) of the lids is more often met with in women than in men. 4. Not only do many cases of the latter resist specific treatment in a marked degree, but they show a strong tendency to relapse after being apparently cured. 5. As a rule, syphilitic ulcers and gummata of the eyelids are more painful than those met with on other parts of the skin.

**Citric Acid in Milk.**—Professor Soxhlet, a French chemist, has demonstrated that cow's milk naturally contains citric acid in an almost constant proportion of one grammie to every litre. A good animal yields, therefore, at a single milking, as much of this acid as is contained in two or three lemons, and the annual aggregate throughout an extensive dairying neighborhood must be something enormous. It occurs in the form of a calcareous salt.—*Druggists' Circular and Chemical Gazette.*

## DEAFNESS AS A RESULT OF NASAL AND DENTAL DISEASES.\*

By D. H. GOODWILLIE, M. D.

In order to better understand this subject, it may not be amiss to call attention to the anatomical relation of the internal nasal passages and that of the internal ear by means of the Eustachian passage, which intimately connects the two.

By reference to the illustration (Fig. 1) of an antero-posterior section of the head, the cavity of the nostril is shown *a*, *b*, *c*, represent one side of the nostril, the superior, middle, and inferior turbinate bones. Between these are three passages (*meatus*) ; the inferior meatus (14) is especially important to act as a drain for the secretions that fall into it from the nasal fossa and all the accessory cavities—namely, the frontal sinuses (13), tear duct, maxillary antrum and sphenoid (No. 1), and ethmoid cells.

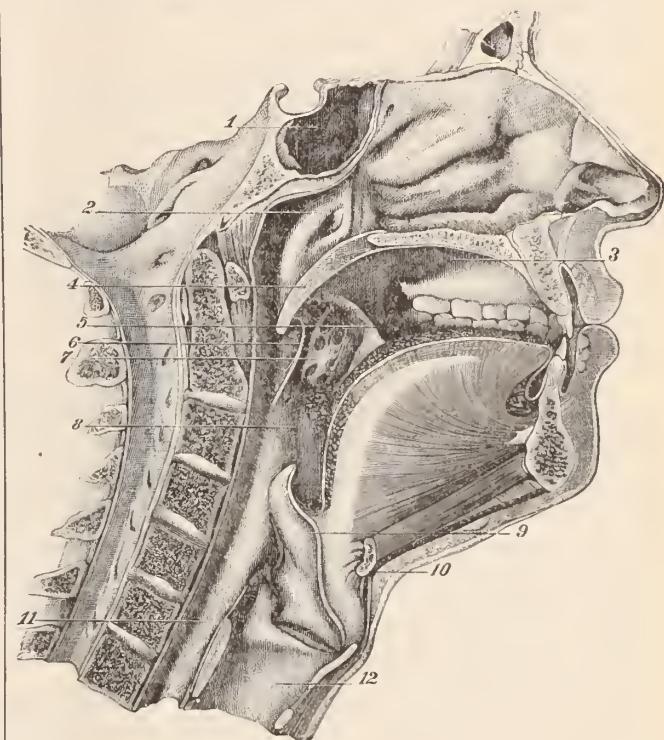

FIG. 1.

The nasal septum separates the two nostrils. At the posterior part of the lower nasal passage (14), and nearly on a line with it, is the Eustachian passage (No. 2) to the middle ear, which contains the tympanum with its contents, the ossicles, membranous walls, and mastoid cells.

The Eustachian tube (No. 2) is provided for the passage of the air from the naso-pharyngeal cavity to the middle ear. The naso-pharyngeal mucous membrane also lines the Eustachian tube, the cavity of the tympanum, the little bones, tendons, ligaments, muscles, nerves, the internal surface of the membranous tympani, and the fenestra rotunda, and extends into the mastoid cells. The tympanum contains air of the same density as that on the outside, in order

\* Read before the Section in Laryngology and Rhinology of the New York Academy of Medicine, April 23, 1889.

to maintain the tension on the inner and outer side of the ear drum; in this condition there will be perfect hearing.

The air passing through the Eustachian tube to the middle ear is controlled in a great measure by the action of the tensor and levator palati muscles. The tensor palati muscle arises from the spina angularis of the sphenoid bone and from the cartilage of the Eustachian tube. It passes around the hamular process of the pterygoid, and there expands into the broad aponeurosis of the anterior surface of the soft palate. When in action it dilates the orifice of the Eustachian tube.

The levator palati arises from the lower surface of the apex of the petrous portion of the temporal bone and from the cartilaginous portion of the Eustachian tube. After passing into the pharynx it spreads out on the posterior surface of the soft palate as far as the middle line, where it blends with its fellow of the opposite side. By its contraction it raises the velum and soft palate. The increase in diameter has a tendency to close the orifice of the Eustachian by elevating the lower border.

By the conjoined action of these muscles in the act of swallowing, the Eustachian tube is rendered patent, and it is thus that intratympanic air pressure is regulated. The free ventilation of the tympanum by the action of these muscles upon the pharyngo-Eustachian orifice is essential to perfect hearing. Any condition that causes stenosis of the tube by thickening of the mucous membrane and retention of the secretions, or interference with the action of the muscles, will prevent the equilibration of intratympanic pressure, and will eventually end in otitis media and its sequelæ.

In several cases that have come under my observation where all the internasal bones had been destroyed and carried away by necrosis, along with the end of the nose, giving an excellent view of the Eustachian orifices, I have been able to observe the action of the muscles, both by direct view and also by a small mirror passed through the nasal cavity to the naso-pharynx, by which the condition of the orifice during muscular action in the opening of the Eustachian tube was reflected. In these cases there was no disease of the ear or Eustachian tube, and hearing was normal.

The action of the muscles may also be demonstrated, when there is stenosis by the thickening of the mucous membrane in the Eustachian tube, by inflating the tympanic cavity; the excess of air will be released by the opening of the tube in the act of swallowing.

The sympathetic nerve connection between the ear and other organs by the anastomosis of the tympanic plexus with nerves supplied from other parts accounts for the reflex phenomena so often observed. By means of branches from the otic ganglion, the inferior maxillary nerve is intimately connected. By the vidian nerve from Meckel's ganglion the superior maxillary of the fifth pair is joined to the tympanum.

The carotid plexus of the sympathetic sends a branch to the glosso-pharyngeal and makes connection between the ear and superior cervical ganglion of the sympathetic. There are various other nerve anastomoses that bring the ear in connection with other organs.

An irritation produced in the external auditory canal

will produce various sensations in the nose, pharynx, or larynx, manifested by coughing, swallowing, or some nasal irritation. In diseases of the nose, throat, or teeth, when gradual and long continued, a reverse condition will take place until trophic changes are produced and deafness is the result.

The intranasal sensory nerves may be divided into those of special and those of general sensation.

The olfactory nerve, a special nerve of smell, occupies the superior and middle turbinated bone and upper part of the septum.

Nerves of general sensation are the nasal branch of the ophthalmic, which supplies the upper and anterior part of the septum and outer wall of the nasal; the anterior dental branch of the superior maxillary, which is distributed to the inferior meatus and inferior concha; the vidian nerve and the upper anterior branch of Meckel's ganglion supply the upper and back part of the septum and superior turbinated bone; the naso-palatine nerve, which ramifies upon the middle of the septum; and, lastly, the anterior palatine nerve, which supplies the middle and inferior turbinated bones.

It may be seen how, from an intimate connection by continuity of tissue, a catarrhal inflammation of the nasal or naso-pharyngeal mucous membrane may be conveyed to the vascular and sensitive mucous membrane and periosteum of the middle ear, and, by developing disease, may impair the function of hearing.

The vast majority of the diseases of the middle ear manifested by deafness are the direct result of nasal or naso-pharyngeal catarrh. A very small minority are from lesion of the dental organs directly through reflex nerve influence, or more often indirectly, by setting up a degenerative process, either producing or accompanying nasal disease, which may end in middle-ear disease and deafness.

The naso-pharyngeal diseases that act as factors in the production of middle-ear disease in a large majority of cases are as follows, namely: 1. Hypertrophic rhinitis, a perverted condition of mucous membrane; hypertrophy of soft tissue covering the turbinated bones, especially the inferior, which contains erectile tissue; occasionally bone hypertrophy; deflected cartilaginous or bony septum, with occasional exostosis. 2. Growths in the nose or nasal pharynx, fibro-gelatinous polypi, naso-pharyngeal fibroid tumors, and adenoid growths. These either close up the Eustachian tube by mechanical pressure or induce a catarrhal condition. 3. Atrophic rhinitis, in which there is a destruction of the internasal tissue, a foetid, pasty catarrh that may also extend to the Eustachian tube, tympanum, and other accessory cavities. 4. Hypertrophy of the tonsils, associated with catarrhal conditions, indirectly obstructs the Eustachian orifice by impeding the action of the muscles and thus prevent intratympanic air renewal. 5. Hypertrophy of the palate from tumors, gummatous, and abscess. 6. Paralysis of the palate, defective action of the muscles from cleft palate, congenital or acquired. In cases of cleft palate I have repeatedly refused to operate on account of suppurative otitis media, although all else was favorable; diphtheria, pertussis, scarlet fever, and measles are most prolific sources in childhood of rhinitis, eustachitis, and otitis media; small-

pox, syphilis, and the various specific diseases of the nose and throat.

The sympathetic nerve connection between the ears and teeth would naturally lead us to a knowledge of reflex disease in these organs. In a paper read before the New York Neurological Society, January 3, 1876, and published in the "Journal of Nervous and Mental Diseases," April, 1876, on "Lesions of the Trifacial," I called attention to the reflex nervous irritations from lesions of the dental organs and maxillary bones as the prime causes of facial neuralgia and as a factor in the production of other pathological conditions in associate parts, with a report of a large number of cases as coming under personal observation.

The branches of the trifacial appear to be very susceptible to reflex actions, which are often peculiar in their manifestations. While one person may suffer from a comparatively slight irritation, in others the same condition will produce little or no results whatever. A low vitality, a great mental strain, a rheumatic or gouty diathesis are often a predisposing cause.

Dentition is a physiological process, and under normal conditions of physical development ought to give little or no disturbance to the vital powers. The physiological process of teething is too often considered a predisposing cause to disease. Now, the reverse is nearer the truth when we consider the anti-physiological method in which children are reared. Non-tissue-building food, bad air, improper clothing, too little sleep, and all the ailments that come at this age will produce ill-developed organs, and consequently faulty functional activity. Under such conditions the dental nerves are quite susceptible to morbid impressions, which may be reflected to adjacent organs. The same influence that produces a reflex nervous action from an erupting tooth may also set up a nasal catarrh, and this may end in ear disease; but a reflex nervous action from an erupting tooth of the first dentition without other complications may only result in otalgia. Middle-ear disease must be preceded by catarrhal disease of the internasal mucous membrane.

At the full development of second dentition, aural disease that may arise from any dental lesion will probably result from the following direct or indirect causes, namely: Pulpitis by exposure of the dental pulp by caries; this may also result in suppurative pulpitis, to be followed by a maxillary abscess. Osteo-dental development in the pulp cavity, periodontitis, periostitis, impaction of permanent teeth in the maxillary bones, maxillary abscess opening into the nasal cavity or into the antrum, setting up antrum disease, to be followed by purulent naso-pharyngeal catarrh and otitis media. Improper artificial dentures are occasionally a source of reflex troubles. Abnormal respiration through the nose from catarrh in its many forms produces also abnormal pulmonary respiration. From the same cause the air in the vault of the pharynx is in a rarefied condition and abnormally affects the intratympanal air renewal.

From what has been said it may be learned that, in order to successfully treat middle-ear affections, all naso-pharyngeal disease must be removed, and that the otologist must of necessity be also a rhinologist. I can not trespass

on your time to go into details on the treatment of the nasal and naso-pharyngeal diseases that may act as factors in ear disease, but there are, however, certain methods of treatment that I desire to bring to your attention.

One of the first things that is to be done in eustachitis or middle-ear disease is the treatment of the nasal catarrh; the removal of pent-up secretions and putting the parts into an antiseptic condition; then follow the treatment, whether it be medical or surgical. Some means must be employed that will accomplish this and do no harm to the diseased parts; the douche does harm and ought not to be used. The treatment can best be made by means of a spray of peroxide of hydrogen (fifteen per cent.). When the peroxide meets the secretion an effervescence immediately takes place, and the sticky, pasty, foetid mucus is changed into foam. Its septic nature is entirely changed, and it can then be readily blown or wiped from the nostrils. The peroxide\* is also a good germicide. Dr. B. W. Richardson, of London, in 1881 called my attention to its remarkable powers. A probe (Fig. 2) wound with cotton should then

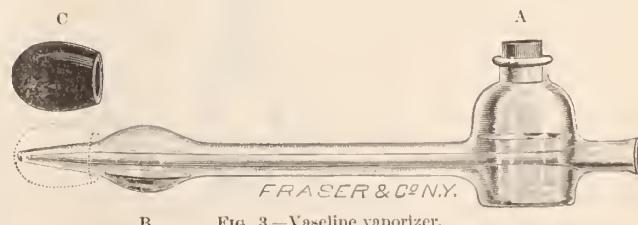

HAZARD, HAZARD & CO.  
W.F. FORD, N.Y.

FIG. 2.—Nose and ear probe and curette. Half size.

be passed into the inferior meatus far enough back to wipe the naso-Eustachian orifice. This should always be done before the Politzer or Valsalva inflation is used, thereby preventing the danger of blowing foul air into the tympanum.

Most thorough antiseptic means should be used before a surgical operation and in the after-dressings. All instruments to be sterilized by dry heat or steam.

For the treatment of eustachitis and otitis media (after the removal of the nasal disease) the most efficient means is in the use of the Politzer or Valsalva method—that is, applying medical vapors by inflation. The patient is directed to take a full inspiration and then to blow gently out through the closed lips; just as he begins to exhale, apply the vapor to the nostril; then immediately close the patient's nostrils and instruct him to breathe strongly out of the nose until the tympanum is inflated. The Politzer method can just as readily be used after the vapor medication has been applied. I have obtained good results from medicated vaseline placed in an instrument prepared for the purpose, liquefied by heat, and then vaporized by air-pressure (Fig. 3). After the nasal disease has been re-

B FIG. 3.—Vaseline vaporizer.

moved the Eustachian catheter or bongie may sometimes be of good service in opening up the tube.

\* "Peroxide of Hydrogen," by Dr. W. A. Dayton, "N. Y. Medical Journal," April 25, 1885, and "Archives of Otology," vol. xiv, No. 1, 1885.

The medicated vaseline I have had prepared for me by Fraser & Co., and put up in tin tubes of half an ounce each for convenience in filling the receptacle of the vaporizer A, Fig. 3. The medicated vaseline is heated to a liquid at the bulb B. The hard-rubber nose shield C is placed over the end *immediately* after the heating and before the application is made to the nostril. Application must be made promptly after the heating.

FIG. 4.—Electric nasal catheter.

Fig. 4 represents the electric nasal catheter for carrying an electrolytic current into post-nasal growths; used also as a Eustachian catheter or bougie. The catheter as now seen is armed with the Eustachian bougie, C, which is to be drawn in before it is used. The bougie is made quite flexible, to better facilitate its passage into the Eustachian tube. When the catheter is passed into the nostril, it is best known to be at the Eustachian orifice by viewing it with the rhinoscopic mirror through the naso-pharyngeal space. Note, for future guidance, the measurements on the scale by running the slide, B, up to the end of the nose; the length that the bougie is passed into the Eustachian tube is seen on the scale at A; it is at this end the electric current is applied. The Eustachian bougie is replaced by a needle when used on post-nasal growths.

The difficulty of a rhinoscopic examination may be facilitated by a palate retractor and a tongue depressor (Fig. 5). By a skillful use of these, the palato-pharyngeal space will be so enlarged as to allow a good examination of the naso-pharynx. By means of the rhinoscopic mirror all abnormal conditions may be seen, as also the passing of the Eustachian catheter or bougie.

FIG. 5.—Tongue depressor and palate retractor.

Nasal catarrh in childhood, especially after diphtheria and scarlet fever, should have prompt and efficient treatment to avoid deafness, improper respiration, alimentation, and development.

The young are very susceptible to any treatment that

wars against the enemy to their vital force in physical and mental growth.

All cases of catarrh in the upper air-passages do not result in deafness. I have repeatedly seen all the internasal bones taken away by disease and the hearing remain normal. Still, the fact remains that nearly all the middle-ear disease ending in deafness is the result of catarrh from the contiguous parts. Dental disease is often the primary cause of nasal catarrh (although it has not been so generally recognized), and the latter may produce deafness.

The following cases may serve to illustrate this subject in a practical way:

**CASE I.**—A. B. A., aged twenty-four, had hypertrophies of the turbinated tissues (Fig. 6, *a* and *c*), over both inferior turbinated bones, with abundant post-nasal discharge. Both tonsils very large, voice husky, deafness coming on for two years. The H. D. L.  $\frac{2}{4}$ , H. D. R.  $\frac{1}{4}$ . Removed both tonsils with the guillo-

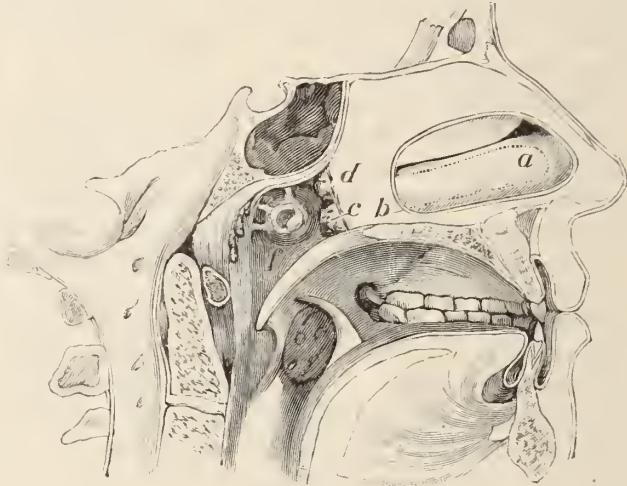

FIG. 6.

tine; then by the rhinoscope could be seen fibrous bands, *f*, passing from the edge of the Eustachian orifice to the pharyngeal folds. These bands were cut away; the turbinated hypertrophies, *a*, *c*, were scarified by the galvano-cautery knife; medicated inflations of the tympanum were applied; the catarrh decreased and the hearing returned. (Dotted line, *a*, represents the size of the inferior turbinated tissues after treatment.)

**CASE II.**—H. D., aged sixteen years, had diphtheria six years ago, with a large amount of false membrane in the nose and on the tonsils. His present condition is as follows: Very little nasal respiration; tonsils and hypertrophied uvula nearly fill up the naso-pharyngeal space; hypertrophied tissues over both inferior turbinated bones; deafness noticed coming on three years ago. H. D. R.  $\frac{2}{4}$ , H. D. L.  $\frac{2}{4}$ . Hypertrophied tonsils, uvula, and turbinated tissues removed, after which he recovered his hearing.

**CASE III.**—Rev. S. W. K., aged forty-eight years, consulted Dr. A. H. Buek for his ear trouble, but, finding upon examination that he had a muco-purulent discharge from his left nostril, the doctor kindly referred him to me. He gave the history of some tooth trouble three years before. At that time some temporary means were made use of, and it apparently passed away. Soon after, however, he began to suffer from facial neuralgia, followed by chills and fever and great prostration, which has severely affected his health. He was then treated for malaria. Following this was a severe rhinitis and post-nasal discharge and otitis media.

Upon making a careful examination, I found the left inferior turbinate bone entirely destroyed by necrosis, and a copious purulent discharge passing into the naso-pharynx. Post-nasal examination by the rhinoscope revealed the naso-pharyngeal opening of the Eustachian tube, left side, quite large and attached to the pharyngeal fold by fibrous bands; a muco-purulent tract down the posterior wall of the pharynx. H. D. L. by contact with a watch; H. D. R. normal. On examination of the mouth, the only remaining molar appeared dead. Suspecting this to be the origin of the trouble, it was removed, and a large trephine was passed up into the antrum by means of the electric surgical engine, and, upon its removal, about two ounces of exceedingly fetid pus passed out. This was a sufficient cause for all the local trouble, and of septicaemia instead of malaria. The patient's hearing began to be affected soon after the pus from the antrum entered the nostril, setting up catarrh and producing the necrosis of the inferior turbinate bone. The inflation of vapor of iodo-vaseline (white vaseline,  $\frac{1}{2}$  j; iodol, 3 j; menthol, one per cent.) to the middle ear, antrum, and all the passages, gave him immediate relief and resulted in great good after the cleansing. Now, after a year's treatment, his health is quite restored, and the hearing of the left ear is  $\frac{6}{10}$ , with no discharge from the antrum. By an examination of the molar tooth you will see the palatine root partially destroyed by the action of the pus. The hole made by the trephine through the alveolar process into the antrum is still kept open.

CASE IV.—D. H. G. had neuralgia on the left side of the head, with extreme sensitiveness at the tragus, with tinnitus aurium, which continued for some weeks. Teeth, ear, and nose were examined, but the cause could not be found. The pain suddenly stopped, but hearing not quite normal. After a few weeks the pain returned, with post-nasal catarrh and synovitis of the temporo-maxillary articulation. Teeth carefully examined again, and a small decay was discovered in the left superior wisdom tooth; the dental pulp was found dead and suppuration had taken place. Thus the mystery of the trouble was solved. The first neuralgic attack was produced by pulpitis, for after the pulp had died, most probably by strangulation of the vessels, the pain suddenly ceased. In a short time decomposition of the dead pulp took place, which excited suppuration in the surrounding cellular bone tissue about the apex of the root of the tooth. The pus found its way through the posterior alveolar process and then into the naso-pharynx, producing catarrh that extended into the Eustachian passage. H. D. L.  $\frac{15}{16}$ .

Treatment consisted in extracting the wisdom tooth, with the removal of any cellular necrosis; the soft parts were prevented from healing until the bone socket was filled with granulations. The post-nasal and Eustachian catarrh was treated by cleansing the parts with peroxide of hydrogen, followed by medicated vaseline vapor used by means of the Politzer or Valsalva method. The Eustachian catheter and bougie were used with good result. Hearing has returned and the nasal catarrh has quite gone. An occasional return of the synovitis is caused by exposure to severe cold winds.

CASE V.—Harry E., now fourteen years of age, had diphtheria when six years of age, followed by paralysis of the palate muscles and those of the lower limbs. There was false membrane at this time formed in the nose.

After his recovery from diphtheria he had an attack of scarlet fever, which was followed by nasal trouble, otitis media purulenta, and deafness (right ear discharging externally).

When I first saw him it was after his recovery from the fever, and his condition was as follows: Tall and slender in form, contracted chest, pleuro-plastic adhesions in posterior part of chest, weight one hundred and five pounds. His left nostril was closed by adhesion from a deviated septum to the turbinate tissue, and

with no respiration. The right nostril contained hypertrophic tissue, with little respiration. A post-nasal examination revealed a fibroid tumor growing from the pituitary fossa, and a thickening of the pharyngeal folds pressing against the Eustachian orifices, which were hypertrophied.

Treatment consisted in removing under NO, by means of my shielded nasal trephine (Fig. 7), the hypertrophied cartilage

FIG. 7.

and bone from the left nostril (the deviation and adhesion closed the nostril its entire length). After the operation one of my nasal intubation soft-rubber tubes (Fig. 8) was put into the nostril, thus giving the patient great comfort by permitting him to breathe through it. The tube was readily removed when

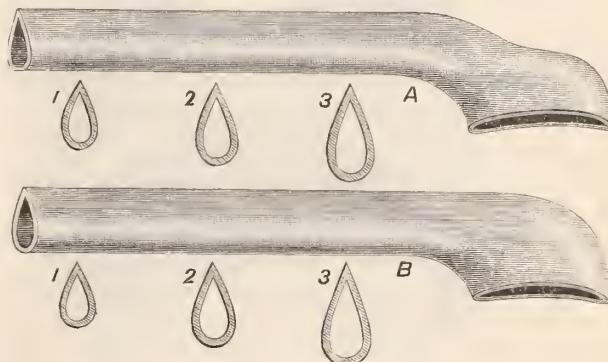

FIG. 8.—Nasal intubation tubes.

necessary for the cleansing of the nostril by peroxide of hydrogen, and as easily replaced. After having worn the tube for some three months and the parts had healed and were in normal condition, it was removed. The fibroid post-nasal growth was subsequently removed by means of electrolysis, the electrolytic nasal catheter and needle (Fig. 4) being used. By means of the inflation of medicated boro-vaseline vapors (white vaseline,  $\frac{1}{2}$  j; boric acid, 3 j; menthol, one per cent.), the ear trouble passed away and his hearing in both ears became normal.

CASE VI.—W. R. B., well developed and formerly very robust, has for several years been in a declining state of health, the cause of which appeared obscure. When first seen by me he complained of great exhaustion, with chilly sensations, fever and night sweats, pain in the right side of the face and head, skin sallow, liver torpid, and troubled with constipation and a muco-purulent catarrh discharging from right nostril. H. D. R. ear,  $\frac{6}{10}$ ; left ear and nostril normal. Believing his trouble to be from some septic origin, I discovered it in a maxillary abscess (which came from a decayed tooth filled some years since), the exit of the pus being into the nostril, setting up the purulent catarrh, extending into the frontal sinus and into the internal right ear, producing deafness.

The treatment consisted in trephining the abscess through the alveolus, and removing also some cellular necrosis. A fistulous opening was found through to the floor of the inferior meatus and into the nostril. By good antiseptic dressing to the abscess and nostril the opening from the abscess in the jaw into the nostril closed, after which the bone cavity soon granulated and healed. A cholagogue with saline mineral waters was administered, followed by tonics. Medicated vapor inflation was made to the internal ear, and after three months' treatment the patient was able to attend to his business. His hearing very much better. H. D. R.  $\frac{3}{4}$ .

CASE VII.—A. E. L., when quite young, began to suffer

from naso-pharyngeal catarrh, non-respiration through the nostrils, and consequently mouth breathing and defective pulmonary development, with nasal tone to voice.

This condition was produced by ailments incident to childhood, in which the nasal trouble received no treatment at the proper time. When I first saw her, at the age of twenty-two years, deafness had been gradually coming on for a number of years, until now the watch could only be heard by contact to the ear. The ear drums were contracted.

Fig. 9 represents the case. Inferior turbinate tissue hypertrophied and extending backward to near the Eustachian ori-

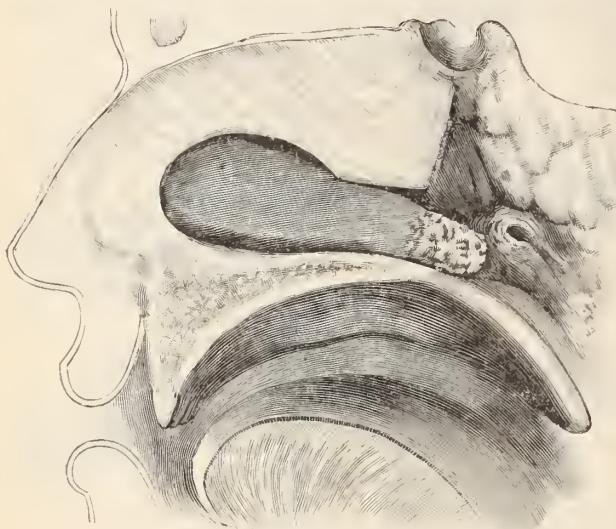

FIG. 9.

fice. By a posterior rhinoscopic view, by means of the mirror and palate retractor (Fig. 5), the adenoid growths could be seen pressing down on the Eustachian orifice, which, together with the catarrhal conditions of the tube, prevented air entering into the tympanic cavity.

After thorough cleansing with peroxide of hydrogen, the anterior two thirds of the hypertrophic turbinate tissue was treated by scarification with the electro-cautery knife; the posterior hypertrophy removed by means of my forceps snare. One of my internasal tubes was introduced after the operation, and worn with comfort until the parts healed and contraction took place. The adenoid tissue was removed by the posterior nasal forceps. By these means the nasal respiration was restored, mouth breathing ceased, and the whole body responded to a change for the better. Inflation continued for some time after the preliminary treatment, with the result of H. D. R.  $\frac{5}{6}$ , H. D. L.  $\frac{6}{6}$ , which was better than anticipated, considering the condition.

160 WEST THIRTY-FOURTH STREET.

**Alleged Contagiousness of Cancer.**—"A small commune in Normandy, Saint Sylvestre-de-Courcelles, with a present population of only 379, as compared with 500 twenty years ago, has in the eight years 1880-1887 lost no fewer than eleven of its inhabitants, between the ages of sixty-two and eighty-three, from cancer—a proportion of 15 per cent. of the total mortality. All but one of the cases occurred in males, and in as many as eight the cancer was seated in the stomach. Such facts have led Dr. Arnaudet ('L'Union méd.', No. 52) to conclude that cancer is contagious, and is propagated through the medium of water. It is true, he remarks, that not one of the eleven persons mentioned were water drinkers, but then they drank cider, which is made with the pond water of the district. Dr. Arnaudet thinks this sufficient ground to advocate the use of antiseptics and of boiled water as prophylactics against cancer, as well as against typhoid fever or phthisis."—*Lancet*.

## A CASE OF GUNSHOT WOUND OF THE HEAD; BULLET LOCATED BY MEANS OF THE TELEPHONIC PROBE. OPERATION; RECOVERY.

BY GEORGE R. FOWLER, M. D.,  
SURGEON TO ST. MARY'S HOSPITAL AND TO THE METHODIST EPISCOPAL  
HOSPITAL, BROOKLYN, N. Y.

ON December 11, 1888, I was requested by Dr. Burger, of this city, to visit with him M. H., a five-year-old boy, who, while playing with a younger brother, suffered a gunshot wound of the face from the accidental discharge of a thirty-two caliber revolver. Dr. Burger saw him immediately after the accident, and simply dressed the wound with a carbolized-water dressing, pending efforts to locate and remove the missile.

Upon my arrival I found the little patient lying upon the lounge, with the region about the left eye swollen, and suffering considerable pain. The face and eye were burned with powder, showing that the pistol had been fired at close range. A bullet wound with blackened edges was observed upon the left side of the face, just below and about on a line with the infra-orbital foramen. After thorough disinfection of the surrounding parts, the wound was probed, but the only information obtained by this was the fact that the anterior wall of the antrum of Highmore had been perforated by the ball. The probe passed directly backward and was arrested at the depth of an inch, but whether by bone or the bullet could not be determined. The telephonic probe was then brought into requisition in the following simple manner, as suggested by Dr. Girdner, of New York: An ordinary metallic sound-gauge was attached to about two feet of ordinary insulated copper wire, and the other extremity of this latter was attached to one of the binding posts of a telephone (receiver); from the other binding post of this instrument a similar piece of wire passed to the eye of a silver pocket-case probe. The sound-gauge was held firmly pressed against the surface of the cheek of the child, and, with the telephone applied to my own ear, I passed the probe again down through the wound, and heard the characteristic rasping, clicking sound in the telephone, which announced the contact of the probe with some metallic substance in the tissues. Following the course of the probe, the ball was extracted without difficulty from the sphenomaxillary fossa by means of a Péan forceps. The antrum was then cleared of blood clot, and further search revealed the bony fragments resulting from the crushing of the anterior and posterior walls of the antrum, which were removed. The ball had passed directly through the antrum, and had lodged in the sphenomaxillary fossa. The fragments of bone representing the comparatively thick anterior wall of the antrum, as well as those resulting from the crushing backward of the thin posterior wall, were easily identified upon removal. The bullet itself bore upon its further extremity a deep indentation where it had impinged upon the sharp ridge on that portion of the greater wing of the sphenoid bone which separates the zygomatic fossa from the sphenomaxillary fossa.

**Pasteurism and the Rabbit Pest in Australia.**—"It is reported that Dr. Germont and Dr. Loir, who were sent to Australia on behalf of M. Pasteur in order to give practical proof of the efficacy of his plan for exterminating rabbits, have returned much dissatisfied with their reception in the colony. They allege that a law was passed preventing the introduction of microbes, and that the Rabbit Commission reported against M. Pasteur's method without having a public trial. As a consequence of this, M. Pasteur refused to accede to the request of a number of sheep-owners to have their stock vaccinated for anthrax. Altogether the impression brought home by the French scientists is evidently that they have not had fair play."—*Lancet*.

## A FATAL CASE OF ICTERUS NEONATORUM.

By JOHN R. HINKSON, M.D.,  
BLISSVILLE, LONG ISLAND CITY.

Mrs. V., an emaciated woman, aged thirty-two, mother of seven children, had been troubled with symptoms of renal calculi for about a year. She was confined on July 1st, the presentation being left shoulder, dorso-anterior. I administered chloroform and performed bipolar version early in the first stage. Labor continued for about six hours, and when the body of the child was born the head was arrested and was extracted after some delay with considerable difficulty. The occiput was anterior, and the method used in extraction was by pressing the fingers of the left hand on the back of the neck and by carrying the feet well forward with the right.

The child, a female, when born was asphyxiated and artificial respiration (Sylvester's method) was performed for over an hour before she recovered. The child appeared perfectly healthy till the following morning, when it showed symptoms of jaundice, which became well marked on the next day, with considerable conjunctival congestion, and death occurred late that evening.

On making an autopsy, I found a large extravasation of blood behind the peritoneum in front of the right kidney, the gall bladder was moderately distended, and the left kidney was larger than the right.

The nurse told me on the evening after birth that the child did not pass water, so I ordered her to place her in a warm bath, after which she micturated freely.

I am unable to say whether the jaundice was the cause or the result of the extravasation, but I think it probable that jaundice was caused by the pressure of the tumor on the duodenum and bile duct, although I do not believe there was any violence used in delivery or resuscitation to account for the hemorrhage.

**Toxic Symptoms produced by Glycerin.**—“Dr. Jaroschi recently reported to a Prague medical society a case which had come under his care of a man who, having been induced by something he had seen in a popular journal concerning the virtues of glycerin to take large quantities of it, soon became seriously ill. He suffered from vomiting, painful defecation, and pain in the calves of the legs. Under suitable treatment, the glycerin being of course interdicted, he was not long in recovering. The aetiology of the case is not very clear, but it seems that the glycerin used was bought, not from a chemist's, but from an oil shop, as it was cheaper there, and it is said that the glycerin of commerce not infrequently contains a very appreciable quantity of arsenic; at least Ritzert, who investigated the matter some time ago, reported that he had found ‘large quantities’ of arsenic in commercial glycerin. As glycerin is now very frequently prescribed for rectal use, and as patients frequently purchase it at oil shops, it would appear to be important to get the question of its liability to contain arsenic settled, and if any uncertainty be found to exist, it would be well to caution patients to buy their glycerin at a chemist's.”—*Lancet*.

**Prognosis of Cirrhosis of the Liver.**—“Professor Semmola, of Naples, in a clinical lecture on cirrhosis, published in ‘Il Progresso Medico,’ maintains that the prognosis of the disease depends entirely on the quantity of urea excreted during twenty-four hours, as he has proved to his own entire satisfaction in seven cases. He teaches that increase in the secretion allows a much more favorable prognosis than a decrease. The quantity of urea secreted corresponds, according to him, with the functional activity of the hepatic cells; so that the extent of nitrogenous metabolism is proportionate to the number of normally acting cells. For the treatment of the disease Professor Semmola recommends an exclusive milk diet, which must be systematically and regularly administered.”—*Lancet*.

FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, AUGUST 24, 1889.

THE “TICKETED HOUSES” OF GLASGOW.

A VERY singular sanitary provision obtains in Glasgow whereby any poor class of house that is in danger of overcrowding may be marked with a tin ticket. This ticket must state the cubic contents of the house and the number of inmates who may be received. It is placed upon the outer door. A system of night-inspection over such houses is maintained by the police, whose duty it is to prosecute, if overcrowding takes place. It is a police measure, but it had its origin in typhus-fever prevalence and restriction. The “ticketed houses” are avoided by the better class of tenants, and landlords are always given timely warning before a new one is added to the list, so that the reputation of the property may be saved by the exclusion of the overcrowding people. Dr. James B. Russell, medical officer of that city, gives a history of this system in the Glasgow “Sanitary Journal,” and points out the high death-rate that occurs in these homes of the very poor. From the figures given it appears that nearly 25 per cent. of the population of Glasgow consists of families who have but one room, and nearly 45 per cent. of those having two rooms only. These two classes grouped comprise a little less than 70 per cent. of the whole city. The size of the family occupying a one-room house is, on the average, 3·17 persons, while in the two-room house the average is 2·92. The mean death-rate of these two classes, taken together, is given at 27·74 in a thousand; of those who live in houses of three and four rooms it is 19·45, while in houses of five rooms and upward it is only 11·25. Dr. Russell goes yet more thoroughly into his subject, in that he ascertains how much is paid by every class of tenant for each 1,000 cubic feet of air; the “ticketed house” brings in a better rental, on the cubic-foot basis, than the model building with its many attractive features. “Poverty,” he says, “instead of receiving a discount, has to pay interest.” The poor not only get “an adulterated property,” as the author terms it, but are charged for it more than others who are able to pay for better housing. Dr. Russell quotes the New York Tenement House Act of 1888 with high commendation, and hopes that the day will come when Glasgow will explore some of “the unexhausted resources of legislation,” instead of experimenting with such half-way measures as the “ticketed house” system, “if only the people will wake up to the fact that health has proprietary rights, as well as heritable property.” The slowness of the legislators appears to beget in him a kind of righteous impatience, as if he were the paid advocate of the abject poor—and advocate he certainly is. He sharply charges the owners of this lowest class of property with imposing taxes not only on health, life, and a purer air, but on “character and fortune.”

His argument is that there is a degradation and loss of the future necessarily implied in a descent to the "ticketed house." They who dwell there take on a depraved *morale* that is in keeping with the State-permitted vileness of the domicile; their character has the ticket on it, as well as their tenement.

#### PARTURITION IN RUSSIA.

CERTAIN articles by Mr. George Kennan, which have appeared in the "Century Magazine" during the last year or more, have given important information in regard to some phases of Russian political and social life. It would seem from these that the famous *mot* of the first Napoleon was still pertinent: "Scratch a Russian and you'll find a Tartar." That much of Russia is still barbarian was shown by the statistics presented by Dr. Krayevich at the recent Third Congress of Russian Physicians. It was stated that there were five million births annually in Russia, and that of this vast number only one hundred and fifty thousand received assistance at the hands of physicians. One million two hundred thousand are assisted by either physicians or midwives, but the latter, as a rule, are poorly trained and unintelligent. The remaining three million eight hundred thousand are unattended by any obstetric assistance; that is to say, that number of women experience the pains and dangers of parturition yearly with no more assistance than can be furnished by the members of the household or the neighborhood. It is also stated that the midwives tend to increase, rather than to diminish, the death and disease which accompany parturition. Another Russian (Kotovschikov) reported that the mortality from puerperal fever was seven to each thousand births—that is, thirty-five thousand deaths annually from this one disease. The average number of children borne by a Russian woman being four, it follows that parturient women are exposed to this serious danger four times during the child-bearing period. Add to this the fact that, while many women escape with their lives, the performance of what should be a natural function entails upon them disease and deformity which makes them useless for life. In other words, one hundred and seventy-five thousand women annually suffer seriously from want of proper attention during the parturient and puerperal periods, including the thirty-five thousand who die from puerperal fever. To remedy this terrible condition of affairs it is proposed that all midwives be required to attend courses of instruction which shall fit them for performing their work antiseptically. This is well as far as it goes, but what of the thousands and hundreds of thousands to whom a midwife is never accessible? It seems hardly credible that in a so-called civilized country so little advantage could have been derived from the beneficent advances and improvements of the last quarter of a century. Surely the lot of our Russian *confrères* in stemming this tide of disease and death is a hard one! And to do this in an atmosphere in which suspicion and intolerance check the best results and the freest endeavor but increases the labor and its hopelessness. Could there be a more suggestive commentary upon Russian institutions and Russian development than these statistics?

#### MINOR PARAGRAPHS.

##### SIR ANDREW CLARK.

A VERY interesting occasion was that recently at the London Hospital, when Sir Andrew Clark was made the subject of a portrait on behalf of his associates and other friends. According to the "Lancet," Dr. Clark made a feeling response, and became autobiographical, narrating the trials of his student life. He had been thrown on the world without a friend, his parents died before he knew them, no relative had he to whose home he could resort, he went to London without letters, and he had there just one acquaintance. Added to this his health was poor. He had a small patrimony and a great love for work. By some chance he became an assistant in the London Hospital; at this stage an opponent said of him: "Poor Scotch beggar, let him have the place; he can not possibly live more than six months." He offered these and other reminiscences for the encouragement of his juniors, and especially for those who love work for the work's sake.

##### HYDROPHOBIA FROM THE CAT.

THE "Bulletin of the North Carolina Board of Health" reports the death of a child, two years of age, at Wilmington. The child was bitten on its face by a cat, at Florence, S. C., and in about five weeks hydrophobia appeared. The child died early in the attack, "but all the symptoms were well marked." This is said to be the first death by hydrophobia known to have occurred in Wilmington.

##### MIDSUMMER CHARITIES.

AT Long Beach and Arverne-by-the-Sea, the charitable people have not forgotten the sick children left behind in the cities. At the latter place, the financial results of an evening's entertainment have been made over to the babies' ward at the Post-graduate Hospital. From Long Beach, a check for \$1,030 has been sent to the "World's" Sick Babies' Fund, the proceeds of a fair held by the ladies sojourning at the hotel at that place.

##### THE "FLINT DISEASE."

DR. W. S. FORWOOD addressed the Medical and Chirurgical Faculty of Maryland, at its last annual meeting, on the subject of the pulmonary disease of quarrymen. He stated that the "flint disease" was frequent and fatal among those who worked in the quarries of Harford County. Few of the men escaped, and, as a rule, their lungs were permanently damaged, even if they gave up the occupation after a year.

##### MITHRIDATISM.

PROFESSOR LANKESTER proposes, in "Nature," that this new word be admitted to the scientific vocabulary, to signify that immunity from the effects of a poison which is induced by the administration of gradually increased doses. The selection of the word has reference to the fable concerning Mithridates, King of Pontus, that he became so charged with the poisons he experimented with that he obtained an immunity from them all.

##### THE LATE DR. ALEXANDER B. MOTT.

DR. AUSTIN FLINT, the secretary of the faculty of the Bellevue Hospital Medical College, writes to us as follows, under date of August 15th: "The faculty of the Bellevue Hospital Medical College desire to record in their minutes an expression of deep sorrow at the death of their associate, the late Professor Alexander B. Mott. Professor Mott was one of the few remaining

members of the original faculty of the college. For twenty-eight years he had given his best efforts to the institution, of which he was one of the founders; and many thousand alumni can bear testimony to the value of his teaching. Endeared to his colleagues by long and intimate association, his death is felt by each one as the loss of an earnest teacher, a good and a true friend."

#### NEW ENGLISH MEDICAL SERIALS.

"*STUDIES in Clinical Medicine*" is the title of a semi-monthly journal which will be edited by Dr. Byrom Bramwell, the pathologist and clinician of the Durham University Medical School. Mr. Jonathan Hutchinson proposes to issue a quarterly, called the "*Archives of Surgery*." It will contain the cream of his voluminous note-books, and will have colored\* and other illustrations. His expectation is to continue the publication not longer than four years.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending August 20, 1889:

DISEASES.	Week ending Aug. 13.		Week ending Aug. 20.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	65	14	29	12
Scarlet fever.....	31	0	42	1
Cerebro-spinal meningitis .....	2	2	1	1
Measles.....	42	1	27	1
Diphtheria. ....	73	23	79	19

**The New York State Medical Association.**—The seventh special meeting will be held in Port Jervis on Tuesday, the 27th inst., under the presidency of Dr. W. T. Lusk, of New York. Dr. W. B. Eager will read "Some Observations on the Use of Concentrated Laetic Acid"; Dr. J. H. Hunt will read a paper on "The Treatment of Typhoid Fever, with special reference to the Cold Water Method"; and Dr. H. B. Swartwout will present a case of empyema.

**The Association of American Physicians.**—The fourth annual meeting will be held in Washington, in the Medical Museum and Library, on the 18th, 19th, and 20th of September. The programme includes the following items: The president's inaugural address, by Dr. Francis Minot, of Boston; "The Early Stage of General Paralysis," by Dr. C. F. Folsom, of Boston; "Tetany," by Dr. James Stewart, of Montreal; "Tetany and a New Theory of its Pathology," by Dr. John T. Carpenter, of Pottsville, Pa.; "Thrombosis of the Cerebral Sinuses and Veins," by Dr. A. B. Ball, of New York; "Chylous Effusions into Serous Cavities," by Dr. S. C. Busey, of Washington; "Substitutes for Opium in Chronic Diseases," by Dr. J. F. A. Adams, of Pittsfield, Mass.; "A Remarkable Case of Slow Pulse," by Dr. D. W. Prentiss, of Washington; a discussion on "The Relation between Chlorosis, Simple Anæmia, and Pernicious Anæmia, including Leucocthaemia and Hodgkin's Disease," by Dr. Frederick P. Henry, of Philadelphia, and Dr. F. Forchheimer, of Cincinnati; "Primary Cancer of the Duodenum," by Dr. E. N. Whittier, of Boston; "Primary Cancer of the Gall-Bladder and Duets," by Dr. John H. Munsler, of Philadelphia; "Gastric Neurasthenia," by Dr. G. M. Garland, of Boston; "Specimens from Two Cases of Cretinism," by Dr. W. F. Whitney, of Boston; "The Anatomical and Physiological Relations of Lesions of the Heart and Kidneys," by Dr. H. F. Forman, of Philadelphia; "The Contagium of Diphtheria," by Dr. P. Gervais Robinson, of St. Louis; "A Supplementary

Inquiry into the Frequency with which Lead is found in the Urine," by Dr. James J. Putnam, of Boston; a discussion on "The Relations of Rheumatism to Rheumatoid Arthritis," by Dr. William Osler, of Baltimore, and Dr. Morris Longstreth, of Philadelphia; "How far may a Cow be Tuberculous before the Milk becomes Dangerous as a Food-Supply?" by Dr. Harold C. Ernst, of Jamaica Plain, Mass.; "The Bacillus Tuberculosis," by Dr. J. T. Whittaker, of Cincinnati; and "Hot-Air Inhalations in Tuberculosis," by Dr. E. L. Trudeau, of Saranac Lake, N. Y.

**The Chicago Medical Journal and Examiner.**—The suspension of this journal has been announced, in its forty-sixth year. It has undergone a number of changes of name and plan of conduct, but for the greater part of its career it has represented the best side of the Chicago profession. We suspect that where weekly journals exist and can be supported, the permanence of the monthly periodical, not special in character, will generally be threatened and perhaps lost.

**The American Otological Society.**—The annual meeting was held at the Pequot House, New London, on July 16th. Dr. Oren D. Pomeroy, of New York, was chosen president, and Dr. J. J. B. Vermyné, of New Bedford, was re-elected secretary and treasurer.

**Typhoid Fever in Philadelphia.**—There are between 400 and 500 cases of fever in Philadelphia, many of them in the Kensington district. Twenty new cases having occurred in that district, the authorities have taken steps to discontinue the use of some part of the water supply that contains Delaware River water of a suspicious character.

**The Chicago Board of Health.**—Dr. Oscar C. De Wolf has resigned the position, held by him for thirteen years, of health officer of Chicago. He is to be succeeded by Dr. Swayne Wickersham.

**The American Dermatological Association.**—The next annual meeting will be held in Boston, during the three days beginning September 17th. For particulars, address Dr. George H. Tilden, of No. 122 Marlboro Street, Boston, secretary and treasurer.

**A Medical Library for Chicago.**—The collection of books and journals comprising the private library of the late Dr. J. S. Jewell, of Chicago, has been purchased by members of the profession in that city, with a view to building up from it a great medical library. The ease with which the funds necessary to save this collection from dispersion under the hammer of the auctioneer were raised presages the early founding of a medical library worthy of a great city like Chicago.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending August 17, 1889:*

- ROGERS, B. F., Surgeon. Detached from the U. S. S. Alliance and to wait orders.
- HARMON, G. E. H., Surgeon. Ordered to the U. S. S. Constellation. August 13th.
- LOWNDES, C. H. T., Assistant Surgeon. Ordered to the U. S. S. Constellation. August 13th.
- DECKER, C. J., Assistant Surgeon. Detached from the U. S. S. Lancaster and granted four months' leave of absence.
- BALDWIN, L. B., Passed Assistant Surgeon. Detached from the U. S. S. Ranger, ordered home and to wait orders.
- HARVEY, H. P., Surgeon. Ordered to the U. S. S. Ranger.
- LOVERING, P. A., Passed Assistant Surgeon. Ordered to the Receiving Ship Wabash at Boston, Mass. .
- SIEGFRIED, C. A., Surgeon. Ordered to the Naval Station at New London, Conn.

## OBITUARY NOTES.

**Alexander B. Mott, M. D.**, died on the 12th inst., after a short illness. He was a son of the renowned Dr. Valentine Mott, and inherited much of his father's aptitude as an operator. He was for many years a teacher of surgery, having been one of the original members of the faculty of the Bellevue Hospital Medical College. He was a graduate of the Medical Department of the University of Pennsylvania, of the class of 1850. He was a general practitioner, and was much esteemed by his patients. He rarely contributed to medical literature, and was not often heard at medical meetings. Among his meritorious undertakings may be mentioned the establishment of the Mott Memorial Library, having his father's collection for its nucleus, and an endeavor to secure the equipment of an institution for carrying out the Pasteur plan for the prevention of rabies in New York.

## Letters to the Editor.

## METHYLENE BICHLORIDE AS AN ANÆSTHETIC.

LIVONIA, N. Y., August 20, 1889.

*To the Editor of the New York Medical Journal:*

SIR: In your Paris correspondence dated June 28th, published in the "Journal" for August 17th, is mentioned some experimentation with chloride of methylene. I employed the article, bichloride of methylene, as a substitute for chloroform and ether several years ago in a few cases of ovariotomy, on account of its being so strongly recommended by Sir Spencer Wells. I do not know that any one else in western New York has employed it, except in one instance hereafter mentioned.

In my hands it has proved a very pleasant and satisfactory anaesthetic. Its action was very rapid, requiring not over five minutes to induce complete anaesthesia, and the patient as rapidly passed from under its influence, so that its administration demanded the closest care on the part of the one having it in charge. It was followed by little vomiting as compared with chloroform or ether; it seemed less depressing than chloroform and somewhat more so than ether, although I employed it in too few cases to judge of its comparative safety. In a case of ovariotomy of Dr. J. W. Whitbeck's, of Rochester, at which I was present, at my suggestion methylene was employed; but, the operation bidding fair to be prolonged, it was deemed best, after an hour and a half, to substitute ether as possibly being safer. Methylene seems best adapted to operations which are likely to be completed within an hour and in which the absence of vomiting is important. The article is exceedingly volatile, requiring to be kept under water. I have of late employed ether on account of its recognized safety and cheapness (taking waste into account), and not because bichloride of methylene is not more pleasant to use. CHARLES H. RICHMOND, M. D.

## THE NIGHT TERRORS OF CHILDREN.

SARDIS, OHIO, August 6, 1889.

*To the Editor of the New York Medical Journal:*

SIR: In a recent number of the Journal you referred to an article in the "Albany Medical Annals," by Dr. G. L. Ullman, on "Night Terrors of Children," in which he not only condemned severe measures, but advocated patience and nervous sedatives. In your last issue, Dr. J. G. Biller, of Correction-

ville, Iowa (a seemingly appropriate name), mildly criticizes this treatment, and cites the case of his own child to prove that "spanking," if not a specific in such troubles, is at least of "great benefit." Did it not occur to the father that the fear of this peculiar medication may have deterred the child from exhibiting his terror after becoming fully awake, especially if it was an heroic dose? Aside from the judicious advice of Dr. Ullman, did it not suggest itself to Dr. Biller that attention to the alimentary tract, worms, indigestion, etc., might have been a much better corrective to the poor little fellow's nervous condition than the *external application* to which he was subjected?

B. DENNIE, M. D.

## Proceedings of Societies.

## NEW YORK ACADEMY OF MEDICINE.

## SECTION IN LARYNGOLOGY AND RHINOLOGY.

Meeting of April 23, 1889.

Dr. C. C. RICE in the Chair.

**A Case of Syphilitic Adhesion of the Tongue and Soft Palate to the Posterior Wall of the Pharynx.**—Dr. J. E. NICHOLS presented a case of this sort. The initial lesion had been developed sixteen years before. Two years after this the patient had fallen on his face and sustained a fracture of the nasal bones, which had been followed by ulceration and the discharge of particles of bone. Some time after this the patient had, as he had expressed it, "caught a cold," which had settled in his pharynx, and after the period of soreness had passed away there had been much contraction of tissue there. Subsequently it had been found that the septum was perforated, and still later that both the bony and the cartilaginous septa had disappeared. Contraction in the hard palate had also become developed. After several years the patient had begun to notice that he had difficulty in swallowing and breathing. Now, owing to the extensive adhesions between the soft palate and root of the tongue, and the posterior wall of the pharynx, an opening of only half an inch or less in diameter existed, through which air and food could enter the throat. The adhesions also included the surfaces of the posterior palatine arches. The epiglottis was still free and visible. Phonation was normal.

From time to time ulcerative inflammation became developed in the contracted tissues which afforded the patient great relief, as it caused the opening at the back of the throat to become somewhat larger, and so seemed to be a beneficent effort on the part of nature to prolong life. The use of oesophageal bougies had afforded no lasting relief in the way of enlarging the opening, but a marked gain in general health had followed a very frequent introduction of the bougie (sixteen times each week) during a short period, when the speaker had had the ease in charge, at the Charity Hospital, and the patient had increased remarkably in weight for the time. This had been due apparently to the better breathing thus made possible to the patient. This treatment not having been continued after the term of his service had expired, the speaker could not say what ultimate results might have been obtained by a more or less incessant use of the sound, but he feared that no permanent change in the size of the passages could be so obtained. He presented the history of the case in the hope of hearing some opinions as to the best treatment that was available in such a case. He himself thought the galvano-cautery might be used successfully.

Dr. BEVERLEY ROBINSON remarked that the cases belonging to the class to which this belonged were always very annoying and troublesome to deal with, whether by the knife or the galvano-cautery. Whatever operative measures were undertaken to increase the size of the passages, the result was apt to be disappointing, owing to the abundant formation of cicatricial tissue, or else a subsequent continuation of the old inflammatory process, which was especially difficult to prevent. It really came down to a question of our being able to secure for the patient a practically continuous series of dilatations, for we could rarely do anything else for his relief.

While this subject was in the field he wished to again allude to a matter to which he had already called attention, but which his recent experience had continued to prove to him had a good basis in fact. He referred to the peculiar effect of monochlor-acetic acid when applied to a cut surface or, especially, one eroded by a suppurative process. The eschar which resulted differed from that left by any other caustic application in that it remained *in situ* until the scar tissue formed under it was entirely healed up. This acid, therefore, had a peculiar usefulness where subsequent adhesions of cut or eroded surface were feared.

In the class of cases under consideration he had employed different sorts of dilating instruments, had torn through the obstructing tissue, used scissors, cautery, and escharotics, but had come finally to the conclusion that the most good could be effected by the use of graduated steel sounds. Whenever possible, the patient should be taught to use a suitable dilator himself, so that he could operate on his own throat daily or oftener, and secure the maximum of relief from his dyspnoea.

Dr. DAVID WEBSTER suggested that Dr. Goodwillie, having had much experience in plastic operations in cavities lined by mucous membrane, could probably impart valuable information as to what the chances of success would be for an operation made with a view of getting an opening in such a case as the one under consideration, and securing its permanency by transplanting flaps of mucous membrane on to the raw surfaces at the outset.

Dr. D. H. GOODWILLIE replied that he could best answer the question raised by Dr. Webster by relating the history of a case somewhat similar to the one just presented, with the exception that there was a cleft of the soft palate, which had been under his care. Here, also, had been adhesions of the soft palate to the posterior pharyngeal wall. He had been in great doubt as to whether he should get an opening from the posterior nares to the throat by releasing the adherent parts, since the passage so made would be lined by a large amount of secondary tissue, the instability of which he had been well aware of. However, he had decided to release them a little at a time, with short intervals between sufficient to allow of the desired change in the tissue, and so avoid the otherwise inevitable ulceration of the soft secondary tissue. Accordingly, he had in a series of operations, continuing for many weeks, gradually cut away the palate from the posterior wall, and, having freshened the edges of the cleft palate, succeeded in getting it to unite by first intention, although in secondary tissue. Such an operation needed great patience and care. The nose must be kept during the treatment in the most thorough manner antiseptic, as when preparing to operate for cleft palate. He was opposed to the use of the cautery or caustics in this class of cases, owing to the suppuration of the secondary tissue which followed its employment. Quite a different method or device, with which he had recently had very encouraging success, was a thin plate of gold of suitable shape and convexity, which he fastened to the upper surface of the palate. Minute button-headed pins passed through the primary and

secondary tissue at the side of the cleft palate and entered screw-holes on the plate, so that the two halves of the palate united by sutures could be held together securely and the whole separated from the pharyngeal wall at the same time. The line of union would be protected from the nasal secretion.

Dr. H. HOLBROOK CURTIS remarked that he had seen several such cases treated in Paris by the introduction of large probangs, and especially of smooth leaden dilators which were left *in situ* for several hours. He had not made use of the cautery or of acids in these cases. In his experience, dilators were our only practical resource. A cutting operation, however extensive, would have to be followed by the persistent use of the dilator as healing went on, and probably after it was complete.

Dr. E. V. AGRAMONTE thought that in the present case it might as well be recognized that the real difficulty under which the patient labored was an atresia of the glottis and the consequent slow asphyxia. We not only needed to dilate the passage, but to keep the dilator in more or less permanently, and so why not do at once what would soon be absolutely necessary to the continuation of life—put in a tube?

The CHAIRMAN remarked that five or six years ago he had had two such cases come under his care, and that in looking up the literature of the subject at that time he had found accounts of several ingenious devices for keeping the parts separated after operation. One of these was to have the patient wear a thin lead plate on the palate which was held in place by a strand of silk fastened to the top of the plate and leading forward through the nose, and another from its inferior edge passing down, to be fastened to one of the teeth. Another was to make an artificial opening into the naso-pharynx through the hard palate, split up the soft palate into folds, freshen their anterior surfaces, make raw corresponding surfaces on the roof of the mouth, and obtain union of the flaps of the soft to the hard palate. He thought most patients would object to such an operation as this.

It was to be remembered, in cases of syphilitic faucial adhesions like the present, that there was a large amount of cicatrization above and below the point where the palate was adherent, and for this condition of the parts dilatation and traction needed to be kept up all the time.

**A Naso-pharyngeal Polypus.**—Dr. J. W. GLEITSMANN presented a patient having such a growth who had first come to him in February, 1888, complaining of a difficulty in hearing. He had found a large, soft tumor in the upper pharynx, attached upward and inward from the orifice of the Eustachian tube. There had been no nasal breathing through the right nostril. He had attempted vainly to remove it by the knife and then by a snare. With each attempt it had slipped out of his reach. He had, however, succeeded in making a number of punctures in it with the galvano-cautery needle. This had caused a contraction of its substance which had lasted for upward of a year, but now it had reappeared and blocked up the whole of the right posterior nares. What treatment was now in order he was in some doubt about. Had he best use the cautery a second time?

Dr. ROBINSON thought, from what had been said, that the growth must be a mucous polypus. He had once had a similar difficulty in attempting to remove a slippery post-nasal tumor by a snare or knife. Finally, with an applicator he had injected it with chromic acid and withered it up. It could not be denied that these tumors sometimes had a way of slipping upward so that no instrument would enable one to grasp them.

Dr. CURTIS took an opposite view, and believed that a snare could be adapted so as to reach around any such tumor by the aid of a hook or wire.

Dr. A. H. SMITH had had only a few cases of naso-pharyngeal polypus, and had always been able to snare them off. There had

been no recurrences in his cases. In the last of these cases the tumor had been of more than leathery hardness, and its pedicle had proved to be as resistant a piece of fibrous tissue as he had ever met with. The loop of an écraseur, consisting of the best piano-wire, had been passed around it, but when he had attempted to bring the loop home it had met with a resistance which it could not overcome, and he had finally broken the wire in his attempts, the pedicle, however, remaining firmly fastened in the end of the instrument into which the wire had drawn it. Traction on the handle of the écraseur had finally torn the whole growth away from its attachment to the basal process of the occipital bone. There had been no recurrence. No hemorrhage had followed this forcible extraction either, but he would like opinions as to whether such a procedure as a means of extracting all fibrous polypi from the naso-pharyngeal space could be regarded as a safe one.

Dr. GLEITSMANN replied to Dr. Curtis that he had tried the method of removal by snare in each of two cases of the sort under discussion, and had succeeded both times, but in one case he had met with such difficulty that it had finally been necessary to put the patient under chloroform. Then, after long and tedious trials, he had succeeded in getting the loop about the base of the tumor, and, after keeping it there for many hours, the growth had sloughed away. So he agreed with Dr. Robinson that it was sometimes very hard to get any instrument around the pedicles of these growths.

Dr. CURTIS said he had been speaking only of mucous polypi; but in the case of the denser fibrous growths he had always succeeded in extracting them by giving a little ether, using a tongue depressor, and grasping the tumor with a double curette forceps.

The CHAIRMAN remarked that he had been accustomed to use a heated snare to remove the fibrous growths.

**A Painful Fungous Growth of Unknown Character at the Base of the Tongue.**—Dr. CURTIS presented a patient from whose mouth a growth of problematical origin had recently been removed, the site of the tissue being still visible on the tongue. Eight days before coming to the speaker the patient had noticed the appearance of a growth at the base of his tongue, behind the circumvallate papillæ. Its growth had been very rapid, so that in a few days it had filled the patient's mouth to the roof with its long tendrils or lashes, which had given it the appearance of a certain sea-weed. Its growth had been attended much of the time by intense pain in the tongue and throat. It was evidently of fungous origin, being without sensitiveness when touched, although the surrounding parts had been so sensitive that the patient had been unable to swallow.

There were no descriptions in the books corresponding to such a growth. There had been no difficulty in disposing of the invading cells or spores, whatever their nature had been. The body of the growth had first been amputated and its site of attachment thoroughly scraped with a sharp enrette. The lashes referred to, of which the growth was composed, were blackish or brown in color. The patient had been unable to tear them away with his fingers, such was their toughness, and also the pain so produced in the base of the tongue.

Dr. GOODWILLIE thought the growth papillary in character. Such growths appeared very often on the palate, and were sometimes half to three fourths of an inch long.

**A New Cautery Loop for Lateral Pharyngitis.**—Dr. GLEITSMANN exhibited a new instrument for the destruction of granular tissue in the pharynx behind the posterior pillar of the fauces. It consisted of an electrode armed with a wire loop of a composite metal (iridium and platinum), through which the current of a galvanic battery was to pass. This metal had the advantage of being more elastic than platinum, so that when

crowded through the narrow faucial opening it afterward regained its elliptical shape.

Some operators applied chromic acid, and even sulphuric acid, in the treatment of this condition. It had the advantage of being much more expeditious than Jarvis's snare. Jarvis himself had said that fully half an hour should be occupied in cutting through the hypertrophic granulations of the pharynx. With this instrument a patch or successive patches of the hypertrophied tissue could be burned away to just such an extent as the case might demand. This could also be done without risk of doing damage to the pillars.

**A New Nasal Electrode.**—Dr. GLEITSMANN also exhibited an electrode designed to facilitate the application of the faradaic current in the nose, naso-pharynx, or larynx. The faradaic current was of peculiar service in allaying a cough due to an irritation of a branch of the trigeminal nerve acting reflexly, and therefore called the trigeminal cough. The instrument was made by Tiemann & Co., and the price was only fifty cents.

**A New Nasal Forceps.**—Dr. GLEITSMANN also exhibited a forceps especially designed for the extraction of pieces of bone from the nose after the soft parts had been cut away. It had great strength of bite, as could be seen by trying it on the finger-nail. It was adapted for entering a very small space and there exerting great force.

**Deafness as a Result of Nasal and Dental Diseases.**—Dr. GOODWILLIE then read the paper of the evening. (See p. 205.)

Dr. SMITH remarked that any disease affecting the posterior nares might spread to the middle ear, especially in syphilitic disease where the palate was adherent to the posterior wall of the pharynx. He was prepared to believe that an irritation starting in a decayed tooth might act in the same way. He could scarcely see how a vapor could be passed into the middle ear against the air pressure which an injection of the Eustachian tube must at once set up in its cavity. If an opening through the tympanum existed, it might be possible to start an air current through it, but, considering the small caliber of the Eustachian tube, he hardly saw how a vapor could be pressed through its length into the middle ear. At least considerable compression would be necessary.

Dr. ROBINSON said he was glad to have the question raised at this time of the aural complications of nasal disorders. It had always seemed to him an unfortunate fact that the ear and eye were so closely connected together in the public mind when thinking of a state of disease in either. It was possible for a man well acquainted with the treatment or diagnosis of affections of the eye to know little or nothing of those of the ear, and vice versa. He was convinced that the amount of trouble in the ear that could not be traced to nasal conditions antecedent was very small. Fully eight tenths of the cases coming to him treated for aural affections were of troubles really depending for their origin on inflammatory or septic conditions in the nose or throat. Here neither an oculist nor an aurist was the proper one to carry out the treatment needed to restore the hearing, but a laryngologist. Diseases of the middle ear caused most of the affections of hearing, according to the late Dr. Agnew, and certainly most of these were due to pharyngeal disorders.

He had often noticed a general opinion in the profession that obstructive diseases of the upper air-passages were more frequently followed by aural difficulties than the atrophic affections of these same areas of mucous membrane, whereas it was, as a fact, just the other way. Before he had recognized the true relation here he had often been surprised to have people come to him for the treatment of obstructive diseases of the nasal passages in whom he found no ear trouble, either subjective or objective. It was really hard to say how far nasopharyngeal diseases directly caused aural disorders, since often

the two seemed to begin and progress simultaneously. At the same time he should say it was always in order to get rid of obstructive diseases of the nose, even if not sure that by so doing we could cure or prevent aural disease. He was opposed to the use of douches in the naso-pharyngeal space in the treatment of obstructive disorders, not on account of their tending to bring about aural affections, but because they directly increased the amount of the discharges. With regard to atrophic diseases, he believed that there was no form of local treatment which did more than prevent an otherwise more rapid march of the disease.

Some patients were seen only after the aural catarrh had gone on for years, and these patients were often unaware of their deafness, or else unwilling to admit it to themselves. The chances of success in treatment was in such cases much lessened or entirely destroyed by this delay in beginning it.

Another matter which he had come to have a very strong conviction about was that, in both the hypertrophic and the atrophic forms of nasal catarrh, a great deal of benefit was to be derived from the use of some modifying agent, and by far the best one he had ever used was the compound tincture of iodine of our pharmacopœia. Its application sometimes seemed to bring about a better condition in the form of hypertrophy, accompanied by gland atrophy even. He did not believe it necessary to the integrity of the aural apparatus that air should pass through the nasal chambers; we saw too many cases where the hearing was good in spite of nasal obstruction.

A very convenient substance to use as a menstruum in applying drugs in the nasal chambers was the cosmoline oil, so called. It was fluid at ordinary temperatures, and so the trouble of heating the reservoir or spray-tube was done away with. He used it in combination with a small amount of carbolic acid. At the same time it must not be forgotten that no chronic nasal, aural, or throat disease could be cured by any local plan of treatment. General constitutional building up by diet, climate, exercise, etc., must in these cases be chiefly looked to for lasting relief.

Dr. WEBSTER spoke of a class of patients that came under his notice quite frequently, who had had deafness coming on a long time, it being due to a slowly developed and chronic aural catarrh. He believed that when that condition was reached—and it was usually accompanied by an atrophic condition of the mucous membrane in the nose and pharynx, a fact which furnished its own suggestion—very little could be done for the local condition by local treatment. He advised these patients in regard to the functions of the skin, exercise, a change of climate and occupation, diet, and all other measures acting on the general health. In regard to the aetiology of diseases of the ear, he was in full accord with the opinion that had been given to the effect that they were almost always due to wrong conditions in the throat, and only very rarely occurred as idiopathic affections. However, he was surprised to hear Dr. Robinson say that the aural affection came *pari passu* with the nasal, or that we were unable to infer that it might not. Against this view he would oppose the well-known fact that an irritation of the posterior nares would produce inflammation of the middle ear, as where acute otitis media succeeded within a day an operation for the removal of a polypus. There could be no doubt here that an inflammation set up by the operation traveled along the Eustachian tube and produced an acute inflammation of the drum of the ear.

As to the question raised whether obstructive or atrophic diseases of the nasal passages were most apt to produce otitis media, he had always supposed that the aural disease began during the obstructive stage of the catarrhal disorder in the nose. All atrophic inflammations were at first hypertrophic.

The patient came to us for the aural trouble long after the hypertrophic stage had been succeeded by the atrophic. Although he had heard much about otitis media being due to dental diseases, he had never seen a case of this sort. He had, however, seen many instances where otalgia accompanied caries in a tooth, and where, at the same time, no other cause for it could be found.

Dr. O. D. POMEROY said he could not believe that disorders in the teeth caused ear troubles of any inflammatory sort. He agreed with Dr. Webster that carious teeth often caused otalgia, but never otitis. There was no reason why inflammation in the ear should follow an affection in a tooth. He had certainly never met with an instance where such a connection showed itself, but the secondary otalgia was common enough. In fact, the only other causes ordinarily met with of pain of a neuralgic sort in the ear were malarial poisoning or some obscure affection of the fifth nerve in that branch of it connecting with the ear.

There was one heresy of belief in many medical and other minds which he should like to explode, and that related to a supposed causative connection between the first dentition and suppurative otitis media. Because they might at times or even often occur together seemed to him a begging of the question, if we gave that as a reason for holding this belief. The chief cause of suppurative otitis media in children of all ages (obtaining in nine tenths of all cases) came in the shape of a throat disorder, especially of some infections sort.

He was very glad to find himself seconded by Dr. Goodwillie in the matter of the uselessness of the aural douche. He had held this belief for five years past, and it had grown stronger with each year. Enough douching, as a fact, might itself cause chronic otitis media. The use of peroxide of hydrogen in the way described by Dr. Goodwillie he could heartily indorse. The liquid should be really charged with the gas to do effective work. To have it "live" it needed to be kept under pressure in a siphon, just as carbonated waters were prevented from losing their charge of gas. Dr. Goodwillie had called attention rather strongly to a danger he supposed to exist—that in using the Eustachian catheter, unless special precautions were taken (such as wiping out its outlet with a piece of cotton on a probe), foul air might be blown into the Eustachian canal. He did not believe there was any such danger, or that these special precautions were called for in any way. Then, as to the theory that the Eustachian tube was opened and shut in just such a way by the motions of swallowing, etc., he did not think we had definite knowledge on this point; neither could we, in his opinion, determine, from an inspection of the outlet, whether enough air or not was entering the canal. To get a real proof of this canal being patent or not a very simple expedient would suffice, namely, to inflate the cavity of the middle ear and observe whether hearing was thereby much improved. Most practitioners paid too little attention to the condition of the Eustachian tube. Inspection would not tell what it was either, but inflation would do this. We should find, in case of much swelling of the walls of the canal being present, that an excess of air would not empty itself from the tympanic cavity.

With regard to what had been said respecting a connection between obstructed nostrils and ear affections, in his opinion good nasal respiration was of importance, not because it favored the keeping up of a supply of air in the tympanic cavity so much as because the parts were thus kept free from accumulations of the secretions. He thought any apparatus for making applications of spray to the Eustachian tube by which air was withdrawn violently or forced in was almost certain to injure the ear.

Dr. CURTIS said he had treated five hundred cases of deflected

septum and had been much struck on observing a relief from tinnitus aurium and otitis media in a large number of these patients after the restitution of the nasal passages to their natural caliber and so insuring a supply of air to the Eustachian tube. Moreover, an abundance of air should pass through the inferior meatus; a supply passing through the middle meatus, in other words, would not answer. The relief of nasal obstructions not only had the effect just mentioned of relieving tinnitus and otitis media, but caused an increase of body weight and of general constitutional vigor, as in many instances where he had operated for deflection of the septum. In the case of one patient the amount of oxygen in the blood had increased after such an operation from six and a half to thirteen per cent. Nothing could indicate more clearly than did this the systemic improvement brought about.

Dr. W. A. DAYTON said he could not agree with Dr. Robinson that we did not meet with aural disease to any great extent when the nostrils were closed. He was also opposed to the inflation of the tympanic cavity with a spray of vaseline, if that indeed was possible to do. Once inside, it had no means of escape, and, having no great power of remaining aseptic, would cause suppurative inflammation.

Dr. ROBINSON said he must still hold to the view that bad aural troubles depended rather on the presence of an atrophic than a hypertrophic condition in the naso-pharynx. They occurred in either case, but the percentage of bad cases of aural disease was much greater in the former. He knew it was an opinion generally received that obstructive troubles in the naso-pharynx were generally followed by anal disorders as a result. Obstructive troubles might and often did exist together with good hearing, and so when disorders were present in both of these regions at the same time it was difficult to prove that the naso-pharyngeal troubles were the cause of the aural. We had to be content with the fact that in certain cases they went together.

Dr. GOODWILLIE said, in reply to the remarks made in reference to the entrance of vapor of vaseline into the tympanic cavity, that the purpose of the vaseline vapor was to carry an antiseptic or any medicinal agent into the Eustachian tube where it was wanted; he had never seen any results which contra-indicated the use of the method as he had placed it before them. In the treatment of naso-pharyngeal affections he made little use of sprays, preferring, as he did, impalpable medicated powders as indicated in each case.

#### MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Meeting of May 27, 1889.*

The President, Dr. ALEXANDER S. HUNTER, in the Chair.

**The Therapeutics of Rheumatism in Infants and Children.**—Dr. A. JACOBI, in a paper with this title, opened by calling attention to the frequency with which rheumatism occurred in children and infants. Valvular affections of the left side of the heart were usually secondary to rheumatism, and not to scarlatina. Many cases of rheumatism in children did not develop cardiac symptoms; but, on the other hand, endocarditis was sometimes the first symptom of rheumatism, even in mild cases; the two facts contrasted strongly and must be borne in mind. The slightest symptom of chorea minor should lead to an examination of both heart and joints. Chorea minor due to a rheumatic affection of the spinal membranes might be, not the final, but the earliest symptom of rheumatism and rheumatic endocarditis. "Dentition," "malaria," "worms," or "colds" were too often the diagnoses given in cases of rheumatism in children. This was partly because an idea of the rare occur-

rence of the disease in children was rooted in the minds of many practitioners, and partly because diagnosis was sometimes quite difficult. Fever in small children was a common symptom, but every disturbance in a child was apt to raise the temperature. The elevation of temperature in rheumatism might be slight and irregular. Swelling of the joints was apt to be trifling in amount and easily overlooked; and the pain (spontaneous or on pressure) might be much less severe than pains due to fatigue, rachitis, syphilis, eolie, or otitis. In every doubtful case, where a child showed signs of discomfort, safety required that the heart and joints should be examined. Diagnosis was especially hard if only a single joint, such as the hip or knee, was affected. Other joints might become involved subsequently. But too often such a condition in a young child, requiring really careful and repeated examinations to determine correctly, was almost disregarded by the physician, and the mother was assured that the child's uneasiness was caused by "growing pains." He would emphasize the fact that in a large majority of cases the so-called "growing pain" indicated the presence of rheumatism and the liability to irreparable heart injuries.

As regarded treatment, a change of residence from localities in which rheumatism was apparently endemic was often desirable. Alkalies were often indicated. Cold and moist weather, damp houses, etc., frequently brought on rheumatism in the children of rheumatic parents, and in such children treatment must be mainly preventive. The systematic use of cold water would modify, and sometimes entirely remove, such a tendency. A cold wash, sponge, wet sheet, shower-bath, or bath (according to the child's strength or power of reaction) should be given daily. If in any case this was followed by chilliness, then tepid water containing alcohol might be used at first. Warm clothing should always be worn for the remainder of the day after any cold-water application. Among the various local measures mentioned for the relief of swollen and painful joints, the speaker called especial attention to swathing of the part in cotton and flannel, and to the application twice daily of a solution of iodoform in collodion, brushed copiously over the swollen surface. For endocarditis, absolute rest, cold applications over the heart, and salicylate of sodium were to be recommended.

After referring to gonorrhœal articular rheumatism, nodulated rheumatism (*i. e.*, the appearance of small neoplasms on tendinous and periosteal structures), and peliosis rheumatica (a localized form of purpura), which were occasionally met with and required no special treatment in children, the speaker considered muscular rheumatism. In this form also the best preventive treatment, when a tendency to the affection had appeared, was the regular and systematic use of cold water. In certain cases the injection of a small dose of morphine, the use of the interrupted current, the administration of the salicylate, antipyrene, acetanilide, or phenacetine, and a few subcutaneous doses of one twelfth of a grain of pilocarpine, had given relief. Where a real inflammation was present in a muscle, warm baths, a mild continued current, and small doses of the bichloride of mercury would aid in recovery.

Dr. W. H. THOMSON said that many years ago his attention had been drawn to the aetiology of rheumatism, he being then a medical student in Syria, and hearing from his father (then engaged in explorations) what seemed to him paradoxical statements relative to the prevalence of rheumatism among the Arabs of the desert. He had heard that acute rheumatism was as common a disease among the Arabs in the arid country south of Palestine as among the fishermen of Norway and Scotland. He had asked himself then and since what reason there should be for the appearance of a disease either identical or similar among peoples living under apparently opposite conditions of life, in

respect to weather—that is, in climates presenting the extremes of warmth and dryness and a never-clouded sky on the one hand, and incessant fog, rain, and chilly winds on the other hand. He had become satisfied that the cause of rheumatism in either case must be a common one, but not the same as the cause of gout, for gout was nowhere to be met with in Mohammedan countries, unless in the few sections where alcohol was used (as in parts of India, where a drink made from fermented rice was drunk); at least it was very rare. It was safe to premise that rheumatism, so far as climate was concerned in its causation, was connected with changes in temperature, while gout was the outcome of excesses in the diet and in the use of fermented liquors. What, then, was there in common in the conditions of life of a man living in a tent in a burning climate, never having enough water, and a fisherman on the shore of the Baltic drenched with water most of the time? He would answer, Chilling of the skin when moist. This might occur as well in the deserts of Syria as in lands covered with fog half the year round. In the desert there was great heat during the day, the sand became heated as if in an oven, and when a party of travelers lay down to sleep, some time after sundown, on this warm sand, they were in a profuse perspiration, and naturally provided themselves with little in the way of coverings. But the sand radiated its heat very rapidly into the cloudless sky, and before sunrise bitter cold would succeed to the heat of the evening. Consequently the wet skins of the uncovered sleepers became badly chilled; and that rheumatism should follow such exposure was most natural. He had heard his father say that he had never suffered more from cold than just before dawn at the base of Mount Sinai.

No one should attempt to diagnose the early stage of rheumatism by an examination of its articular habitat, a joint. A swelling in a joint might be due to gout, trauma, gonorrhœa, or rheumatism; the symptoms in the joint were the same in each case, and so many mistakes were made. Examine the pulse, and no one familiar with the contrast presented by rheumatism and gout in this respect should fail to determine whether it was rheumatism which the patient had in the joint, or gout affecting the heart and arteries. In scarlatinal rheumatism the pulse was often hard, and there was often much uric acid present in the blood and urine; sometimes there was a formation of pus and true textural changes, which were absent in simple rheumatism, and often pyæmia was developed.

He was inclined to believe in the existence of some yet unknown function of the skin connected with respiration in its widest sense; he thought that a failure of skin-action of some sort was a means of causing the accumulation in the body of the matters which were morbid of rheumatism. Quinsy and acute articular rheumatism were sometimes associated, the latter following the appearance of the former. In the genesis of rheumatism there was usually a chilling of the skin, so naturally the warm bath acted as an anaesthetic; moreover, any bath rendered the urine alkaline—even a vinegar bath. Flannel had a peculiar usefulness from first to last. Oily inunctions, and especially inunctions of cod-liver oil, were advisable for the same reasons. This oil had first been introduced as a remedy for chronic rheumatism, and he himself placed great reliance on its effects, both externally and internally.

As to the connection between rheumatism and endocarditis in children, he fully concurred in Dr. Jacobi's warning lest it be overlooked. Endocarditis, he wished to state emphatically, might occur with only the most insignificant indications of rheumatism. He had recently seen a fine boy suffering from only a moderate attack of arthritis with the temperature between 99° and 100°, or else normal; the disease had been contracted by sitting on the ground while watching a game of ball.

In spite of all he could do, endocarditis had come on in thirty-six hours, and it would probably leave him with a permanently crippled heart.

To prevent injuries to the heart in children, contracted in this way, we must be on the lookout for the preceding rheumatism, and especially if chorea appeared, which was the normal order in the development of rheumatism in children, the articular affection coming subsequently. He dreaded "growing pains," and put a child on the use of cod-liver oil at once when they were complained of. As prophylactic measures he would advise the application of suitable oils to the skin and the wearing of flannel both summer and winter.

As regarded the therapeutics proper to a case of endocarditis, he had no faith in the power of salicylic acid, either in treatment or prevention; it was useful in articular disorders, not where the heart was involved. Antipyrine or phenacetine was preferable.

But, it might be asked, Why should the heart have this peculiar liability to develop severe lesions during an attack of rheumatism? When rheumatism invaded other parts and structures in the body it did not produce such injuries, or anything like as severe ones. If we found a joint in a state of redness, pain, and swelling such as rheumatism produced, we should say the prognosis was bad unless the attack proved to be rheumatic, for in that case the symptoms would pass away. If such a joint was examined just after death, it presented few indications, or perhaps none whatever, of the inflammatory process recently so active in it, whereas the heart did present permanent structural lesions. The explanation of this difference could be derived from a consideration of the unresting nature of the heart, and the necessarily intensified action of the rheumatic poison on the wall of a serous cavity subjected to such constant mechanical strain. If a man having rheumatism in his knee should kick a hundred and forty times in a minute, he would probably cause the development of structural changes which would remain for life; consequently, the importance of compelling the heart to beat slowly. In children the heart-beat was much more rapid than in adults; and, correspondingly, heart complications in rheumatism were more likely to be developed. He therefore recommended full doses of aconite, and not of digitalis. Aconite allayed the irritability of the heart; also alkalies were to be given; and finally the utmost care exercised to protect the chest, so that no chilling of the sensitive cutaneous nerves should occur; especially should the chest area overlying the heart never be bared of covering.

Dr. J. LEWIS SMITH remarked that in thirty years of practice he had seen many cases of acute rheumatism in children. For fifteen years he had kept a record of the cases met with in the outdoor department of Bellevue Hospital, in which rheumatism was developed in patients under fifteen years of age. In seventy-eight of these cases there had been a cardiac bruit. As regarded age, he had not met with a single case where the patient was under one year old, and very few where the age was less than two years. In these very young patients there had been little swelling, but some tenderness in the joints. In most instances the disease in children commenced in the lower extremities—a matter of surprise to him—and tended, more or less, to travel upward. He agreed with previous speakers that in most instances the local manifestations were much less pronounced than in adults. There were many walking cases in children under ten years of age.

As regarded "growing pains," often, after finding a cardiac bruit in a child, and questioning the mother if it had not suffered from rheumatism in the past, he had been answered that the father or the mother was subject to the disease, and that a few months previously the child had had "growing pains." It

would be well to teach the laity that there was always a pathological condition behind "growing pains," and that by calling in a physician as soon as they were complained of, endocarditis and possible injury for life might be prevented. Sometimes oedema was the first pathological indication to attract attention, a swelling of the feet, shortness of breathing, and perhaps a hacking cough, being noticed before the other symptoms appeared. In one instance a child of twelve years had been brought to him suffering from lividity and coldness in the right hand and the left leg. He had soon been able to determine that the child had had a severe attack of rheumatism, and that evidently a deposit of fibrin had formed in the heart, emboli from which had lodged in the brachial and femoral arteries. The pains suffered from and the bruit were to be looked to for a diagnosis of endocarditis in children; the rheumatism which had caused it might have been latent. The heart would become enlarged after the disease had lasted more than a year. Quite often, in children, the pulse would be very rapid, showing the difficulty with which the heart was pumping the blood; for the same reason the enlargement took place.

He agreed with Dr. Jacobi that rheumatism was often the cause underlying the development of chorea minor. In one hundred and sixty-five cases of chorea minor of which he had kept a record, only eighteen had been due to rheumatism.

As to treatment, he had found the salicylate of sodium of great value if used early. He gave it internally, and also packed it around the affected joint.

Dr. H. D. CHAPIN remarked that while it was now recognized that rheumatism was a common disease in children, it was often difficult of diagnosis. There was no pathognomonic symptom, and we must depend on recognizing the composite picture of the disease. Wandering pains, endocarditis, hydræmia, and chorea were manifestations of one and the same condition. They might be met with together instead of following each other. If we paid attention to pain in a limb or joint without looking further, it would be necessary to remember that not all pains were due to rheumatism. Bruises may have been received which gave no external signs; and, still more commonly, pain was due merely to muscular weariness, and especially soreness in the joints, following play. When rheumatism was present, it was even more apt to cause pain in the morning than in the evening, while pain due to the child's being tired would not, of course, be complained of in the morning. Heredity should always be given much weight.

Children having endocarditis were commonly allowed to get up too soon. He agreed with preceding speakers as to the importance of complete rest in the treatment of the affection. In fifteen or twenty out of sixty cases that he had met with, tonsillitis had appeared either before or after the rheumatic trouble. The causes of rheumatism seemed to be acidity in the stomach and bowels, derangement of the hepatic function, and a checked activity of the skin; in treating it, therefore, each of these factors should be kept in mind. Hot alkaline baths, a careful diet, and iron internally would often prevent the recurrence of the attack.

Dr. A. SEIBERT thought rheumatism in children a disease due to infection quite as much as to heredity. He had seen it develop in young children whose parents had never suffered from it, but were attacked some time after their children. This had always occurred in families living in damp and dirty dwellings. Its infectious origin explained those cases in which endocarditis appeared before either a joint affection or chorea. He placed the disease in the same category with fibrous pneumonia, meningitis, and diphtheria; statistics had shown that it was most frequent in the same houses as the latter. He did not believe the mere chilling of the surface of the body could give

rise to all the complications which attended rheumatism in children; and, moreover, young children were kept quite carefully indoors in bad weather, and did not get exposed to cold and wet or chilling of the surface.

Dr. J. C. PETERS replied to this that the houses of the poor were but too commonly damp and cold, and that children were very often the leading sufferers from this, owing to the carelessness of their mothers about their under-clothes. In most of the cases he had met with it had been necessary to order better under-garments. In treatment he had found lithia (as distinguished from lithia water) of considerable value.

Dr. A. CAILLE took much the same view as Dr. Seibert, believing the disease infectious, and hoping that in the new era of medical chemistry now appearing some substance would be found which would combat the poison of the disease.

#### NEW YORK ACADEMY OF MEDICINE.

##### SECTION IN NEUROLOGY.

*Meeting of May 10, 1889.*

Dr. L. C. GRAY in the Chair.

##### Localization of Lesions of the Great Nerve Plexuses.—

Dr. C. K. MILLS, of Philadelphia, by invitation, read a paper with this title, dealing particularly with lesions of the lumbosacral and brachial plexuses. He referred to gross lesions (not neuralgias, etc.), such as would result from neuritis, neuro-noma, aneurysms, abscesses, etc., and might occur in or adjoining any nerve plexus; also to lesions of special causation in the sacral plexus due to rectal or uterine disorders, or to a partial dislocation of the hip joint. In the case of the brachial plexus, also, a dislocation at the shoulder might act in this way. Considering first lesions of the sacral plexus, the speaker remarked that he had met with two cases in which pains and disturbances of motion or sensation were caused by intrapelvic growths making pressure on this plexus, and three or four similar cases where the symptoms were due to psoas abscess. Several of these patients had till then been treated for sciatica. Pelvic cellulitis might give rise to the same symptoms in either male or female patients. One form of puerperal paralysis was probably due to pressure on the sacral plexus incidental to a prolonged labor or the use of instruments. In one of his cases galvanism, massage, antilithic remedies, and ovariotomy, employed in succession, had failed to relieve symptoms which had finally been found due to injuries of the plexus received in childbirth. In another case pain and soreness deep in the pelvis had persisted for years after the birth of the last child, and were at last traced to a neuritis in the roots of the sciatic nerve. Such a condition as the last (neuritis) could be discovered by passing a finger (in the rectum) over the surface of the pyriformis muscle, where it escaped through the obturator foramen, till the nerve strands were palpated. In most cases, symptoms arising from lesions of the plexuses were unilateral. Large compressing lesions gave symptoms much resembling those due to lesions of the cauda equina—that is, pain, anaesthesia, analgesia, anaesthesia of the bladder and rectum, atrophy of parts below the knee, sweating, and vaso-motor disturbances. These ordinarily were bilateral or partly so.

A diagnosis as to the particular strands of the plexus involved could often be made by a study of sensory projection in nerves known to supply certain limited areas—such as the dorsum of the foot, the back of the thigh, the inner side of the middle toe, etc. The course taken by the ball in the case of President Garfield might possibly have been determined in this way. Still, as the symptoms were bilateral, there may have been in addition a spinal concussion, or extravasation paralysis, thus

giving a double set of nerve lesions, partly spinal (corresponding to where a vertebral body was penetrated) and partly such as would arise from a lesion of the lumbo-sacral nerve.

Considering next lesions of the brachial plexus, here neuritis, neuromata, tumors, and traumatic injuries were to be taken into account. In many of the cases presenting, no possible cerebral or spinal paralysis was to be differentiated. The strand of this plexus affected could often be determined by attention to the muscles and cutaneous areas in the arm supplied from it. The condition of the pupil might, in certain cases, throw light on the problem, since there was a connection between one certain strand of the plexus and the sympathetic nerve. Pain was often projected, and, by studying segmental localization, a diagnosis could be made. Sometimes surgical interference could be guided so as to bring about entire relief. Demarquet had recorded such an instance, and Dr. C. K. Briddon another. The day previous he had himself seen a case in which he could locate in the brachial plexus the lesion giving rise to the symptoms.

Dr. C. L. DANA said that, according to his experience, and especially the studies made by him in two cases operated on by Dr. Abbe, the distribution of given cervical nerves to various muscles was very wide, and a given muscle received its innervation from a number of different nerve strands. The courses of the nerve supply for sensation had been found still more various. Consequently, the distribution of anaesthesia could not point very definitely to lesions of nerves at a point just outside the cord.

Dr. W. M. LESZYNKY instanced a case in which a diagnosis had been made by Dr. Mills's method of segmental localization.

Dr. M. A. STARR thought the paper opened up a subject which was not yet fully worked out. He had seen several very obscure cases in which it had been impossible to separate the probability of the existence of a lesion high in the lumbar plexus from that of a lesion of the cord at an adjoining point. There were some points in Dr. Mills's paper which would aid in a working out of this intricate matter. To the proposition that sensations were delayed in lesions of the cord, but not in those of the nerves, he must object. Arsenic and alcohol gave rise to peripheral paralyses in which sometimes sensation was much delayed. In his experience, severe pain about the perineum and post-sacral region was regularly due to a lesion in the cord.

Dr. DEAVER, of Philadelphia, present by invitation, thought that in many cases in which pain returned or became even worse after an ovariotomy, there was probably a lesion of the sacral plexus. In undertaking operative treatment for such lesions, access to the pelvis might be obtained by trephining the pelvis laterally or posteriorly, by going through the sacro-sciatic notch, or perhaps by a laparotomy.

**A Case of Spinal Resection for Fracture causing Paraplegia.**—Dr. R. H. M. DAWBARN read an account of such an operation. (See vol. xlix, p. 711.)

Dr. DEAVER instanced a case in which the patient had been operated on by a colleague of his immediately after reaction set in (subsequent to the receipt of the injury). The condition of the patient had been improved very little, if at all, showing that the damage had already been done at the time of the operation, and that the process of degeneration had begun. It was the opinion of Dr. Agnew, of Philadelphia, and of others, that the injury was done at the time of the accident, in most of these cases where fractured vertebrae were displaced so as to make pressure on the cord. Still, an operation such as Dr. Dawbarn's did not make the condition of the patient worse; it might, on the other hand, improve it, and was safe.

Dr. DANA remarked that he knew of four cases where such an operation had been done—all within the nineteen months

previous. One of these patients had been much improved, and three slightly benefited. He would also call attention to Dr. Abbe's method of reaching the spinal canal by making a flap; primary union was obtained and the operation was short—much less time than the three hours used by Dr. Dawbarn being required. He had quite recently preserved a spinal column and cord showing a condition which operation would have helped, at least so as to have prolonged life.

Dr. STARR instanced a case of Brown-Séquard's paralysis which had recently come under his notice. The patient, when trying to stop a sled on which he was descending a hill, by putting down his heels into the snow ahead of the sled, had been thrown up into the air, and had fallen on his back. He had been unable to rise, having suffered from the first with total motor paralysis in the left leg and partial paralysis in the right leg. An operation had been done, the eighth, ninth, and tenth spinous processes having been removed. The haemorrhage had been severe, and in this respect Dr. Dawbarn's operation had much merit. A callus was found which had been making a unilateral pressure on the cord, and was removed. Some improvement had followed, and still, after five weeks, the patient's actual condition was not materially altered, although the wound had healed perfectly. He thought we could not hope for much improvement in operating after such accidents to relieve a paralysis. When the growth of a tumor made a gradually increasing pressure on the cord, its fibers were forced apart rather than severed, and there the excision of the tumor might give entire relief. But where the fibers were ruptured, as in traumatic injuries they were apt to be, we could not expect them to become reunited.

Dr. S. T. ARMSTRONG, of the United States Marine-Hospital Service, instanced one case where paralysis following a traumatic injury to the spine had led the surgeon in charge to operate for the relief of a supposed compression. Soon afterward gangrenous spots had appeared in different parts of the body, and the man had died from infection following the operation. In another case a seaman had fallen into the hold of the ship on to his back, and became at once paralyzed in his lower extremities. No operation had been attempted, owing to the sinking condition of the patient, but the necropsy had shown degenerative changes in the cord such that any operation would have been futile. He thought the present record of operations of this sort was not good enough to warrant the surgeon in undertaking such an operation as a matter of course, or with the expectation of obtaining an improved condition.

The CHAIRMAN remarked that the spinal cord would endure considerable injury such as came from a vertebral dislocation and still recover its continuity of outline and its normal functions, especially if time enough were allowed it. This might be looked for even when the dislocation had lasted for a considerable time. In Pott's disease the cord often withstood much pressure without permanent injury. The important sign was the appearance of muscular atrophy. If the muscles had become much atrophied there was not much hope of getting relief by an operation. In traumatic myelitis no great amount of recovery should be looked for after a successful operation in the first few months, but in the course of six or seven months these patients might perhaps do better than at first seemed probable.

Dr. DAWBARN replied to Dr. Dana that Dr. Abbe's cases had been of a non-traumatic sort—one of tumor and one of neuritis. The long duration of the operation, of which he had read an account, had been due to the unexpected wide deviation of the eleventh spine toward the left, and to adhesions between the theca and the bones. Experiments on a number of cadavers had shown that ordinarily the operation could be done very rapidly. To what Dr. Armstrong had said as to the futility of

the operation, he would reply that we only hoped for a cure, while if we succeeded simply in improving the patient's symptoms the operation was justifiable.

**An Hallucination Peculiar to Chronic Alcoholism.**—Dr. M. D. FIELD, of the Blackwell's Island Insane Asylum, read a paper giving an account of ten cases of this sort. The symptom was one he had seen only in these ten cases, all of alcoholic dementia. A patient presenting it, while he had perfect knowledge of his surroundings and his own relation to them—knew that he was confined in an asylum and how long he had resided there—would nevertheless tell his attendants in the most circumstantial manner that on the previous day he had been away from the building, and would describe where he had gone and what he had seen. He would seem unconscious that there was anything improbable in his narrative, and, if questioned, would assure one that he had often before been on such excursions. Some who gave these accounts were confirmed ripples, yet had this delirium of having recently taken a long walk. One patient, for instance, suffering from a double peripheral neuritis and from phthisis, would always, if asked if he had walked out the day before, answer that he had made several miles. At one moment such a patient realized that he had not left the hospital in months; in the next he assured any one conversing with him of his trip, and described it. This curious mental aberration was common to men and women, and to all ages and grades of life. The particular sort of liquor the patient had been addicted to had no relation here. He would here remark that a majority of the cases of alcoholic insanity which came into Bellevue Hospital were the result of drinking what was known as mixed ale, and not of indulgence in the stronger liquors.

## Reports on the Progress of Medicine.

### ELECTRO-THERAPEUTICS.

BY G. G. VAN SCHAICK, M. D.

**Electricity in the Diagnosis between Certain Cases of Hysteria and Epilepsy.**—Dr. A. Didier ("Lyon médical," No. 49) presents a careful study of the effects of faradaic electrization as a diagnostic means, in certain difficult cases, between hysterical attacks and epileptic seizures. According to the author, faradism is by far the best agent at our disposal for the purpose of arresting the hysterical crisis, or of preventing it, and he cites a number of cases which serve well to substantiate his statements. For diagnostic purposes it enables one to distinguish between epileptics and patients suffering from hysteria, whether epileptoid or convulsive (Charcot), inasmuch as in the first the attack is not modified by this sort of treatment, whereas it is checked in the latter. His method of treatment consists in the application of electrodes along the course of the aura, using a faradaic current of fair intensity. Not only does he assert that faradism possesses a markedly abortive effect on the attacks, but he has also observed a decidedly curative action upon the disease itself.

**On the Treatment of Uterine Tumors by Electricity.**—Since Apostoli first brought out his statistics of patients treated and cured or materially improved by his method, a profuse amount of literature has appeared on the subject. For the last few months, however, we do not hear quite as much about the matter. It would seem as if the devotees of the method were quietly working up both its technique and its statistics, while its detractors were either informing themselves about a procedure which they commonly decried without the slightest personal knowledge thereof, or had made up their minds to allow time, the best judge, to decide upon the merit or the worthlessness of the method.

The statements of Dr. Thomas Keith, one of Apostoli's strongest supporters, as well as a peerless hysterectomist, are of great interest.

After speaking ("British Medical Journal," June 8th) of the other methods of treatment, including the old idea of using the interrupted current with large needles, now fortunately abandoned, he uses the following strong words: "The only treatment (not surgical) worth speaking about that I have seen do any good, and which, at the same time, is free from danger to life if the treatment be undertaken by one who has respect for a strong electrical current, is that brought before us by Dr. Apostoli. If any one should have held on firmly to hysterectomy it is myself, as my results after it are better than those of any other." Dr. Keith further states, in regard to the first two patients upon whom he tried electricity, that "the results got in these two first attempts convinced me of the value of this treatment, and I ceased thenceforth from doing hysterectomy, or even removing the ovaries for bleeding fibroids."

Dr. James H. Aveling, in reference to the same subject, takes the moderate view, which is the one commonly held, as we believe, by investigators into Apostoli's method. In the "British Medical Journal" for May 25th he states that all that his present experience will justify him in vouching for the efficacy of this method of treatment is that in some cases it will cause a fibroid tumor of the uterus to entirely disappear, that in others it will remove it partially, and that in most cases the symptoms which have caused the patient to seek assistance may be relieved or quite cured. In support of this statement he relates four cases treated by electricity with very gratifying results.

**The Treatment of Cancer by Electricity.**—Dr. Parsons ("British Medical Journal," April 27, 1889), believing that cancer cells are natural tissue cells which have taken on an abnormally active growth from some stimulating cause, but over which the nervous system has in some manner lost its control, has applied electricity in four cases of cancer, which were either too far advanced for a cutting operation or in whom the patient had refused to submit to one. The destruction of healthy tissue is, of course, bound to take place equally with that of the neoplasm, but the former has a recuperative power not possessed by the latter. Hence he argues that the electricity may injure the cancer cells beyond recovery, while the normal tissue may easily regain its pristine healthy state. The vascular supply of cancer being so great, no such general and dangerous sloughing occurs such as would take place in uterine fibromata by the use of the interrupted current. This current was the one he employed in his four cases, under anesthesia, by transfixing the tumor and all the tissues immediately surrounding it with fine needles, so as not to injure the skin. The current was at first of ten milliampères, which was then increased and flashed through the tumor from fifty to a hundred times. The tumors shrank and became harder, while the pain was lessened and the general health improved.

**The Treatment of Tumors by Electricity.**—M. Darin (*Id.*, May 11, 1889) considers that the treatment of tumors by electrolysis is applicable under the following conditions: 1. When no other treatment is practicable. 2. When electrolysis offers advantages which the numerous surgical methods do not possess. 3. When the patient refuses to submit to surgical treatment. He has employed electrolysis with entire success in a large cancer of the left breast in a woman aged seventy-four; in a case of scirrhus of the right breast, with enlarged glands in the axilla; in a cancer, of the size of an orange, which appeared in the axilla after being twice extirpated from the corresponding breast; in a hydrocele which had lasted fifteen years; in a case of prepatellar hygroma; in a wart upon the cheek which had existed ten years; and in many other tumors of less importance.

**Electricity in Gynaecology.**—Dr. P. Bröse ("Deutsche med. Wochenschr.," June 13, 1889) states that he has followed Apostoli's method since four or five months, which he considers too short a time in which to reach any very positive opinions concerning its value. He reports three cases, the first being one of multiple uterine myomata. The patient suffered from hemorrhages at irregular intervals and from pain. The treatment caused a diminution in the size of the tumors and a relief of the symptoms. The second case was one of intramural myoma, in which the tumor became smaller and both the hemorrhage and pain were relieved. The third case was similar to the second. The author considers the method as being a safe one providing too strong currents are not employed. He has used electricity in six cases of fungoid endometritis, the hemorrhage not being as quickly relieved as it generally is by the eurette, but the effect was lasting. Five cases were cured,

the haemorrhage disappearing in some after the first application, while in others six to nine applications were required. In some cases leucorrhœa was not entirely removed. He has used the method in order to dissipate old perimetritic exudates in six cases. In three of these complete absorption took place—*i. e.*, the mass became contracted, but adhesions remained. The symptoms were relieved. In cases of diffuse exudates, old adhesions, and cicatricial tissue, his opinion is that the best means of promoting absorption is by massage and the application of the faradaic current. He has also used galvanism with success to combat constipation in women.

Dr. Engelmann's apparatus has been used by Dr. E. G. Orthmann, who reports ("Berliner klinische Wochensehrift," No. 21) a series of ninety-five cases treated in the clinic of Professor A. Martin, of Berlin, most of the patients being outdoor ones. Of these patients, thirty-six were suffering from perimetritis, most of them being complicated by chronic metritis and endometritis, or by retroflexion. Galvanic currents were the ones usually applied, of a strength of 60 to 80 milliampères. In order to relieve pain, the flat negative electrode was placed over the abdomen and the positive ball electrode was introduced into the vagina. In old cases where the pain was not so marked the order was reversed, the negative being inserted for its abortifacient effect upon the adhesions and residual exudates. When chronic metritis and endometritis were present a sound-electrode was introduced within the uterus. For special effect upon the endometrium a pure metallic electrode covered with cotton was passed in the uterus. The number of séances needed were from six to eighteen, two or three times weekly, lasting for five minutes. In one case a complete cure was effected in a sterile married woman who was suffering from perimetritis with chronic oophoritis upon the left side, ten sittings being required. In twenty-four other cases there was decided improvement, the pain being relieved. In the eleven remaining cases there was no change for better or worse.

In twelve cases of parametritis of the chronic variety which were treated as above described, the ball electrode being usually passed up to one or the other side of the vagina, no actual cure resulted. In eight there was more or less improvement. In five cases of parametric or perimetritic exudates there was marked improvement among three of the patients after six to twelve séances, there being a slight diminution of the mass, relief of tenderness, and disappearance of subjective symptoms. In one case there was no change, while the condition of another was made worse, the patient suffering from a large exudate extending to the umbilicus. It was twice punctured with a platinum wire with a current of 100 milliampères. In six cases of chronic oophoritis, periophoritis, and salpingitis there was a very good result in one case, the woman suffering from dysmenorrhœa with enlargement of the left ovary. There were twelve sittings, the negative electrode being used in the vagina with a current of from 50 to 100 milliampères. The ovary diminished in size and the infiltrations contracted. In three other cases there was some improvement, while another patient developed fever after the sixth sitting and the treatment was discontinued. In the latter a laparotomy demonstrated the existence of a purulent salpingitis and abscess of the ovary.

Among the menstrual disorders there were twenty-six cases of marked dysmenorrhœa; eight of these caused by chronic endometritis, metritis, oophoritis, perimetritis, or retroflexion; in sixteen the trouble originated in stenosis of the cervical canal. In all these cases, as in the preceding ones, other methods of treatment had proved useless. The negative sound-electrode was usually introduced within the uterus, the strength of the current varying from 30 to 50 milliampères. A small number of sittings, repeated once or twice weekly, usually effected some improvement. A cure followed in six cases due to stenosis, and in all cases there was marked improvement in the pain. The stenosis frequently diminished, even in patients in whom previous dilatation had proved useless. In two cases of membranous dysmenorrhœa there was great improvement; in one no membranes had passed for seven months. The author has never observed any dangerous results.

In four cases of amenorrhœa a cure was effected, the menses being brought on in each case. In one case of profuse menstruation every two weeks, with endometritis, the menorrhagia was relieved in five sittings, beginning with 50 and increasing toward the last to 75 milliampères. In all these cases the electricity was used as a last resort, and

Dr. Orthmann strongly recommends the use of electricity in the treatment of dysmenorrhœa. In other cases it is harder to determine its exact value, as we are compelled to depend upon the subjective feelings of the patients.

**The Treatment of Constipation by Electricity.**—The following we take from the "Medical News" of July 13th: Dr. Hammond, says the "Revue de thérapeutique médico-chirurgicale," has successfully treated forty-one cases of habitual constipation with a galvanic current. The negative pole is placed in the anus and the positive pole is applied to the abdomen. Faradization was found useful in promoting a healthy tone of the muscles of the abdomen. In connection with the treatment, saline aperients should be administered.

**Electrical Excitability of the Columns of the Cord.**—From a series of experiments ("Univ. Med. Magazine") Dr. E. T. Reichert infers that when the spinal cord is directly irritated by electrical currents the fibers of the posterior columns constitute the part excited; and, since the roots of the spinal nerves are so highly excitable, it is more than likely that these impart to the posterior columns the property of direct electrical excitability.

**Electro-cataphoresis.**—Dr. J. I. Pennington, of Baltimore, read before the Baltimore Medical Association, May 13th ("Maryland Medical Journal," July 6th), a report of a case of deep-seated gluteal abscess which, after being opened, refused to heal properly, leaving a sinus about two inches long, which gave much trouble. As the patient, a lady, refused to be operated upon without anaesthetics, while her husband would not allow her to be given chloroform, Dr. Pennington washed the part with a little chloroform to remove the oily particles from the skin. He then saturated some absorbent cotton with the anaesthetic and applied the positive pole of a Barrett battery, using a current of twenty cells for fifteen minutes, after which he introduced a director, then a curved bistoury, and made a cut two inches long with several smaller ones. The lady asserted that she had felt no pain.

**A Cure of Nocturnal Incontinence.**—Dr. R. Jamin reports ("Abeille médicale," May 13, 1889) favorable results from the electrical treatment of a case of nocturnal incontinence of urine in the case of a young girl aged fifteen, in whom he and others had obtained no amelioration by prolonged medicinal treatment. He employed direct faradization with an olive-tipped bougie applied to the urethra, after the advice of Guyon. The girl had urinated in bed nearly every night for a number of years. After eleven applications she only micturated in bed once during a period of four months.

**The Electrolytic Treatment of Oesophageal Stenosis.**—Dr. J. A. Fort ("Gazette des hôpitaux," March 19, 1889) treated a patient suffering from fibrous stricture of the oesophagus situated from three to four centimetres from the cardia. The man had been reduced from a hundred and forty-six pounds in weight to a hundred and fourteen. Only an olive of five millimetres could be forced through, and with difficulty. The oesophagus was not dilated. The patient was fed with a tube and somewhat improved. Dr. Fort at the first sitting employed a current from eight Gaiffe cells during two minutes. One plate was placed over the left part of the stomach, the other at the seat of the stricture. The pulse rose from 72 to 90. He only complained of a dull feeling during the day. The next day he was able to partake of soup and boiled eggs without the stomach tube. The second application consisted of sixteen cells, giving a current of thirty milliampères. No blood appeared, the patient vomited, and the reflex nervous symptoms were rather marked. He had some dull pain during the day. The day after this he was able to eat light food. Finally a sound of forty-two millimetres was introduced by Dujardin-Beaumetz. The result will probably be temporary, but is a very useful one.

**On the Effect of the Galvanic Current upon the Gastric Secretions.**—Dr. A. Hoffmann has established from experiments on men and animals the fact that an electrical current stimulates the excretory apparatus of the stomach. To test this fact the patients were galvanized, the broad anodal electrode being placed on the back and the cathode upon the stomach ("Berliner klinische Wochensehr., April 1, 1889). A current of fifty milliampères was used. The contents of the stomach were then removed by gastric expression with a tube. They were then examined and compared with those obtained on the previous day, when no electricity had been used. The patients were not allowed any food

for some time before the experiment. The author obtained the following results:

1. In gastric cancer the electricity, having been applied during twenty minutes, three to five hours after meals, caused no increase of hydrochloric acid in any of the patients.

2. In nervous dyspepsia: In one case in which no free hydrochloric acid could be found in the gastric contents electrization caused its appearance. In another case, although no free hydrochloric acid could be demonstrated, the acidity of the stomach contents was increased.

**Electrolysis in Stricture of the Urethra.**—This matter is one upon which there has perhaps been more controversial discussion than upon any other application of electrolysis. Excellent observers have reported successes in large numbers of cases, but the matter is still considered by many to be *sub judice*. Mr. Lavanne, after a long series of experiments, concludes ("Abeille médicale," Feb. 11, 1889) that electrolysis in urethral strictures gives results which are no more lasting than internal urethrotomy or diversion. He is in favor of rapid dilatation. M. Fort, in the "Journal des sociétés scientifiques," reports having operated in two cases during the past year without any return of the trouble. In the "Gazette des hôpitaux" he reports another successful case of urethral electrolysis in a man that had had a stricture since 1882. The writer calls attention to his method of linear electrolysis, which is not a prolonged application of currents of a low intensity, but a regular urethrotomy without incision, giving a cut by molecular destruction, which is followed by a soft, non-retractile scar. Dr. Chaplet, in the "Gazette des hôpitaux," reports having personally suffered from a stricture since the year 1863, due to an old blennorrhagia. Until recently he suffered from retention, and at one time had a false passage. Being predisposed to haemorrhage, he feared a cutting operation, and had recourse to electricity. Dr. Fort passed upon him a No. 15 electrode, later a No. 18, with the result of curing the vesical catarrh from which he suffered, and of improving his general health.

**Electricity as a Therapeutic Agent.**—Under this title, in the "Medical News" for March 30th, Dr. M. Allen Starr makes the following statements, some of which are not in perfect accord with the generally accepted opinion:

1. Static electricity offers nothing beyond an interrupted galvanic current, and fails to furnish those effects which are most desirable in the treatment of disease.

2. A constant galvanic current can produce chemical changes which aid nutrition or destroy tissue, according to the strength employed.

3. A constant galvanic current can transfer medicines into the body from without.

4. An interrupted galvanic current, or a faradaic current, can excite various organs to functional activity, thereby aiding their nutrition.

5. It is questionable whether the pathological state causing organic diseases is in any way influenced by electricity.

6. If functional diseases are benefited, it is in an uncertain manner, it being undecided whether it is by influencing the molecular condition, the chemical changes, or the electrical state of the organ affected, or by the state of mental expectation induced. The agent is therefore used empirically, and the physiological indications for it are as yet uncertain. As a therapeutic agent its use is very limited, and carefully balanced scientific observations are still needed to establish its proper sphere.

Professor Starr says that he can not close his paper without stating that, after the constant use of electrical treatment for the past six years, he has been disappointed in the results obtained. His experience coincides with that of Gowers—that the therapeutical effects of electrical applications have been much exaggerated, and are really very limited and quite uncertain.

## Miscellany.

**The Health of Connecticut.**—According to the State Board of Health's "Monthly Bulletin," the total number of deaths reported from 166 towns during the month of July was 1,329, including 10

from measles, 4 from scarlet fever, 7 from cerebro-spinal meningitis, 35 from diphtheria and croup, 7 from whooping-cough, 21 from typhoid fever, 15 from malarial fever, 8 from typho-malarial fever, and 6 from puerperal fever. There were also 127 deaths from consumption, 24 from pneumonia, and 17 from bronchitis.

**Sulphonal.**—In his Croonian Lectures, an abstract of which is given in the "Lancet," Dr. T. Lauder Brunton says: "Sulphonal appears to be one of the most effective of all the newly introduced hypnotics, and, although it does not, like morphine, compel sleep, it induces sleep in a pleasant manner, and has few disagreeable effects and little or no danger." It will be seen by Messrs. Schieffelin & Co.'s advertisement that the cost of sulphonal has been materially reduced—a fact well calculated to encourage its more general use.

## ANSWERS TO CORRESPONDENTS.

**No. 282.**—An examination has to be passed. For permission to appear before the board, and for information as to the time and place of its session, apply to the Secretary of War.

**No. 283.**—Filter the solution.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

Original Communications.

WHAT IS VERITABLE PARALYSIS OF  
THE POSTICUS (POSTERIOR CRICO-ARYTENOID)  
MUSCLE?\*

BY DR. JELENFFY,  
BUDAPEST.

THE arytenoid cartilages must be fixed in order that the crico-thyroid muscles should be enabled to stretch the vocal cords. The fixation can not be effected by the ligaments, because they are too long, would soon be dilated yet more, etc.

The fixation can be done by muscular force only. This force must be exerted in the direction from before backward. There is only one muscle which acts in this direction—the posticus. But the lateral muscles must likewise be in full action in phonation. If both muscles were antagonists, and antagonists only, the posticus would not be able to fix the cartilage, because the antagonist muscles would paralyze each other. Therefore these muscles must be so arranged anatomically that, when contracted simultaneously, their concerted action, instead of paralyzing each other, would result in a force antagonistic to that exerted by the crico-thyroid muscle. That is possible only if the insertions of the posticus and lateralis correspond to the annexed diagram (Fig. 1)—that is, if the insertion of the posticus falls totally or partially *inward* of the insertion of the lateralis. In that case, when the two muscles are in simultaneous contraction, the posticus finds its hypomochlion in the insertion of the lateralis, *b*, and this draws (*a* *b* being the rigid cartilage) the vocal process (*a*) in the direction of *d*, producing the requisite force antagonistic to the crico-thyroid muscle.

falls totally or partially *inward* of the insertion of the lateralis. In that case, when the two muscles are in simultaneous contraction, the posticus finds its hypomochlion in the insertion of the lateralis, *b*, and this draws (*a* *b* being the rigid cartilage) the vocal process (*a*) in the direction of *d*, producing the requisite force antagonistic to the crico-thyroid muscle.

But this force is not comprised in the contraction of the posticus alone. The contraction of the lateralis combines with that of the posticus to the same end, the lateralis muscle, on the other hand, finding its hypomochlion in the insertion of the posticus, *e*, and so drawing the vocal process again in the same direction toward *d*.

There exists no other possibility of the fixation of the arytenoid cartilages during phonation. Therefore the anatomical arrangement of the muscles *must* be conformed to this supposition. And so it really is. The insertion of the whole internal portion of the posticus, which takes its origin from the crista of the plate of the cricoid cartilage, is effectively situated inward of the fibers of the lateralis. This is best seen on inspection of a larynx of greater dimensions than the human larynx—for instance, in that of

an ox. The mutual relations of both muscles appear most clearly when all the other muscles are removed from the cartilage, and only the lateralis and the internal portion of the posticus (the external portion being removed also) are left untouched. To facilitate still better the direct inspection of the insertions, the superior part of the arytenoid cartilage is to be cut away horizontally at the level of the upper margin of the insertion of the lateralis. Then one can absolutely satisfy himself that the insertion of the internal portion of the posticus really lies inward of the insertion of the lateralis. If the origins of both muscles are now detached from the cartilage, and the whole cartilage taken out of the articulation, the vocal process goes inward if both muscles are pulled.

In consequence of the anatomical arrangement of these muscles, the arytenoid cartilage is inclined backward in still another way. While the fibers of the internal portion of the posticus adhere, in the whole, in a horizontal line, those of the lateralis go downward on the whole length of the muscular process. In consequence there is developed another variety of the above diagram, standing here vertically, but with the same results (Fig. 2).

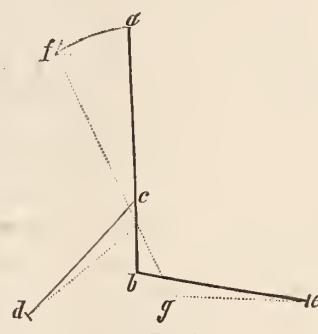

FIG. 2.

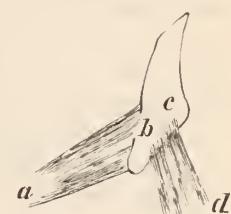

FIG. 3.

The external portion of the posticus is in no wise able to hinder this mechanism, because the only question for that portion is that its insertion should be rotated. Its insertion and its fibers running almost completely vertically downward, while the most rotating fibers of the lateralis run almost horizontally, it is not in the least able to hinder the rotation (Fig. 3).

The external thyroarytenoid muscle participates in producing the tension of the vocal cords principally in the same manner as the lateralis.

The insertions of the posticus and of the thyroarytenoideus internus being situated *vis-à-vis* of each other (Fig. 4), by the simultaneous contraction of both muscles the arytenoid cartilages are approximated to each other. Thus, even in associated action with this muscle, the posticus becomes a closer of the glottis.

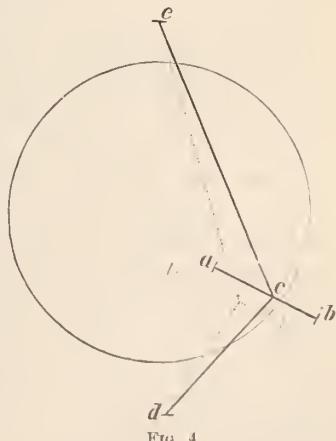

FIG. 4.

\* Read by J. Solis-Cohen, M. D., before the Laryngological Section of the American Medical Association, June, 1889.

If the contractions of the muscles are imitated with threads, the effects described become manifest.

Physiological facts correspond with the deductions based on anatomical grounds. In looking into the singing larynx, we see that the arytenoid cartilages become the more erect the higher the pitch of the tone made. There is no other muscle to effect this than the posticus.

When the pneumogastric nerve is irritated by very strong electric currents, the vocal cords become extraordinarily stretched between the anterior and the posterior stretching forces (Krause). In spite of this, the arytenoid cartilage is not drawn forward and downward by the posticus, but backward. That this muscle, too, is acting simultaneously is proved by a direct experiment we made with Regeczi. Irritation of the recurrent laryngeal nerve produces an energetic occlusion of the glottis. But, if we then cut the closers (*internus included*), the larynx is *opened* with equal energy on irritation of the recurrent nerve.

As the experiments of Hooper, of Donaldson, and of Semon and Horsley show, feeble irritation of the nerve causes opening, and stronger irritation causes closing of the glottis. (The most recent experiments of Donaldson prove the same, because irritation with slow rates of interruption is only a feeble irritation.) In the animal narcotized very deeply, irritations of the recurrent nerve cause opening. The narcosis becoming less deep, closing of the glottis occurs again. This shows that the posticus is more irritable than the closers, and that the narcosis has no influence on it, its action manifesting itself both before and after the development of the influence of narcosis. If the animal dies from an overdose of ether, irritation of the recurrent nerve still causes opening during some short time, and then closing is produced again. This fact has induced the false interpretation that the irritability of the posticus is soon exhausted after death. But we have, with Regeczi, cut the closers here again, and again irritation of the recurrent nerve produced energetic opening. This experiment, in both its variations, might be regarded as decisive of the whole question—perhaps still more so if it is associated with the cork experiments of Krause. If, after the stabilization of the vocal cord in the middle line, the closers are cut through, the arytenoid cartilage immediately moves outward, the posticus making unweakened energetic movements on irritation of the recurrent nerve. Thus it is proved that here the posticus is not paralyzed, but that all the muscles are in primary contraction. The consequence of these laws is that, with paralysis of the posticus, the voice can not be normal, because then the force *d c* (Fig. 1) would fall out of the category, and the whole line *a b* (the arytenoid cartilage) is drawn forward by the forces *a f* and *b e*, in physico-formulary sense, without resistance—in reality, with so much resistance as the lax capsule and its ligaments are able to develop. The vocal cord can then only be stretched so much as on the dead larynx without special fixation of the cartilages—*i. e.*, only to a very slight degree. The physical consequence must be feeble vibrations of a low, very little variable rate; in other words, a feeble, deepened, monotonous voice if the affection is on both sides, a troubled voice if it is on one side only.

In the descriptions of cases of so-called “paralysis of the posticus” many instances are to be found supporting my law, although the observers thought that they saw paralysis. They are to be seen, even if the pathological situation is created artificially (Krause). If the animal is narcotized, its glottis is somewhat less narrow; if it awakes, the glottis becomes narrowed—actually, the animal endeavors to open the glottis by a contraction of the posticus, but, the closers being contracted at the same time, the posticus, too, becomes (in accord with our formula) a closer. This is the true explanation for the narrowing of the glottis on inspiration, in cases of disease also, which made the impression of “something active” upon more than one observer (Hansen, Schnitzler, Rosenbach, Krause), as is evident from their expressions.

This explains at the same time why the glottis is only closed the more firmly if, in the cases of “paralysis of the posticus,” that muscle is irritated by electricity.

Besides these, there were yet other symptoms of irritation in these cases—for instance, the laryngeal spasms, the laryngeal crises that preceded the stabilization of the vocal cords in the middle line, forming *acute examples* of the malady.

It is clear that “sonorous inspiration,” too, can only have the signification of “inspiration between approximated and stretched vocal cords,” which, again, is possible only with an intact posticus.

The most important symptom of irritation is the contracted state of the transverse muscle, which will be again alluded to.

In what we have just exposed lies the cause of the consecutive atrophy of the posticus. By its contractions, which are simultaneous with contraction of the closers, the dyspnoea only increases. To make this cease, both man and animal contracts only the more this same muscle—the only one that opens the glottis under ordinary circumstances. The muscle in this “circulus vitiosus” becomes overworked, and the atrophy is the result of the overstraining of its forces. The atrophy of its nerve fibers is then consecutive only. This atrophy can commence at the point of irritation (as in cases of aneurysm, cancer, etc.).

When atrophy is already developed, the arytenoid cartilage bends forward and the voice is troubled, as shown in the descriptions of many cases.

The greater irritability of the posticus is a proved fact, and a particularity of this muscle, which it possesses in community with the other muscles of organic life. But the supposition is false that the posticus or its nerve fibers should be more vulnerable than the closers. It is a false supposition that the posticus should die earlier after death than the lateralis, because, if immersed in oil that is maintained at a temperature of 35° to 37° C., both muscles die in the same time, as is proved by our experiments with Regeczi. We have recently made three new experiments. In two cases the posticus again lived as long as the lateralis, and in the third case it outlived the lateralis on one side by five minutes, and on the other side by twenty minutes.

We have studied the influence of maintaining warmth upon the intercostal muscles and the diaphragm also, that

are akin to the posticus, and found that the irritability of the pieces kept warm considerably outlasted in general that of the pieces allowed to cool off.

That the diagnosis "paralysis of the posticus with consecutive antagonistic contraction of the closers" is groundless, can even be demonstrated from the standpoint of its champions. Antagonistic contraction is created thus: One muscle makes a contraction and moves the part on which it has its insertion. Relaxing, it has not the power to return to its former length, if it is not stretched mechanically by the weight and elasticity of the parts, or actively by the antagonistic muscle. If it is not stretched, its tissue accepts the new length, establishes itself conformably, and the antagonistic contraction is ready. That is, antagonistic contraction is sometimes absolutely passive. It accomplishes no labor, but is the result of circumstances over which the antagonistically contracted muscle has no power at all. But if the vocal cords are durably fixed in the middle line, there is labor accomplished and maintained, because the arytenoid cartilage, with the soft parts adhering to it, must be pulled upward on the steep upper margin of the cricoid cartilage. Here must be overpowered the weight and elasticity of the arytenoid cartilage and its soft parts. The transverse muscle, therefore, must be contracted actively. If this contraction ceases, the arytenoid cartilage, in consequence of its own weight and elasticity and that of its soft parts, must glide immediately down as far as the articulation allows it—as far as the cadaveric position. And this is another clew to the situation, which is indubitably characterized as a primary contracture, the nerve fibers of the transverse muscle being subjected to the same irritating influences as the nerve fibers of the other muscles.

It is thus clear that, if the vocal cords are fixed durably at the middle line, all muscles that are supplied by the recurrent laryngeal nerve are in primary contraction, the posticus included, and that this last muscle, if contracted simultaneously with the closers, becomes itself a closer, but, in community with these muscles, forces the arytenoid cartilage in a direction antagonistic to the action of the crico-thyroid muscle.

The symptoms of veritable paralysis of the posticus are, if on one side only, with phonation: Voice more or less hoarse, arytenoid cartilage of the affected side bent forward, its posterior surface seen extraordinarily well, its summit lying more forward than that of the sound side. The vocal cord is in the middle line, sometimes even somewhat overstepping it. The process with the vocal cord lies somewhat deeper. The vocal cord appears to be less broad, shorter, and rectilinear. The false vocal cord is much advanced inward, and rectilinear too.

In respiration, the affected vocal cord goes back only as far as the cadaveric position; and the true and false vocal cords remain less broad and rectilinear.

The thinness, rectilinearity, and shortness of the true vocal cord, as well as the inward excursion of the false one, are signs of the antagonistic contractioiu of the internal and external thyreo-arytenoid muscle, there being no force to draw the arytenoid eartilage outward beyond the cadaveric position. The lateralis, too, is established in this length;

that is to say, it is also in antagonistic contractions. In my article, "Zur Anatomie, Physiologie und Pathologie der Larynxmuskeln," I constructed the symptoms of veritable paralysis of the posticus partly theoretically. When I admitted them spontaneously, I had not thought of some of the above conditions which must follow the paralysis of the posticus as mediate symptoms, as being caused by the inevitable antagonistic contraction of the internal and external thyreo-arytenoid muscle. Since then *I have studied them on the living subject and have cured all symptoms completely by faradization of the posticus.*

When the affection exists on both sides, the same symptoms should be observed on both sides. The voice should be weaker, deeper, and monotonous. Respiration might be impeded, but much less so than in contracture. I have seen as yet no such case.

The above symptoms of antagonistic contracture of both thyreo-arytenoid muscles are present also if the crico-thyroid muscle is paralyzed or weakened; but in this case the position of the arytenoid cartilages is symmetrical. Here the symptoms disappear after faradization of the crico-thyroid muscle.

Concerning details, see my articles: 1. "Ueber die Fixation der Arytenoidknorpel während der Phonation" ("Wiener med. Wochenschrift," 1872). 2. "Ueber die electrische Contractilität der Larynxmuskeln nach dem Tode und den 'Aether Effect'" ("Berliner klin. Wochenschrift," 1888). 3. "Zur Anatomie, Physiologie und Pathologie der Larynxmuskeln" ("Berliner klin. Wochenschrift," 1888).

## THE PROGRESS OF THE MEDICAL SCIENCES IN OUR OWN TIMES.

BY HENRY S. STARK, A. B., M. D.

THROUGH the light of modern reason and research the advances made in the medical sciences in our own times have been so great and rapid as to inspire even the most sanguine doubter with the hope that medicine, as based on the "inductive" method of discovery, will soon reach the dignity of an "exact and positive" science, and that its mission, the preservation of man in health and disease, will be fulfilled ere many decades elapse.

Such marvelous changes has time wrought on the art of healing that the principles and practice of medicine of to-day is a transformed science dealing with methods and material different in many respects from that of previous centuries—a science, in short a creation, whereof it may truly be said "the child has been father to the man."

This reformation had its origin in the beginning of the present century with the Parisian school of medicine. The changes this school instituted were so radical, and so completely annihilated the old methods, even to their very roots, that in the course of ninety years the medical sciences suffered a complete transformation and purification.

It was in the beginning of this century that the Parisian school of medicine rose into prominence. Among its leaders were Corvisart, Cruveilhier, Laennec, the discoverer of the method of auscultation and, according to some authori-

ties, the founder of the study of pathology, and later on Magendie and Troussseau. These men based their investigations on the study of pathology, on chemistry, which had gradually replaced alchemy, and on physical diagnosis, a new study, by means of which they attempted to interpret the signs and symptoms of disease to the five senses.

The school adopted methods which must have appeared Utopian to their predecessors; it founded the study of pathology, and gave it an impulse still felt to-day. It exercised for the time an influence over medical minds all over Europe and America, inasmuch as they based all their observations and discoveries on the study of pathological anatomy, seeking for the seat of disease among the simplest structures of the economy and in the ultimate elements of the body, in the firm belief that perfection in the study of morbid anatomy meant perfection in diagnosis and in therapeutics.

The Parisian school was succeeded by the Vienna school founded by Rokitansky. They took up the work begun by the Parisians, added brilliant discoveries, and were succeeded by one who was so great in his works as to form a school by himself, and who is justly considered the greatest pathologist of our times—Rudolph Virchow. Virchow's marvelous work on "Cellular Pathology," the fruit of careful observation and experimentation, appeared in 1858, and was received all over the medical world with enthusiasm. It was especially of inestimable value in ranking the study of medicine among the exact sciences. The aim of the work, as Virchow himself says, is "to offer a view of the cellular nature of all vital processes, both physiological and pathological, animal and vegetable, so as to distinctly set forth the unity of life in all organized beings."

Thus to-day, with the data derived from the study of pathology, we can proceed on rational principles at least to account for the changes in the nutrition, in the arrangements, in the secretions and excretions of the structures of the body in health and disease; we can clearly comprehend the nature of diseases and their lesions, and can interpret and combat the symptoms of the same.

The medical sciences of ancient and middle ages we now consider to have been heretical and wedded to religion, while the more modern medicine—that which extended from the middle ages down to the time of Vesalius in the sixteenth century—we now consider to have been empirical. Vesalius marked an era in the history of medicine—a renaissance, as it were—for by his indefatigable zeal and labors the study of the human anatomy first became firmly established. His personality and those of his contemporaries and immediate successors—Falloppius, Asellius, Harvey, Morgagni, etc.—were influential throughout the scientific world, and it must be admitted that their researches have greatly enhanced the medical sciences. Before his time heresy and empiricism were the fashionable doctrines of the medical charlatans, while their most effective remedies were the amulet and the abracadabra. Since his time down to the present day the medical sciences have been suffering a slow process of evolution, so that to-day we are dealing with a science divorced from priesthood and founded on

facts and phenomena revealed by clinical observation and physiological experiment.

The fallacy of the old medical "systems" of which Boerhaave, Van Helmont, and Brown were founders is now acknowledged, and the attempt to explain the causation and treatment of disease on the "pneuma,"\* "vital forces," "humors," and the "archæus," has been frustrated by the more accurate and better equipped laborers of the nineteenth century, while the theories advocated by these brilliant intellects have fallen into disrepute, and the knowledge they left behind is interesting in so far as it marks an item on the pages of history, standing there solely as a legacy of the past.

It is fortunate that these old "systems" of medicine, and the wild speculations that accompanied them, have nearly all disappeared. One "system" still numbers the onward march of the medical sciences; I refer to homœopathy. It is indeed strange that this system of dogmas and sterile doctrines is still suffered to exist, and even to flourish. Yet, if we may correctly judge the future from the past, the fate of this system is inevitable; the same factors that eradicated the others will be likely, in due course of time, to consign this one to oblivion.

In the medical sciences of to-day we no longer look for the "pneuma," the "vital forces," the "humors," or the "archæus," but rather inquire into disordered functions, impaired nutritions, structural derangements—in short, our knowledge of to-day is not based on heresy and empiricism, but on physiology and pathology; light and reason have succeeded ignorance and superstition.

It is far from my intention to depreciate entirely these old "systems" or to denounce their authors, for, however great their errors, their efforts have resulted in permanent improvement, not alone in medicine, but in other departments of knowledge. The theories of these giant medical thinkers, developed and elaborated at a time when the facts of science were few, the technicalities of detail scarce, the methods of investigation crude, were far in advance of the times in which their authors lived; their doctrines were believed by their contemporaries to be the consummation of the ideal of medical knowledge, and formed a basis for the classification of diseases which, however unscientific when submitted to modern tests, was a marvel of ingenuity and originality of thought. The errors of these "systems" served later investigators as a practical school for in-

\* "Pneuma," πνεῦμα, "vital principles or forces." Terms used probably by Hippocrates *et al.* to denote something different from the immortal soul on the one hand and the mortal body on the other, endowed with intelligence and appointed as a sort of internal guardian angel to avert danger and cure the maladies of the body over which it presides."—J. R. RUSSELL, "Art of Medicine."

"Archæus," ἀρχαῖος, of Van Helmont. The archæus is the curative spirit which, working upon the raw material of water or of fluidity by means of a "ferment," excites all endless actions which result in the growth and nourishment of the body.—J. R. RUSSELL, "Art of Medicine."

Humors of Hippocrates were black bile, yellow bile, the blood, and phlegm. Out of the excess or deficiency or misproportion of these four humors there arise diseases; by restoring the correct proportion, diseases are cured.—J. R. RUSSELL, "Art of Medicine."

struction, guiding them to the advancement of a more exact science and arming them against the unscientific tendencies of the times.

In tracing the progress of the medical sciences of our own times, and in contemplating the changed complexion of events in medical thought and methods, it will naturally suggest itself to our minds to inquire, firstly, into the influences to which we attribute the marvelous results achieved by men of our own day, and, secondly, into the extent in which these sciences have fulfilled their ultimate mission.

I venture to state that the progress of the medical sciences in our own time has depended directly and proportionately on the corresponding progress made in the sister sciences; to physics and its correlative branches—mechanics, optics, acoustics, electricity; to organic chemistry; to biology; to natural history, and all the other sciences, abstract or concrete, practical or theoretical. The association between the sciences, moreover, is so universal and inseparable that the gradual development of any one depends on the correlative development of the others. This relationship becomes apparent when we study the history of medicine through its various eras—the primeval, mediæval, modern, and contemporaneous—for we then see that the progress in medicine has been simultaneous and running in the same channel as the improvements made in the other sciences, and that the great discoveries in the one branch have depended on the great discoveries in the general sciences. For instance, the discovery of the laws of reflection and refraction of light led later on to the construction of the microscope, spectroscope, ophthalmoscope, etc., and their subsequent application to the art of healing; the discovery of the laws of the conduction of sound-waves gave birth to the stethoscope; so the urometer depends for its employment on the principles of specific gravity, and so the broad principle is applicable not only to clinical apparatus, but to all branches of the medical arts and sciences. We see it exemplified in physiology, where our knowledge regarding the functions of nutrition and the nature of reproduction has been wonderfully enriched by comparative studies in biology; in therapeutics, where the introduction of new medicaments has depended on the brilliant discoveries in organic chemistry and in botany.

The lesson that these observations teach is that a great discovery often requires the experience of generations for its practical application to the arts and sciences, nor can we estimate the value or importance of it at the time it is made, for while a particular discovery may appear insignificant *prima facie*, yet it may stimulate and encourage experimentation so as to lead to other discoveries, which latter may prove of inestimable value. The properties of the loadstone and of amber were known to the ancients, yet centuries elapsed before the wonders of magnetism and electricity were revealed and put into practice; the laws of the transmission of sound-waves through different media were known long before the methods of auscultation and percussion were employed in diagnosing the condition of subjacent parts of the body.

To the inquiry to what extent the medical sciences have reached their ultimate mission I would answer that it has

been established beyond all question that the recent appliances of intellectual sciences and the great increase in human knowledge have placed at our disposal means with which the physician can lessen human suffering and mitigate pain, can maintain health and abort disease. Secondly, some of the epidemics and plagues that formerly depopulated countries and baffled all human skill have been robbed of their terrors through our elaborate system of quarantine and our improved laws of hygiene; thus the ravages of typhus and typhoid fevers, of Asiatic cholera and yellow fever, occur less frequently, and are almost unknown in certain quarters that were visited at regular intervals. Thirdly, the treatment of other diseases has been so modified and improved that the great sacrifice of life that formerly attended them has considerably diminished; thus the dreaded disease small-pox claims few victims since the brilliant discovery of Jenner; the progress of tuberculosis of lung or of bone can be oftentimes retarded by the judicious administration of cod-liver oil in the former and the early resort to the knife in the latter; the frightful mortality that formerly accompanied puerperal fever has given way to absolute safety in the lying-in chamber, while the frequency of surgical diseases—as septicæmia, pyæmia, gangrene, and erysipelas—has been diminished by the recent improvements of modern surgery; and so throughout the whole category of diseases improvement in the method of treatment has been followed by improvement in such rapid succession that it has been computed by some English observers, from a comparison of hospital reports and census statistics, that the term of human life of the individual and of the masses collectively has actually been lengthened.

Despite our brilliant researches and our ever-increasing successes, we have not attained perfection, nor can it be expected that we ever should, for that would mean life everlasting, a principle at once at variance with the laws of nature. Life is a cycle beginning and terminating in death, and death is as necessary for the perpetuity of the human race as life itself is. We must ever bow to Nature's laws and never defy her. Since the vast fabrication of human knowledge has been built upon her teachings, it is well to remember the words of the French philosopher Condillac: "All our knowledge we owe to Nature, that in the beginning we can only instruct through her lessons, and that the whole art of reasoning consists in continuing as she has compelled us to commence."

The ideal of the medical sciences, therefore, is still a desideratum. There are medical problems which are no nearer solution to-day than they have been for generations past. There are still mysteries connected with medicine which are as deep as the Sphinx and as dark as the Sibyl. Nor can we as yet have hopes of that millennium when disease shall cease to exist and the physician's vocation shall be a lost art. Hippocrates's aphorism will ever hold true: "Life is short, art is long, experience deceptive, and judgment difficult."

While I purpose now to describe briefly some of the most important events in the history of medicine in our own times, yet I do not intend that this shall form a chronological recapitulation of all noteworthy events, nor a

biography of the half dozen great men who have played leading parts on the world's medical stage. It will be convenient for my purpose to divide the subject into general medicine and general surgery, using the terms in contradistinction.

Foremost in importance among the brilliant innovations of the nineteenth century is the rise and development of the "germ theory of diseases" and the new science it has given birth to—bacteriology—a study which now occupies a place in the regular course of study in many of our medical schools of learning.

Perhaps no biological theory or problem has ever attracted a greater share of the attention of the medical world, nor has resulted in more lasting benefit to mankind, than the theory that certain diseases owe their specific character to the presence in the system of minute organisms derived from without. The germ theory is not the production of mere chance nor the result of accidental discovery, but is the inevitable outgrowth of a long chain of experiments covering a number of years, carried out by Schwann, Tyndall, Pasteur, Lister, and others on the theory and nature of the parallel processes of fermentation and putrefaction.

Just how much the germ theory has accomplished it is difficult at the present time to determine on account of the uncertainty of many of the data and because we do not know what bearing our knowledge of to-day may have on future discoveries, especially since the pathogenic relations between bacteria and diseases are not yet clearly understood.

We can not assume that a particular disease is caused by a particular micro-organism simply because that bacterium, bacillus, or what not, is invariably found in that malady. There are still other conditions to be fulfilled before the chain of thus reasoning by analogy can be complete. Klein has formulated several laws governing the relation between micro-organisms and diseases which seem to cover the ground. He says: 1. "It is absolutely necessary that the organism in question is present in the blood or diseased tissues of man or of an animal suffering from the disease." 2. "It is necessary to take these organisms from their *nidus*, to cultivate them artificially in suitable media outside the body; . . . to go on cultivating them from one culture to another for several generations, in order to free them from every kind of matter derived from the animal body from which they have been taken in the first instance." 3. "After having thus cultivated the micro-organisms for several successive generations, it is necessary to re-introduce them into the body of a healthy animal susceptible to the disease, and in this way to show that this animal becomes affected with the same disease as the one from which the organisms were originally derived." 4. "It is necessary that in this so affected new animal the same micro-organisms should again be found." (See "The Practitioner," London, March, 1884.)

The number of diseases for which micro-organisms have been discovered is legion, but only a few of these—such as malignant pustule, relapsing fever, tuberculosis, and perhaps hydrophobia—have fulfilled the requirements of Klein's

laws, and only for these can the germ theory be said to be established.

What we do know, is that the germ theory offers a satisfactory explanation of the morbid agencies by which certain of the infectious diseases are communicated, and that the treatment of these diseases has undergone radical changes in conformity with our advanced views.

If we estimate the value of the germ theory, not by what it *has* accomplished but by what it *promises* to accomplish, we are inspired with the hope that we shall soon understand the nature of the morbid agencies that create disease, and shall be able to destroy their power of communication and of propagation.

Another event which marked an era in the medical history of our own times was Schönlein's discovery in 1839 that the contagiousness of the disease of the scalp called favus was due to a vegetable parasite or fungus. This was the first of a series of brilliant discoveries on parasitic diseases of man, of animals, and of plants. The constant presence of fungi in herpes tonsis, pityriasis versicolor, aphthæ, and other diseases has since been established.

Other discoveries in general medicine which may be mentioned *en passant* were: The establishment of the non-identity of the two affections typhoid and typhus fevers by Louis in 1839; before this date, the specific difference in aetiology, pathology, and symptomatology between the two diseases was unknown; the true and certain character of many of the diseases of the kidney was first announced by Bright in 1837; important contributions have been announced in our knowledge regarding the localization of diseases of the brain and spinal cord. Recent additions to nosology are Addison's disease of the suprarenal capsules, first announced in 1855; Graves's disease, exophthalmic goitre, to which attention was called only within the last few years; Hodgkin's disease, pseudoleucæmia, first described in 1832.

Gerlach's experiments to show that consumption may be contracted by drinking the unboiled milk of tuberculous cows deserve also to be mentioned here as a comparatively recent discovery.

In the domain of therapeutics the same activity has been manifested as in the other branches of medicine. The great number of new drugs and remedial agents that have been added to our therapeutic resources is certainly encouraging evidence of the great reform in medicine which recent times have realized. The discovery of these drugs, which have taxed organic chemistry and botany to their utmost, is a healthy indication of the great benefit that is to be derived from the application of the "experimental method" to the medical sciences.

Yet, when we examine the list of these new drugs, we can not help remarking how few of them will stand the test of time and experience, and how few there are which might be considered in the light of specific remedies to counteract particular diseases. It is a well-known fact that most of the new medicaments that are destined to stay in the *materia medica* never reach organic disease, but only palliate the symptoms incidental to such disease. This is true of the new antipyretics, anaesthetics, analgesics, hyp-

noties, and cardiac stimulants; an exception to this rule is, however, found in the new antiseptic medications based on the germ theory of disease.

The deplorable scarcity of specific remedies was already recognized as early as the beginning of the seventeenth century by the great scientific luminary, Sir Francis Bacon, in his "Novum organum." In this work he states that he finds a "deficiency in the receipts respecting the cure of particular diseases, . . . and that medicine was to be improved by the discovery of remedies for the cure of particular diseases, which discoveries were made, not in years, but in ages."

Our most important therapeutic resources are acquisitions of the last fifty years. To this category belong the inhalent anaesthetics—ether, chloroform, nitrous oxide; the local anaesthetics—cocaine and methyl chloride, which last gives promise of a great future, especially in the treatment of neuralgias; the cerebral sedatives—the bromides and chloral; the use of the salicylates in rheumatic affections; the antiseptic medicaments especially employed in gastrointestinal and pulmonary affections; the new antithermic remedies and cardiac tonics, which are too well known to require enumeration here. Of remedial agents other than drugs we would cite hypodermatic medication, the numerous precious uses of water and of electricity, artificial digestion by mouth or rectum, the pneumatic differentiator in pulmonary complaints, stomach irrigation (lavage), forced feeding into the stomach (gavage), intestinal irrigation *per rectum* (enteroelism), and a horde of others too numerous to note in this paper.

Surgery, as an art and science, may with propriety be said to have witnessed the greatest improvements of all branches of medicine. The history of surgery of the nineteenth century is the history of an uninterrupted series of successes, culminating in a new modern system. This flourishing and improved system of modern surgery owes its existence to (1) the use of the anaesthetics, (2) the application of the Listerian principle, (3) the introduction of Esmarch's elastic bandage to control profuse haemorrhage during operations, (4) the elaboration of surgical appurtenances, (5) the extensive yet perfect method of reporting the results of observation through that great avenue of communication, the medical press, and through society reports, personal intercourse, and international congresses.

It is fair to assume that, as far as the saving of human life or misery is concerned, the anaesthetics have played the most important rôle. Their practical application is one of the wonders of science. Hippocrates's saying that "to relieve pain is a divine work" is most beautifully demonstrated here. I would consider the three most brilliant achievements of modern surgery the use of the inhalent anaesthetics, the application of the antiseptic theory, and the use of the elastic constrictor for the production of artificial anaemia.

Many of the crowning triumphs of modern surgery are due to the Listerian principle. To the eminent author of this method of treatment mankind owes a debt of incalculable gratitude for having, more than any one before or after him, advanced operative surgery to so high a degree

of perfection. The aseptic method initiated by Lister in 1865 is briefly nothing more or less than an exact method founded on a special theory. The exact method is the prevention of putrefaction in wounds, whether surgical or traumatic, by destroying the septogenic power of the aerobic micro-organisms by means of certain antiseptic drugs—carbolic acid, originally—and certain antiseptic precautions. The special theory is the germ theory. Listerism is thus one of the branches of bacteriology.

Lister was not the first to demonstrate the noxious effects on wounds of micro-organisms suspended in the air; the experiments of Pasteur, which preceded Lister's—especially those which led the eminent Frenchman to discover the yeast plant and its relation to alcoholic fermentation, and his later discovery of the lactic-acid fermentation—formed the basis of Lister's discoveries and labors. Pasteur, therefore, was the first who demonstrated the living nature of fermentation and its kindred process, putrefaction, while Lister was the first to systematize a method of wound-treatment based on these discoveries.

At a lecture delivered by Sir Joseph Lister, on October 10, 1876, at the Charity Hospital, New York, he frankly acknowledged this, and said: "When Pasteur showed that putrefaction was a fermentation, it occurred to me that here was a chance for improvement; we may prevent putrefaction if the cause is not the access of air, but of living organisms developed in the air, and which in the blood are the causes of putrefaction." ("Medical Record," 1876.)

Listerism is the *sine qua non* of modern surgery. Time and experience have demonstrated the soundness of the principle, while the results alleged for this practice have been more than realized in the certainty of success with which operations are now undertaken which hitherto were regarded as unwarranted and unjustifiable. It has almost abolished suppuration, secondary haemorrhage, and erysipelas, while, on the other hand, it has increased the proportion of recoveries after operations, so that, in amputation of the extremities alone, the percentage of recoveries has increased, on an average, from sixty-five to eighty-five per cent.

To the introduction of the aseptic method we owe those remarkable achievements in intra-abdominal, intra-cranial, and intra-spinal surgery which are now every-day occurrences in our hospital wards. Among the many successes attributed to this method are: primary healing of sutured wounds; the substitution in selected cases of exsection and resection of joints for amputation; plastic operations, including skin-grafting and transplantations; operations for deformities and operations in special branches of surgery; union by suture of nerves, tendons, muscles, bones, with complete restoration of functions; exploratory operations for diagnostic purposes, etc.

This, then, is a *résumé* of the more important innovations that have signalized the latter half of our century. In the race for advancement the medical sciences have outstripped many of the other sciences, proving that medicine is not stationary but eminently progressive, while the results achieved demonstrate that medicine is no longer theoretical and speculative, but practical and experimental. The ex-

perimental method of research and the inductive method of discovery have been mainly influential in creating and developing medicine on its present renovated basis. Irrational speculations, sterile theories, and dogmatic systems have fallen into insignificance when compared with the importance that now attaches to the *clinique*, the microscope, and the test-tube as fields for study.

Our knowledge of to-day is as nothing when compared with what we soon shall know. The present is a stirring, hopeful age; the future, however, is pregnant with grander inspirations. The spirit of the times indicates an everlasting struggle of science and humanity for *light, more light*.

270 EAST SEVENTH STREET.

EXPERIMENTS RELATIVE TO THE  
THERAPEUTICAL VALUE OF  
THE EXPRESSED JUICE OF THE TESTICLES  
WHEN HYPODERMICALLY INTRODUCED INTO  
THE HUMAN SYSTEM.

BY WILLIAM A. HAMMOND, M. D.,  
WASHINGTON.

At a recent session of the *Société de biologie* of Paris Dr. Brown-Séquard created considerable astonishment by describing certain experiments which he had performed upon himself with the expressed juice of the testicles of dogs and guinea-pigs. This juice, mixed with a small quantity of distilled water, he injected by means of a hypodermic syringe under the skin. He stated that the effect was such that he felt as though he were at least ten years younger; his capacity for mental and physical work was greatly increased. Peristaltic action of the intestines, which had been absent for several years, returned, and he likewise regained power over the bladder and its sphincter. I do not dwell longer upon his experiments, for the details of them have been published in nearly every medical journal of the country, as well as in probably every newspaper in the United States. It will be sufficient to say that they were confirmed by Dr. Variot, who experimented upon three old men, and who obtained nearly identical results with those which followed Dr. Brown-Séquard's injections upon himself. Dr. Variot made use of rabbits and guinea-pigs.

My own experiments began on July 24th, and my method of procedure was as follows: I used the testicle of the young ram, stripped it of its coats, cut it into small pieces, and crushed them in a Wedgwood mortar till they were reduced to a pulp. A quantity of pure water equal to about half the bulk of the crushed testicle was then triturated with it, and the mixture was then filtered through Swedish filtering paper. The liquor, previous to being injected, was examined microscopically; it was always found to consist of oil globules in small quantity, red blood-corpuscles, white blood-corpuscles, numerous cells having very much the appearance of the blood-corpuscle-holding cells of the spleen, a large amount of morphological matter, consisting of the tissue of the testicles, and very generally spermatozoa. In one instance some of these latter were

alive; in all the others they were dead. I injected from fifteen to thirty minims each time. Usually the place selected was the anterior portion of the forearm; at other times it was the arm near the insertion of the deltoid muscle.

In nearly every case the liquor was injected under the skin within an hour and a half after the death of the animal. In no case was it used at a later period than three hours after the animal was killed. In some of the cases it was injected within three quarters of an hour.

CASE I.—The first experiment was performed upon myself; not that I thought I required the injection for any infirmity, but simply in order that I might experience in my own person any ill effects of the injection before proceeding to use it in the cases of other persons. I can not say that I experienced any particularly strengthening effects or any marked degree of mental exhilaration, but a result ensued for which I was entirely unprepared and to which my attention had not been in the slightest degree directed.

In May, 1888, while attempting to get on a railway train which was in motion, I found that it was going so rapidly that I could not keep my footing long enough to make a spring to the platform. I was obliged to let go or run the risk of being killed. I was thrown some thirty feet, striking on my left shoulder and bruising my left side. The left arm, as a consequence of the fall and the straining it had received while holding on to the car, became almost useless for certain purposes. Up to the time of the injection it had been the seat of constant pain. I could not put it behind me or place it on top of my head, nor put on my coat without assistance. The injury seemed to have been mainly concentrated upon the deltoid, coracobrachialis, triceps, and latissimus dorsi muscles. The symptoms had not been mitigated in the least up to seven o'clock on July 24th, when I took the hypodermic injection. I went to bed at about eleven o'clock that night. When I awoke in the morning the pain was gone and I could move my arm in all directions as well as ever I could in my life, and it has remained perfectly well ever since, up to this date, August 26th. I can perform any movement of the arm of which it is capable, and it is absolutely free from pain under all circumstances.

The local effects of the injection were scarcely noticeable; there was a little diffused erythema, but nothing else.

I took a second injection on July 26th, but I observed no general effects therefrom. Locally, however, there was a good deal of disturbance. At the point where the syringe had entered, a swelling as large as a walnut appeared, and the parts around were inflamed and painful. Suppuration followed; the abscess was opened several days afterward and about a drachm of pus was evacuated.

CASE II.—The patient, a man, aged sixty-five, had suffered for several years with insomnia and feeble heart. His pulse was weak, averaging ninety-five in a minute, irregular both in rhythm and in strength, and intermitting regularly every third beat. There was no valvular disease, and I regarded the heart trouble as being one of simple cardiac weakness probably due to fatty degeneration. An injection of the fluid, prepared as described, was made under the skin of the left forearm on August 4th, at about ten o'clock in the morning. I failed to note the effect upon the heart at the time, as my mind was directed toward the relief of the insomnia and some marked depression of spirits under which he labored. But at about three o'clock that afternoon I felt his pulse. The intermittence had disappeared, the cardiac impulse was stronger than I had ever noticed it in him, and it had fallen in frequency to eighty-five. He told me that he felt more cheerful than he had for a long

time. He walked more erect, and could mount a staircase without his respiration becoming accelerated. That night he slept well, but there was no after-relief of the insomnia. His pulse, however, remained regular and strong till August 24th, when the irregularity reappeared and the heart again became weak. This patient, aware of the abscess in my arm, preferred not to take another injection, and I did not press the matter on him.

**CASE III.**—A man, aged thirty-four, had been for several years affected with impotence and at times great mental depression, both apparently resulting from excessive sexual indulgence. He had not been able to accomplish sexual intercourse for over a year, owing to the impossibility of obtaining sufficiently strong erections. The first injection was made on August 10th at about eleven o'clock in the morning. In a few minutes the pulse had risen in frequency from 78 to 96, and there was marked mental exhilaration. During that night and the following night there were strong erections, and the improvement in the mental condition continued. On August 12th a second injection was made, without apparently increasing the intensity of any of the observed phenomena. On the 14th the third injection was made. Mental exhilaration was still well marked, and repeated erections occurred during the day and night. On the 16th he had sexual intercourse, which he described to me as being entirely satisfactory. There were no further injections. To-day he informs me that there has been a slight decrease in his sexual power, but he attaches very little importance to this fact, as he thinks he has enough in reserve.

**CASE IV.**—A man, aged thirty-six, with sexual impotence; in other respects apparently in normal condition. Erections have been very feeble with this patient for several years past, although sexual intercourse has not been impossible. The first injection was made on August 10th, with the immediate effect of increasing the frequency of the pulse from 80 to 92. During the day he repeatedly informed me that he had never felt better in his life; that he felt strong and in perfect health. No notable effect, however, was produced upon the sexual organs. On August 12th the second injection was made. Mental exhilaration was not so strongly marked as after the first, though there were some feeble erections during the night. The third injection, on August 14th, was followed by stronger erections. On August 18th the patient had sexual intercourse, the erection being somewhat more vigorous than upon recent occasions. On August 21st the fourth injection was made, and there was sexual intercourse that night, of improved character. No further injections were made in the case of this patient, as he was obliged to return home on the 23d.

**CASE V.**—A man, aged fifty, suffering from cardiac weakness, nervous dyspepsia, spinal irritation, and general physical debility, with a strong tendency to hypochondria. The first injection was made on August 10th. He experienced at once some degree of cardiac excitement. That afternoon he walked a distance of four miles, a feat he had not been able to accomplish for over a year. There was also a noted improvement in his appearance, and he became altogether more cheerful than he had previously been. The following day his condition still remained improved, the cardiac impulse was stronger, and the pulsations were fifteen fewer in a minute than they had previously been. On August 14th the second injection was made. His physical strength was still markedly better than it had been, as shown by his ability to walk farther and with less fatigue than before being placed under this treatment. His stomach had also got into a greatly improved state, though I do not attribute this entirely to the injections, as on the day that he began taking them I also began washing the stomach out every morning with warm water.

**CASE VI.**—A man, aged fifty-six, a stone mason by occupation,

had suffered for a year with lumbago, during the greater part of which period he had been unable to work at his trade. On August 4th I made an application of galvanic electricity to the lumbar muscles, with the effect of giving immediate though temporary relief. He came back on the morning of the 5th somewhat improved, but not able to stoop over as he would have to do at his occupation. He received his first injection at about ten o'clock. Within ten minutes he was entirely free from pain and could move his body in any direction, bending his spine backward, forward, and sideways with entire ease and comfort. The next day he went to work at his trade and has remained well ever since.

**CASE VII.**—A man, aged eighty-three, with hemiplegia, the result of cerebral haemorrhage two years previously. He had some use of the right arm, but dragged the corresponding leg at every step. The first injection, on August 14th, was followed by immediate improvement in his walking, the right foot being lifted clear of the ground at each step. He returned on the 16th, with the left arm (into which I had made the injection) inflamed and swollen with indications of the formation of a small abscess. The improvement in walking, however, still continues and he says he feels better than he has for a long time. I thought it better for him to take no further injections until the inflamed arm was well, and he has not yet returned.

**CASE VIII.**—A woman, aged sixty-five, had suffered from melancholia and fixed delusions for three months. The first injection, on August 12th, produced no apparent effect except inflammation at the point of injection, with indications of the formation of an abscess, which, however, did not go on to suppuration.

**CASE IX.**—A man, aged fifty-four, of good general health, but suffering from muscular rheumatism, chiefly manifested in the lower extremities, causing pain, stiffness, and difficulty of walking, had also slight lumbago. The first injection was made on August 12th. He returned on the 14th and stated that the pains, stiffness, and difficulty of locomotion had entirely gone, and that he felt in better condition than he had for many years past. The second injection was made on that day, and the third on the 16th, but on this occasion, instead of using the liquor prepared as I have described, I, without his knowledge, substituted water. On Sunday, the 18th, he returned and stated that the last injection had done him no good, and that he was not quite so well as when I had last seen him. Without telling him of my proceedings, I gave him an injection of the testicular juice. On the 22d he reappeared with the statement that he was entirely well and that he did not see the necessity of continuing the treatment, and I have not seen him since.

**CASE X.**—A man, aged sixty, suffering from the effects of excessive mental work and from cardiac asthma. He entered my consulting-room gasping for breath and almost exhausted, though he had walked less than fifty paces. On examination, I found cardiac irregularity and weakness, with a pulse of 96. On August 21st he received the first injection. His heart immediately became stronger and more regular and his pulse fell to 80. The difficulty of breathing disappeared. On the 23d he returned. The heart and respiration were regular; the pulse was 82 and strong. He then received his second injection. To-day, August 26th, I saw him for the third time. He states that his health is good and that he experiences no difficulty in breathing, in walking, or in climbing staircases. At his first visit I prescribed some pills for him, consisting of licorice and magnesia, and impressed upon him the idea that whatever improvement he experienced would come from these pills. He did not know until to-day what the injection was, and he attributed the manifest change in his health to the inert medicine I had prescribed.

It is not necessary for me to draw any conclusion from these experiments, as they speak for themselves. It will be seen that there is evidence to show that we have in the testicular juice a valuable addition to our *materia medica*, the precise worth of which, however, it is not yet in our power to establish. It is only the sensational newspapers that speak of it as an "elixir of life" or as an agent capable of making an old man permanently young again. It seems to be the chief object of some of these mediums for communicating intelligence to distort the truth, not only by the use of sensational headings printed in large letters of a grossly misleading character, but to misinterpret, misconstrue, and misquote the medical information given them at their solicitation. The venerable originator of the method of treating certain infirmities and diseases to which this paper relates has been abused, not only by an irresponsible press, but by physicians who ought to have exhibited more consideration and decency than they have shown; and they have done this not in the medical journals but in any newspaper to which they could obtain access. If they had had the intelligence and the forethought to be the first to make use of his discovery, we should have had no such exhibitions as we have had during the last few weeks.

One point further seems to call for some consideration. I have observed that some of the experimenters sterilize the testicular juice before using it. If there is any virtue whatever in the liquid, it would be entirely destroyed by such a process. It might as well be boiled as sterilized. Experiments with such a substance are absolutely valueless. Sufficient immunity against the propagation of disease can be obtained by examining the fluid microscopically before it is injected into the system. Whatever is capable of killing the germs of disease would be equally capable of killing the vital germs upon which the testicular juice depends for whatever efficacy it may possess.

In conducting these experiments I have been assisted by Dr. E. L. Tompkins, who made several of the preparations and injections.

## SOME UNUSUAL MANIFESTATIONS OF TUBERCULOSIS OF THE LARYNX.\*

By CLARENCE C. RICE, M.D.,  
NEW YORK.

THE object of this short paper is simply to cite several cases of laryngeal tuberculosis which have come under my observation during the past year. None of the pathological conditions to be described are entirely unique. In quickly reviewing the vast amount of literature which has been written on laryngeal consumption during the past two years, I have found laryngeal lesions somewhat similar to those observed in my cases described by writers. And these writers are, with few exceptions, members of this association. In fact, it would be difficult to find any subject pertinent to laryngology which can not be found thoroughly treated in the "Transactions" of this society.

It is not altogether an Hibernianism to say that unusual

\* Read before the American Laryngological Association at its eleventh annual congress.

manifestations of laryngeal tuberculosis are rare, because tuberculosis of the larynx manifests itself with but little variety in pathological conditions. We know where to look for its first appearance; we can predict the mode of its extension; and the stages of its destructive process follow one another with remarkable regularity. It is well to tabulate cases of any disease which present lesions at all unusual, because these are the cases which are somewhat difficult of diagnosis. It would be worse than a waste of time to cite the different opinions and the reasons on account of which they are held at the present time. As to the aetiology and pathology of laryngeal phthisis, we believe that in five years from now there will remain but very few of the minority who to-day think that the name of tuberculous laryngitis does not describe the pathological condition in, we were going to say, all cases of laryngeal disease associated with pulmonary phthisis. The question as to the existence of *primary* tuberculosis has been fully discussed by this association. And we know, too, the opinion of nearly every leading laryngologist as to the curability of laryngeal consumption. In addition to the very truthful description of this disease in Cohen's text-book, published nine years ago, but which requires but little revision to-day, we find in the first volume of the "Transactions" of this association a paper on "Bucco-pharyngeal Tuberculosis," by Bosworth; in the second volume, "Primary Tuberculosis of the Larynx," by Cohen, and "The Therapeutic Value of Rest in Phthisical Laryngitis," by Robinson; while such papers as "Tubercular Ulceration of the Tongue," by Bosworth, "The Progress of Laryngeal Phthisis," by Porter, and "The Laryngeal Affections of Pulmonary Phthisis," by Robinson, are published in the third. In the fifth (1883), "Treatment of Laryngeal Phthisis," by Ingals, and "The Healing of Ulcers in Laryngeal Phthisis," by Jarvis. De Blois cites "Cases of Buccal Tuberculosis" in the sixth report. Robinson contributes a paper on "Alimentation in Laryngeal Phthisis" in the seventh. In the eighth we find a paper by Delavan on "Buccal and Lingual Tuberculosis." At last year's meeting we heard two papers pertinent to the subject—viz., "A Specimen of Stricture of the Larynx with Extensive Cicatrization from a Case of Ulcerative Tuberculosis," by Cohen, and "Residence at Certain High Altitudes as a Means of Cure for Laryngeal Phthisis," by Wagner.

In addition to these, valuable monographs have been published outside the "Transactions" by members of this association. This much and more has this association accomplished in the way of investigating laryngeal tuberculosis. And nothing new can be stated at this meeting.

There is one clinical point relative to laryngeal tuberculosis which I think has received too little attention, and that is the frequency of the active co-existence of tuberculous and syphilitic laryngitis. This is, of course, especially true in hospital and dispensary practice. Many cases of larynx disease which it is difficult by their lesions to classify are combinations of tubercular and syphilitic disease. It is a mistake to try to relegate such cases solely to either one of these diseases. The prognosis will depend upon which one of these two diseases is the more active. Students who ex-

pect to find the laryngoscopic illustrations of text-books easily corroborated by the laryngeal mirror should be taught the coexistence of tubercular and syphilitic laryngitis, and should consequently expect to find the characteristic laryngoscopic appearances of either of these diseases marked by a case in point:

Mr. F. Y., aged thirty-five, superintendent of a manufactory, came to me in 1886. He had suffered with throat symptoms for six months. Soreness over larynx and pain in swallowing had been excessive for a few weeks at a time, and had then become much less troublesome. One parent had died of pulmonary phthisis. The history pointing to syphilis was obscure, though he had had venereal disease other than gonorrhœa. He had lost twenty pounds in weight, and had a slight cough. His temperature was about 100° F. Slight dullness over one apex and change in quality of respiration. The appearance of the larynx at his first visit is shown in Fig. 1. I was struck with

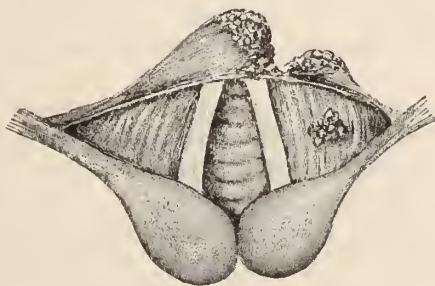

FIG. 1.

the extensive destruction of the epiglottis as compared with the intralaryngeal degeneration. The arytenoids presented the typical semi-oedematous swelling, and there was slight ulceration on both sides of the larynx, but the larynx as a whole presented a much healthier appearance than would have been expected if the destruction of the epiglottis had been occasioned by tubercular infiltration and ulceration. The man, though a little emaciated, seemed to me to have sufficient vitality to recover. None of the tubercular bacilli were found. He was put on increasing doses of the saturated solution of potas. iodid.; the ulcerated surface of the epiglottis was treated with iodoform in ethereal solution every day. The ulceration of the epiglottis was controlled as if by magic, and complete cicatrization took place. The ulceration in the laryngeal cavity also healed, but the arytenoid remained enlarged. His general health improved. The loss of the epiglottis gave him little discomfort. He regained his weight. He remained in good condition for almost a year, when he caught another cold. His cough increased, and in two months his larynx was the seat of a typical ulcerative tuberculous process. These ulcerations were confined to the cavity of the larynx. He lived about six months. There was also rapid degeneration of the lung tissue.

Here undoubtedly was a case where syphilis and tuberculosis were blended. The epiglottis was destroyed by syphilitic ulceration, but the interior of the larynx was tuberculous. The epiglottis was healed by appropriate treatment, but the club-shaped arytenoids remained.

Had the entire process been tuberculous it would have been impossible to control the extensive ulceration of the epiglottis. Deep contractile scar tissue, so characteristic of syphilitic ulcerations, covered the epiglottis. I think this combination of tuberculosis and syphilis is far more common in the larynx than is supposed. Some of the cases of

cure which have been credited to the tuberculous process should, I believe, be placed under the head of syphilis. The results of treatment will in some of these cases of ulcerative laryngitis be the only way of determining the quality of the inflammatory process. A second case, quite similar to the above, I have seen this winter; the same great destruction of the epiglottis was present, but the tubercular indications of the larynx were more marked than in Case I. The effect of appropriate treatment on the syphilitic portion of the lesion is wonderful in these cases, and for a time the physician is almost deceived into the belief that he can heal the larynx, but the tuberculous process soon asserts itself and the end is only shortly delayed.

A second pathological condition which frequently complicates to a small extent the usual laryngoscopic appearances of a tubercular larynx was present in a remarkable degree in a case which I saw one year ago. The pathological condition referred to is the proliferation of the so-called granulation tissue from the bases and edges of the ulcerations of phthisical laryngitis. This condition is fully described by Dr. John N. Mackenzie,\* and is called by him one of granular hyperplasia. I believe that he is correct in the impression that this growth from an ulcerated surface "may be regarded as representative of a connection process—as a natural step toward cicatrization." I would go a step further and say that the degree of vitality remaining in the laryngeal structure may be measured by the amount of this granular tissue which nature is able to construct. The most rapidly destructive cases of laryngeal tuberculosis, and consequently those in which the vitality of the tissues has been more markedly impaired by tubercular infiltration, do not—so far as my experience goes—show much tendency toward the formation of connective tissue. The surfaces melt away without any attempt at repair. The rapidity of the pulmonary and laryngeal process may also be measured somewhat by the presence or absence of this tissue. I cite the following case only because the larynx contained so much of this granular tissue:

W. M., a Hebrew, about forty years old, merchant. Previous or family history of little significance. Though of moderate means, he had denied himself proper food and care, and was in impaired general condition when he contracted the cold some eight months before he came to me. His laryngeal symptoms had come on very slowly—only slight pain and tenderness over larynx. Increasing hoarseness and dyspnoea were his most troublesome symptoms. When I first saw him he did not present the general appearance of a phthisical patient, but the look of a person who had had too little nourishing food, together with the anxious facial expression of one suffering from dyspnoea; a moderate amount of cough was present. Slight rise of temperature. Fig. 2 represents the laryngoscopic appearances of the larynx; they were as follows: Epiglottis slightly reddened and thickened, but not ulcerated. Arytenoids moderately enlarged but not typical. The interarytenoid commissure was filled with a papillomatous outgrowth seen frequently in both tuberculous and syphilitic laryngitis. The dyspnoea was found to be partially due to the lack of abductive power of the vocal bands, but more to the blocking of the laryngeal cavity with both granular tissue and tissue which was papillomatous

\* Mackenzie, J. N., "Archives of Medicine," vol. viii, p. 108.

in appearance. There was little ulcerated surface to be seen, although the sides of the larynx presented the dull-green appearance common to tuberculous ulceration. From the sides of the larynx above the ventricular bands, from the ventricles themselves, and from the vocal bands proper, there could be seen, not only the small, grayish-red, slightly elevated tissue common to ulcerative laryngitis,<sup>\*</sup> but tissue much more prolific in appearance like that springing from the interarytenoid depression. This latter tissue did not, I believe, grow from an ulcerated surface, but was covered by epithelial elements. The case was demonstrated to a class of students, and I intended to remove portions of the obstructing tissue with forceps, both to relieve the dyspnoea and for examination microscopically. The case fell into other hands at the college two days later, and as a strong solution of nitrate of silver was applied to the laryn-

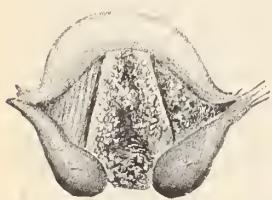

FIG. 2.

FIG. 3.

geal cavity, the appearances as described above were never again seen. When I next saw the case some months later, it was found that the degeneration of lungs and larynx had progressed rapidly, and the larynx presented the usual appearance of a tuberculous process. I saw him a few times and he then disappeared, and I dare say he died within a short time.

In this larynx there were, I believe, two conditions present—(1) a granular hyperplasia, ingrafted upon an ulcerated surface, and (2) a proliferation of those papillary excrescences which are eminently characteristic of the tuberculous process when they are found upon the interarytenoid fold, and which spring oftentimes from the posterior wall of the larynx and trachea. The presence of tissue ingrafted upon ulcerated laryngitis oftentimes renders the diagnosis somewhat difficult, and the appearance may very much resemble a true growth of the larynx, either benignant or malignant. It will be necessary to weigh all the evidence before deciding upon the nature of the disease.

3. Another pathological condition, and to me an unusual one, was seen in a tuberculous patient who is at present under my care. The condition is pictured in Fig. 3. It represents the larynx as it was first seen by me a month ago. I need only say a word as to his history. A tailor, aged thirty-five, good family history, emaciated, cough, considerable dyspnoea. Evidences of pulmonary degeneration on both sides. The vocal bands were adherent along their anterior half. There was but slight respiratory movement of the vocal bands. This loss of motion was not due to the adhesion, but probably existed before the adhesion, and was one of the factors which rendered this adhesive inflammation possible. The loss of motion was due to the enlarged arytenoids, and also to the proliferation of granular tissue, which the figure does not represent, but which existed both above and below the vocal bands. This sprung from the sides of the larynx, and, jutting into the caliber of the glottis, furnished lateral support for the formation of the web of tissue which held together the vocal bands anterior-

ly. All the conditions were in this case favorable to adhesive inflammation. How long this adhesion had existed I do not know. I found that the tissue was not strong, and could be broken through with an ordinary blunt laryngeal applicator. I have broken it through several times, but the gap soon refills because the vocal bands remain immovable and near together. I have seen and operated upon two cases of syphilitic membranous adhesion of the vocal bands anteriorly. In both the web of tissue was so tough that it could hardly be cut or burned. Cohen \* describes and illustrates a somewhat similar case. Speaking of granulations of the larynx, he says that "when occupying both vocal bands, the attrition of the ulcerated surfaces may excite adhesive inflammation, culminating in the formation of an organized web between them." In the particular case cited, he shows the manner of development of that solid web, commencing first from a number of fine membranous bands. And Ingals † speaks of the possibility of adhesive inflammation between the cords resulting from tuberculous ulceration.

This condition must be rare, since phthisical ulcerations show such slight disposition to heal and cicatrize. The very fact that cicatrization is present is a strong argument in favor of a syphilitic process.

Von Ziemssen, ‡ however, treated two cases where the cicatrix could be demonstrated post mortem, but he adds that "it is true that new ulcers generally develop afterward."

Adhesive inflammation in a tuberculous process will rarely if ever be found, unless all the favorable conditions mentioned in my case are present; and even then the bridging across from one vocal band to the other is accomplished more by a filling in of granulation tissue from the sides both above and below the vocal bands, rather than by the formation of a membranous web.

In my case it may become necessary to employ a tracheotomy tube. An O'Dwyer's tube, coated with a gelatinized astringent remedy, might serve the double purpose of dilating the glottis and healing the ulcerations.

I will speak of but one more pathological condition, which I have lately seen in a tuberculous larynx. This condition can hardly be said to be unusual, as it is frequently associated with the ordinary lesions of tuberculosis; but the case to be mentioned is worthy of remark, because this lesion was the only manifestation of disease of the larynx, and because there was some doubt as to the diagnosis.

I saw the case three times in consultation with Dr. H. M. King, who kindly allowed me to manipulate the larynx fully. I obtained the following history :

P. L., Russian Hebrew, aged twenty-nine. In 1886 he swallowed a fish-bone, which fact added to the doubt of diagnosis. In June, 1888, pain in swallowing commenced, followed by hoarseness, increasing dyspnoea, and cough. When I saw him he was but little emaciated or anaemic. His breathing was noisy, and his chief complaint was difficulty in swallowing. I found the condition of the larynx present represented in Fig.

\* Cohen, "Diseases of the Throat," etc., p. 505.

† Ingals, "Diseases of the Throat," p. 355.

‡ Von Ziemssen, vol. vii, p. 842.

4. I may add that the swelling involving the left arytenoid was less regularly rounded, somewhat larger, and extended outward more than is pictured by the drawing. The color of the aryte-

FIG. 4.

noid indicated that an active inflammatory condition was going on. I at first thought that it might be an abscess due to the swallowing of the fish-bone. The swelling could be indented deeply by the pressure of a probe. It was somewhat painful to the touch. I punctured the swelling with a laryngeal lancet several times to ascertain if there was pus, but found none. I also scarified it with the object of diminishing the inflammation. All this produced no benefit, but rather increased the pain in swallowing. The size of the swelling remained the same. I had now arrived at the opinion that I was dealing with a tuberculous perichondritis, as syphilis could be excluded, and because there were slight evidences of commencing pulmonary degeneration. As Dr. King left town at this time, the patient visited the various dispensaries, and finally went to the Mount Sinai Hospital, where he was attended by Dr. A. G. Gerster, of New York, who performed a laryngo-pharyngotomy for the removal of the growth. Dr. Gerster has written an instructive account of the case and the operation, which was read before the February meeting of the Laryngological Section of the New York Academy of Medicine, and published in the April 6th number of the "New York Medical Record." I need not describe the steps of the operation. Dr. Gerster says he decided to operate because of the steady growth of the swelling. Tracheotomy above the isthmus was performed on October 19, 1888, and the tampon cannula employed. The growth, involving the left arytenoid and a portion of the posterior extremity of the left vocal band, was freely excised. The tracheal cannula was removed on October 22d, and the external wound sutured. Union of the soft parts was readily obtained, but not of the thyroid and cricoid cartilages, and a fistulous opening remained. A plastic operation for its closure was performed on January 4, 1889, with good success, I believe.

The foregoing is obtained from Dr. Gerster's account. I saw the patient next when he was presented at the academy. He was very much emaciated, and gave every appearance of a person in the last stages of consumption. He died shortly after. I believe there was necrotic degeneration of the larynx during the last few months. Whether Dr. Gerster supposed the swelling was tubercular in character before the operation I do not know. The microscopical examination of the growth was done by Dr. Cunningham, of the Mount Sinai Hospital, and was as follows:

Several sections were made, and they all exhibited a lymphoid structure with giant cells; tubercle bacilli were present in abundance. Dr. Gerster lays special stress on the fact that this was a localized solitary tumor, the sole manifestation of tubercular disease of the larynx. He does not maintain that the tubercular deposit was primary in the larynx. Dr. King, who saw and examined the patient often, could never satisfy himself that there was any pulmonary

disease until after the operation, and believes that the laryngeal process was primary. I myself believe that deposition of tuberculous material had already taken place in the lungs.

I can not but believe that this was a case of perichondritis of the crico-arytenoid joint, the exciting cause of which was the deposition of tubercle. It seems to me that it is not to be classified with those rare cases of "solitary tubercular tumors" of which Dr. John N. Mackenzie\* mentions two cases, the growth being solitary and in the trachea in one and marked by a formation of submucous nodular growths in the laryngeal cavity in the other. Hennig,† of Königsberg, says that aside from one case of solitary tubercular tumor which he reports, only six additional cases could be found in medical literature. In Hennig's case three tumors, which were afterward found to be tubercular, were removed by the thermo-cautery after laryngotomy. Patient died of pulmonary tuberculosis, as demonstrated by post-mortem examination thirty-seven days after the operation.

The interest in *this* case lies in the obscure manner in which the tubercular infection was received and its strictly localized deposition. I can not believe that extirpation of such growths by external laryngeal operation will add to the patient's comfort or prolong his life. The shock and the exhausting effects of the operation, the annoyance of the tracheal cannula, all hasten the pulmonary degeneration. Skillful endolaryngeal treatment, both medical and surgical, will furnish the most benefit to the patient. Illustrative of what can be accomplished by such treatment, I must before closing cite one case more which the association will, I believe, consider of interest. Figure 4 almost exactly represents the case also, except that the tumor involving the left arytenoid was much larger. It occluded nearly the entire glottis, and the dyspnoea, when the man first called at the office, was so dangerous that I forbade his going home and sent him to the hospital. The air could be seen to suck through the larynx at each inspiration. It was agreed, on consultation, to wait until evening, and then do tracheotomy if the dyspnoea continued as urgent. Moist inhalations acted badly and were discontinued; hot compresses on the outside of the neck gave more benefit than cold. The great relief, however, was obtained by the use of a two-percent. solution of cocaine. This was tried with some misgiving, as we feared an increase in the swelling when reaction took place, but there was no reaction, and nearly all the reduction in the size of the swelling obtained by the cocaine was permanent. I learned this clinical point in this case, that it is far safer to employ cocaine in a greatly obstructed larynx, when the swelling is partly edematous, as it was in this case, than when the swelling is entirely made up of actively congested tissue. In the one the water is driven out not to return, but the expulsion of the blood from the inflamed region can hardly be more than temporary, and the last condition is likely to be worse than the first. The swollen arytenoid was reduced to one third of its size in a

\* Mackenzie, Dr. J. N., "Archives of Medicine," vol. viii, p. 109.

† Hennig, "Berliner klinische Wochenschrift," 1888, No. 28.

week. It was then punctured with the galvano-cautery, and by this means was still further reduced in size. It is at present considerably larger than its fellow, but it is not troublesome to the patient. What the character of this swelling is I do not know. I excised a portion of it with a snap guillotine for microscopical examination, but the sections showed only normal elements. I can find no evidence of syphilis. The patient is a very large, stout, flabby man, weighing more than two hundred and fifty pounds, thirty-two years old, complexion a dirty green; no evidence of pulmonary disease can be found. Patient has been a man about town and has drank and smoked to excess. I do not at all advise extirpation of the growth by external incision, neither do I think removal by cutting forceps would be productive of good results. This case, which may be somewhat irrelevant to the subject of this paper, is cited because it so closely resembles the previous case, which was found to be tubercular. The great size of the swelling, the urgency of the dyspnoea, and the beneficial effects of the cocaine, are its interesting features.

"The unusual manifestations of tuberculosis of the larynx" mentioned in this paper are as follows:

1. In those cases where tuberculosis and syphilis coexist, the lesions of one process mask those of the other. The syphilitic ulcerations, even when combined with a tubercular process, are frequently controlled by appropriate treatment, while the phthisical ulcers defy all efforts to heal them.

2. The typical appearances of a tuberculous larynx are sometimes greatly hidden by the proliferation of two varieties of tissue—the one being ordinary granulation tissue springing from an ulcerated surface, and the second a papillomatous growth made up of normal elements, very much resembling the ordinary papilloma of the larynx—and existing, perhaps, as a mere coincidence, but probably occasioned by the chronic inflammatory condition of the larynx.

3. Adhesive inflammation at the anterior ends of the vocal bands may occasionally take place in a tuberculous larynx, but only when such favorable conditions are present as immovable cords and a general proliferation of tissue.

4. The deposition of tubercle may be localized in one arytenoid, giving none of the typical signs, the larynx as a whole remaining perfectly normal in appearance.

### A CASE OF SYRINGOMYELIA.\*

By HENRY S. UPSON, M.D.,  
CLEVELAND, OHIO.

Two problems present themselves for solution in the diagnosis of every case of disease of the nervous system: first, what is the nature of the lesion? second, where is it located?

The first of these questions is the more important one to solve, except in certain cases of brain and spinal-cord disease in which surgical interference is practicable; at the same time we must not forget that in spinal-cord affections an accurate localization may throw great light on the nature

of the lesion, and may, in fact, aside from the rate of progress of the disease, be the only indication to guide us in determining the nature of the disease process.

In locating a lesion in one or another part of the spinal cord, it is necessary to frame a theory which is in accordance with all of the symptoms which are present; in considering the case before us we will follow this plan, and, after bringing out the clinical features of the case, consider what may be deduced from them with certainty and what with probability.

The following is the history given by the patient:

William M., aged thirty-one, box-maker. The patient two years and a half ago began to notice a tired feeling in his legs and pain in the small of his back. About two years ago he fell thirteen feet and struck on his back. He was considerably hurt, but not unconscious, walked home, and was laid up for three weeks. After this he considered himself well, and went to work as usual.

Six months later there began to be manifest a weakness of both legs, rather worse on the right side, with twitchings of the whole limb which were troublesome but not painful. The patient had more or less pain in the back, with pricking and burning sensations in his legs. The feet and legs have swelled very often. There have been no pains or loss of power in the arms. He has had slight frontal headache occasionally. Has never had double vision.

The patient has had gonorrhœa several times, and has had a good deal of retention of urine, which he has drawn with a catheter. The bowels are constipated. There is no abnormality of the sexual function. No history of syphilis. No insanity or other nervous ailments in the family.

On examination, the pupils are equal and react to light, and with accommodation. The face is very slightly deviated to the left, the tongue protruded straight. In hands and arms good muscular power; no anaesthesia. Triceps reflexes fairly marked on both sides. There is considerable loss of power in the lower extremities, especially in the flexors of the legs and feet. The quadriceps extensor is slightly weaker on the left than on the right side. There is a good deal of twitching of the thighs and legs, partly of the fibrillar kind, and also jumpings and jerkings of the whole limb; these seem to be spontaneous, and not to depend on mechanical or reflex irritation; the patient says these jerkings persist sometimes for a half or three quarters of an hour.

The left thigh is somewhat smaller than the right; the legs are of good size and about equal. Right thigh, 19 $\frac{1}{2}$  inches; left thigh, 18 $\frac{1}{2}$  inches; right leg, 12 $\frac{1}{2}$  inches; left leg, 12 $\frac{1}{2}$  inches; giving a difference of an inch and an eighth between the two thighs, and of an eighth of an inch between the two legs. The right knee-jerk is rather weak; the left knee-jerk is absent, even when tried by the Jendrassik method. There is no ankle clonus. The plantar and abdominal reflexes are lively; cremasteric reflex not obtained. All of the muscles of the lower limbs respond well to the faradaic current. With the interrupted galvanic current, KCC > AnCC, and the response is prompt and quick. There is no deformity of the spine, but slight tenderness on pressure over the lower lumbar vertebrae.

Tactile sensibility is slightly diminished in the lower limbs; pinching is appreciated as painful, but not very acutely. Sensitiveness to heat and cold is much blunted in the lower extremities, especially over the back of the right thigh and the right buttock; in the latter area the patient is not at all able to distinguish between hot and cold objects, and even pinching is not recognized as painful, but is confused with impressions of heat

\* Read before the Ohio State Medical Society at its forty-fourth annual meeting.

and cold. This area of thermal anesthesia is bounded by a line running about on a level with the upper border of the sacrum, and above this line distinctions between heat, cold, and pinching are prompt and invariably correct. Below the line the patient sometimes hazards a guess, usually an incorrect one, but often says he can not tell. Over the rest of the surface of the lower limbs correct answers are occasionally given, especially if there is a great difference in temperature between the two objects; distinguishing moderate degrees of heat and cold is quite impossible. In making these experiments, test-tubes of equal size were used, filled with hot and cold water respectively, and the patient was not allowed to see the tubes. Urine: amber, acid, 1·027; no albumin; no casts.

We are able in this case to affirm with a good deal of certainty the existence of an organic lesion, from the absence of the knee-jerk, and the nutritive changes which have taken place. The same symptoms enable us to exclude lesion of the brain or of the upper part of the spinal cord as the cause of the paralysis, since loss of power caused by disease in those regions is accompanied by exaggerated reflexes and only slight wasting from disuse. The possibilities are therefore limited to disease of the lumbar portion of the spinal cord and disease of the peripheral nerves of the lower extremities.

We will first attempt to ascertain the location of disease of the spinal cord so situated as to be capable of producing all of the symptoms which we have found to exist. Let us, then, consider the symptoms a little more in detail, and first as to the reflexes, especially the knee-jerk; this takes place in the following way: A tap on the patellar tendon causes an excitation of the sensory nerves, which is carried through the posterior nerve roots to the posterior horns of the gray matter in the cord; it is transmitted thence to the motor cells in the anterior horns, and from there along the motor fibers of the peripheral nerve to the quadriceps muscle, which responds by a contraction.

Omitting now any reference to the question whether the knee-jerk is a real reflex, all authorities are agreed that it is dependent for its existence on the path above described, which is called the reflex arc. Excluding a few cases of irritative lesion of the brain, which may for a short time suppress reflexes by inhibition, a loss of the knee-jerk always means disease at some point in the reflex arc.

When the lesion is situated in the sensory part of the arc, as is the case in locomotor ataxia, the quadriceps muscle is ordinarily not paralyzed. When, on the other hand, the motor part of the arc is affected, the same lesion which causes the loss of reflex causes greater or less diminution in the power of the muscle. This tends to show that in this case a lesion of the cord producing the loss of power must be situated in the motor cells of the anterior horns, or in the anterior nerve roots. This theory is strengthened by the presence of a moderate degree of atrophy, which is regularly indicative of a lesion either of the trophic centers in the anterior horns of gray matter, or in the nerves between those centers and the muscles.

The motor symptoms, then—the wasting, the loss of reflex, the paralysis, as well as the twitching—would all be accounted for by a lesion affecting the large motor-ganglion cells in the anterior horns of the gray matter of the cord.

Another possible explanation is this: that the reflex arc is cut by the disease at a point between the anterior and posterior horns of gray matter, and the paralysis caused by an affection both of the anterior horns and of the pyramidal tracts in the lateral column, which, taking place very slowly, would account for the considerable paralysis without the reaction of degeneration.

The sensory symptoms are somewhat peculiar. What is ordinarily called the sense of touch is made up of the ability to distinguish between four different kinds of impressions—those, namely, of pain; of temperature; tactile sensibility, by which we know the forms of objects; and the so-called muscle sense, by which we appreciate the weight of objects and know the positions of our limbs. Although these appear to be parts of the same function, it has been shown that they are represented in different tracts of the cord, so that one of them may be affected by disease, the others left intact. The sensory paths have not all been made out with certainty, but, according to the latest researches, fibers which convey tactile impressions run in the posterior columns of the cord; those of temperature run, probably, in the gray matter, not far from the central canal, or, at any rate, cross from one side of the cord to the other in this region; the same is true of the fibers which convey impressions of pain; fibers devoted to the muscle sense run in the lateral columns.

In this case the temperature sense is in the most affected area quite abolished; sensibility to painful impressions almost or quite so; tactile sensibility only slightly diminished. To cause these symptoms, a lesion of the cord must be in the gray matter, about or near the central canal, encroaching slightly on the posterior columns. A central lesion, then, invading to a slight extent the adjacent anterior horns of gray matter and lateral and posterior columns, would account for all the symptoms which we have found in this case.

The case presents a greater superficial resemblance to locomotor ataxia than to any other disease of the cord—from the defective gait, the loss of knee-jerk, and swaying when the patient stands with his eyes closed; but, on closer examination, the gait is seen to be not at all the typical one of ataxia; there are not the heel-pounding and wild excursions of the legs which are seen in an ataxie of this advanced stage; there is no history of the characteristic lightning pains; and these, with the presence of undoubted paralysis and the peculiar affection of the sensibility, preclude the idea of the case being one of locomotor ataxia.

If it were not for the sensory symptoms the case might very well pass for one of amyotrophic lateral sclerosis; this disease is, however, a purely motor affection.

We have now to consider the possibility of the existence of a lesion of the peripheral nerves of the lower extremities which would account for the symptoms; such a lesion would have to exist on many of the nerve trunks, as the symptoms are quite widespread; such a lesion is, as a matter of fact, usually inflammatory, and is called multiple neuritis. Its causes are many, and the course which the disease runs varies a good deal in individual cases. We may say, in general, that the inflammatory process affects

the motor and sensory filaments of the nerve, and that the result is paralysis with atrophy and anaesthesia in the districts supplied by the affected nerves, giving a clinical picture not very different from the one before us. As a rule, however, the different forms of sensibility are affected about equally, so that when we find a marked loss of the temperature sense without a corresponding diminution in tactile sensibility, we must look for the lesion in the cord, where the paths for these two forms of the sense of touch are separated.

The form of neuritis which is most apt, from its chronic course and the unequal way in which it affects sensibility, to lead to confusion with cases of the kind before us, is that occurring in leprosy; this can, I think, be excluded in this case.

We must suppose, therefore, disease of the central portion of the spinal cord, near the central canal, and extending as far as the motor cells of the anterior horns, and probably involving to a slight extent the lateral and posterior columns. Experience has shown that a slow lesion in this region is almost invariably of the nature of a tumor, composed of a finely reticular structure with scattered cells, of the same appearance as the normal supporting substance of the cord; it is, in fact, a glioma.

The new tissue is soft and highly vascular, and almost always breaks down in part, so as to form one or more cavities, and from this peculiarity the process takes its name of syringomyelia, or cavity formation in the cord.

The cavity may or may not communicate with the central canal, but is never simply an enlargement of the same, as is the case in the condition known as hydromyelus.

Syringomyelia has long been known as a pathological condition, which was usually first recognized at the autopsy. It was a few years ago pointed out by Schultze, of Heidelberg, that many of these cases might be recognized during life. The present case is atypical, in that it affects the lumbar instead of the cervical portion of the cord, but, although the latter is the usual starting point of the disease, cases of its occurrence lower down are by no means unknown. The only case of this affection heretofore put on record in this country was reported by Dr. M. Allen Starr, in the "American Journal of the Medical Sciences" for May, 1888.

The disease is characterized by its long course and the frequent remissions of its symptoms; it is sometimes ascribed to traumatism as a cause, but whether this plays a part in the present case is perhaps an open question; the fall upon the back is at any rate an interesting feature in the history of the case.

No treatment has been discovered which is likely to affect the disease process, although remissions sometimes occur in connection with electrical treatment.

**The Mississippi Valley Medical Association.**—The fifteenth annual meeting will be held in Evansville, Indiana, on the 10th, 11th, and 12th of September. Those who attend are advised to take receipts for full fare, that they may secure return tickets at one third fare. We learn that the titles of nearly a hundred papers have been received for the programme, and that the meeting promises to be larger than any yet held by the association.

ALCOHOL IN FEVERS.

THE July "Forum" contains a paper by Dr. Austin Flint on "Late Theories concerning Fever," in which the question of administering alcohol in fever is discussed with frank fair-mindedness and simple directness. If querulous sentimentalism could be silenced by the contemplation of facts, and the ideal of the situation be taken as the standard of duty, what Dr. Flint says in regard to the use of alcohol in disease would forever settle all controversy as to its morality or immorality. The fever patient is one who is burning up nutritive material so rapidly that, unless an increased assimilable food-supply is provided, he is quite likely to die of starvation. Sustaining measures are imperative. At work a man needs more heat than in repose, and more food. Although the fever patient does no work, he produces an excessive quantity of heat, and this involves of necessity an oxidation of matter. Food or some oxidizable material must supply this much-needed matter, or else the tissues are consumed. Exactly to the degree that the fever feeds on food is tissue saved and subsequent convalescence promoted. It is, however, the condition of the organs and the capability of assimilation that renders the introduction of food a problem which taxes the judgment and skill of the physician to the utmost. What food? And how administered? This must give us pause. A rational consideration of the subject is possible only from the scientific standpoint. Those who would abolish alcohol from the sick-room must first prove their moral right to risk starving a man because he has the misfortune to fall ill. And these same sentimentalists, with their narrow view of alcohol, cry out against vivisection and abstinence from food for purposes of scientific investigation! O perverse and penny-wise generation!

Dr. Flint's own words deserve to be quoted entire and made a part of every reason-loving mind, be it that of layman or that of physician. The preaching comes home to all who love the truth. It would seem that only willful blindness could fail to see and be convinced. Thus says our author: "In the face of the difficulty which exists in supplying matter for oxidation in the body to feed the exaggerated calorific processes, the use of any agent which will meet this want can not logically be condemned on sentimental grounds alone. Even if alcohol be regarded as a poison, it must be remembered that poisons are often useful in medicine and save life. From a purely scientific point of view, it may be admitted that, in perfect health, alcohol is not useful and is deleterious. As physicians study the poisonous action of certain remedies in learning how to use them with happy effect, so what may be called the physiological effect of alcohol may be studied as a prepara-

tion for its use in disease. The symptoms of alcoholic intoxication are due to certain peculiar effects upon the nerve-centers of actual alcohol circulating in the blood. In perfect health, a very small quantity of alcohol will produce some effect of this kind; but this passes away when the alcohol is eliminated by the breath or otherwise, or when it is oxidized. In certain diseases, particularly in fever, very large quantities are tolerated, and this is because the alcohol is promptly oxidized, and makes no impression, as alcohol, on the nervous system. In disease, as in health, even a slight development of alcoholic intoxication is followed by a reaction more or less injurious." The author goes on to state that certain conditions in fever, and these alone, are indications for the use of alcohol—persistence of high temperature, great feebleness, rapid pulse, etc., showing intense and alarming general depression. The value of the agent depends not upon its stimulating effect on the nervous system, but upon its rapid oxidation. Being promptly taken up by the blood, it requires no preparation by digestion, and is oxidized even more rapidly in fever than in health, supplying material for combustion just in proportion to its oxidation. Thus the normal tissues of the body are saved from degeneration and destruction. "There is a theory," says Dr. Flint, "that the carbohydrates of food are deposited in the liver, discharged into the blood as required, in the form of a substance called glycogen, which is converted into alcohol and then oxidized. There are many strong facts and arguments in favor of this view; and, if it be true, the administration of alcohol in fever is simply the introduction of a carbohydrate in such a form that it can be promptly used in supplying material for heat, the digestion of carbohydrates being difficult and slow. A calculation of the heat value of alcohol shows that one quart of French brandy, when oxidized, produces as many heat-units as a man of ordinary size would make in twenty-four hours. As a matter of actual observation, a quart or even more of brandy has been given in cases of fever in twenty-four hours, without any indications of alcoholic intoxication, and with the effect of actually reducing the temperature."

The possibility of confirmed alcoholism growing out of the use of alcohol in fever naturally suggests itself. The possibility of the morphine, chloral, cocaine, chloroform, or other habit exists whenever and wherever one of these drugs is administered. Yet those who withhold these agents risk the sacrifice of a life now and then—a sacrifice to what the more intelligent portion of the community regards as prejudice. So, too, with alcohol. It would be difficult to find an instance of the alcoholic habit directly and solely due to the use of alcohol in fever. The fact is, drunkards are made in the nursery far oftener than is suspected. The pretty baby that is not taught self-control fails to manifest toughness of fiber when adult life demands it. "The child is father to the man." Greed, efforts for gain out of all proportion to physical strength, overworked ancestors, the desire for oblivion from grief, chagrin, and disappointment, are individual and collective factors that help fill the ranks of all forms of inebriety. Diseases of the will far more than diseases of the body lead to intemperance. Because one whose

unwise parents failed to train him and guide him in baby-days becomes a drunkard and dies a drunkard's death, shall we starve our child because he lies ill of a fever? The sophistry of the argument is apparent when deprived of tin trumpets and all silver-gilt tinsel. Yet such is the reasoning of the sentimentalists—those who don't know—concerning the use of alcohol in disease. However great the pride of science, it sinks into insignificance beside the pride of complaisant ignorance. The physiologist, the chemist, and the philosopher alone are capable of expressing a thoughtful opinion upon the questions of the day, of which the use of alcohol is possibly the most important. Dr. Flint's arguments, based upon the facts of the case, are incontrovertible and merit the most careful consideration of all interested in rational living.

#### PRIVATE MEDICAL LIBRARIES.

THE books of the average physician are bought to be read and are bought at the time they are needed. An emergency having arisen, as in a case of difficult diagnosis, the necessary book is purchased, read, and laid upon the shelf, perhaps indefinitely. This will not apply to the buying of "systems" and cyclopædic volumes; the motives that lead to the purchase of these have their root in the idea of a possible future need, as well as an intention to give time to some favorite subject coming within their scope. Private libraries of this class are quite apt to be close counterparts of each other, and will be found to be made up largely of the publications that go through several editions. Many times books are bought for the sake of the authors' names, in order to have either a full or a good representation of the works of some favorite writer, rather than from the impulse of a present want. But the consecutive collection of a favorite author's writings is not frequent, for, when this feature is observed in a physician's library, the instinct of the collector is under process of development. The libraries of some show a partiality for journals, complete files being well cared for in sightly binding. Others contain a large proportion of the transactions of societies, along with other annuals. But these are not the average medical library, about which we are now writing. That type of library is void of any tendency to specialized addition, and must be considered, like the contents of advertised lost pocket-books, "of no particular value except to the owner."

Wherever the impulse of collection creeps in, the value of the library to others is enhanced. This is not truer during the lifetime of the collector than after his decease. The library that has few books which other physicians care to borrow has a painful lack of interest and value when the time comes for the disposal of them under the auctioneer's hammer or otherwise. It is mournful to attend the sale of some libraries, where the attendance on the part of the invited ones is extremely limited, where the responses are spiritless and the net results insufficient to meet the cataloguer's bill. An extreme case of this kind occurred quite recently in the rooms of one of the best of our auctioneers; the estate is actually in debt to the auction

house. A librarian of our acquaintance, who misses very few sales of medical effects, says that he has never seen anything but disappointment result from the disposal of the libraries of physicians. Further than that, he is continually compelled to view the disappointment of widows, who come to him for advice as to the best that can be done with "the late doctor's library." In general, the best thing to do with it is to add it to some established medical library.

### MINOR PARAGRAPHS.

#### ETHYLATE OF SODIUM IN HYPERTRICHOSIS.

DR. ARTHUR JAMIESON in the "Practitioner" reports the case of a child who at three months of age had an unusual overgrowth of hair on the face. The hair was dark and in some places fully an inch in length. It grew on the right side to such an extent that, when that side alone was viewed, the observer could not refrain from a comparison of the infant with a Skye terrier. Dr. Jamieson had, before this case came up for treatment, noticed that when he had used ethylate of sodium for the destruction of naevi, the hair in the vicinity touched by an excess of the drug was apt to be killed. He determined to apply this to the face of the child, but he first made some tentative applications to several small hairy moles. These proving satisfactory, the child was anesthetized and the ethylate was rubbed thoroughly over a portion of the hair-covered forehead until the skin took on an orange color. The hair-follicles, at the end of a month, were found destroyed, with a few exceptions here and there, and the skin was white. He again applied the caustic to the side of the face, leaving the parts adjoining the eye untreated until the child was a year old. The later treatment was slow and limited to isolated follicles that had resisted previous applications. The child, now six years old, is reported free from disfigurement as to the parts formerly overrun with hair, and the skin is said to be smooth and clear. Dr. Jamieson has photographs of the child's face, before and after the use of the ethylate, which sustain the title of that substance as an epilatory. He has used it for the removal of hairy moles, and regards it as superior to electrolysis in many ways. He has found that it removes the discoloration of the skin, besides destroying the hairs, which has not occurred in his practice under any other plan of treatment.

#### HAY FEVER AND MENTHOL.

Two recent communications to the "Lancet" have pointed out the dangers of the continued use of cocaine in hay fever, in respect of the formation of the cocaine habit. One was by Dr. F. de Havilland Hall and the other by Mr. William Hill. The latter has had occasion to resort to the use of menthol, locally applied, for the coryza vaso-motoria in cases where the addiction to cocaine has been established, and he believes that he has found in it an efficient and unobjectionable substitute. He says: "I think we possess in menthol an antiseptic remedy sufficiently resembling cocaine in its anaesthetic and astringent action, and having none of its disadvantages. A Cornish patient of mine, who has been prevented coming for a reapplication of the galvano-cantery, which has hitherto relieved only for a season, has written me to say that he would not be without menthol for worlds, and that he much preferred it to cocaine." Mr. Hill's method is in the use of a 10- to 20-per-cent. solution of menthol in olive oil or almond oil, to be applied to the sensitive area of the nasal mucous membrane in coarse spray or with a brush. He thinks it possible that in the asthmatic varieties of hay fever

the distress may be relieved by insufflations of a strong solution in oil. The drug has been used with success in severe asthmatic attacks, not due to the hay-fever complication, by means of inhalations from the surface of a 20-per-cent. solution. The action is said to be prompt in the relief of bronchial spasm, and one patient stated that the medicine produced a feeling in the head resembling that caused by the inhalation of a few drops of chloroform.

#### PSEUDO-ACTINOMYCOSIS.

DR. FEDOR A. LOESCH has given the name pseudo-actinomycosis to a condition observed by him in seven out of thirty-seven consecutive cases of pulmonary disease, the sputa of which he examined microscopically. His report is given in the "Transactions of the Third General Convention of Russian Medical Men at St. Petersburg," 1889. In these seven cases he found peculiar colorless and pale-yellow bodies resembling the grains found in actinomycosis, the resemblance being found both in their conformation and in their action under chemicals. The sputa in which he observed these grains contained also the bacilli of tuberculosis and elastic fibers. A closer examination proved that the grains were crystalline concretions of a substance allied to leucine. In every case save one where these pseudo-actinomycotic bodies have been found they have been associated with the tubercle bacillus, and there is a strong presumption that they will prove to be a degeneration from that organism. The point of diagnostic difference between the true and false bodies is seen when pressure is applied between two cover-glasses. The false grains break up under this compression into a shapeless detritus, while the true actinomycotic grain is spread out into a bundle of dichotomizing threads; the false grains differ from the genuine in being smaller and in having no central filamentous structure. Professor Afanaseff, of St. Petersburg, has accepted the chief propositions of Loesch in regard to these grains.

#### THE TENTH INTERNATIONAL MEDICAL CONGRESS.

PROFESSOR VON BERGMANN, Professor Virchow, and Professor Waldeyer give notice that, according to the resolution passed at the Washington meeting, September 9, 1887, the Tenth International Medical Congress will be held in Berlin. The Congress will be opened on the 4th and closed on the 9th of August, 1890. Detailed information as to the order of proceedings will be issued after the meeting of the delegates of the German Medical Faculties and Medical Societies at Heidelberg, on the 17th of September of the current year. Meanwhile they ask us to make this communication known in medical circles and add at the same time their cordial invitation to the Congress.

#### A NEW KIND OF COTTON.

A BAD slip of the pen must have occurred in the writing of the following: "Soft corns are best treated by taking away pressure by means of the introduction of cotton wool—that directly off the sheep being the best—between the toes, and the use of some dry powder, etc." The "Montreal Medical Journal" says that this paragraph occurs in a "standard surgical text-book, well known in the neighborhood of Guy's Hospital."

#### CIRCUMCISION AND HEREDITY.

DR. LEVY, a dentist of Stettin, has written to the editor of the "Archiv für pathologische Anatomie und Physiologie und für klinische Medicin" an account of some occurrences in his

own family that have a bearing, he thinks, on a question raised by Professor Weismann at the sixty-first *Versammlung deutscher Naturforscher und Aerzte*—that of the hereditary transmission of acquired peculiarities, such as the lack of a foreskin in Jews. He states that, like his father before him, he was born without a foreskin—as he expresses it, “*regelrecht beschnitten*”—furthermore, that this was the case with his four brothers also, who died in childhood. An occasional natural Apella is to be met with among Gentiles, but this, of course, raises no question of heredity; such a group of them as Dr. Levy's communication mentions is a different matter, however, although not a very convincing evidence of evolution.

#### THE HIGH COST OF FIELD SURGERY.

PROFESSOR GOLDWIN SMITH propounds the theory that one of the great checks to war in the future will be found in the costly nature of modern surgical field-service. In the Austrian armies during the last century there were very few surgeons. “The medical and hospital arrangements of the Federals in the Civil War were of the costliest and most perfect kind.” The humane, “democratic conscience” of these times demands an outlay for the non-combatant part of the business of war which will discourage pugnacity and make for peace. In other words, the higher the development of military surgery, the less war will there be. Professor Smith's paper may be found in “Macmillan's Magazine” for July.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending August 27, 1889:

DISEASES.	Week ending Aug. 20.		Week ending Aug. 27.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	29	12	91	16
Scarlet fever.....	42	1	28	1
Cerebro-spinal meningitis.....	1	1	2	2
Measles.....	27	1	17	3
Diphtheria.....	79	19	70	19

**Faculty Changes.**—Dr. J. Richard Taylor, a graduate of the Medical Department of the University of Pennsylvania, of the class of 1878, has been elected to the chair of pathology, practice of medicine, and clinical medicine in the Medical College of the State of South Carolina, at Charleston, to succeed Dr. John Guitérás, who has resigned in order to accept the chair of pathology at the University of Pennsylvania.

**The New York Polyclinic.**—The annual announcement shows an attendance for the session of 1888-'89 of 383 physicians, making since 1882 a total of 1,883. These figures demonstrate beyond all doubt the popularity of the Polyclinic system of instruction. The most important feature of this year's catalogue is the Polyclinic Hospital. By the enlargement of their property the faculty have established an extensive hospital, which will afford at all times ample material for all clinical purposes. The Polyclinic and hospital buildings have been completely fitted out with all the modern appliances conducive to the healthfulness and comfort of the patients and physicians in attendance. The session of 1889-'90 will open on Monday, September 16th.

**Changes of Address.**—Dr. Henry C. Coe and Dr. G. A. Kletzsch, to No. 27 East Sixty-fourth Street.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending August 24, 1889:*

- SCOFIELD, W. K., Medical Inspector. Detached from the Lancaster.
- HIBBETT, C. T., Passed Assistant Surgeon. Detached from the Lancaster.
- WHITE, C. H., Medical Inspector. Ordered to the Pensacola.
- HESLER, F. A., Passed Assistant Surgeon. Ordered to the Pensacola.
- CURTIS, L. W., Passed Assistant Surgeon. Ordered to the New Hampshire.
- JONES, W. H., Surgeon. Detached from the Pensacola and placed on waiting orders.
- VON WEDEKIND, L., Assistant Surgeon. Detached from the New Hampshire, and ordered to the Pensacola.

**Marine-Hospital Service.**—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the two weeks ending August 24, 1889:*

- LONG, W. H., Surgeon. To proceed to Gallipolis, Ohio, as inspector. August 7, 1889.
- WHITE, J. H., Passed Assistant Surgeon. Granted leave of absence for thirty days, on account of wound. August 16, 1889.
- CONDICT, A. W., Assistant Surgeon. Detached from Revenue Bark Chase and ordered to Louisville, Ky., for temporary duty. August 19, 1889.
- GROENEVELT, J. F., Assistant Surgeon. Ordered to South Atlantic Quarantine Station for temporary duty. August 8, 1889.

#### Society Meetings for the Coming Week:

**MONDAY, September 2d:** Medico-chirurgical Society of German Physicians; Morrisania Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica Medical Library Association; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., City Medical Association; Chicago Medical Society.

**TUESDAY, September 3d:** Medical Society of Virginia (first day—Roanoke); Elmira Academy of Medicine; Buffalo Medical and Surgical Association; Ogdensburg Medical Association; Medical Societies of the Counties of Franklin (quarterly) and Niagara (Lockport), N. Y.; Hudson, N. J., County Medical Society (Jersey City); Androscoggin, Me., County Medical Association (Lewiston); Baltimore Academy of Medicine.

**WEDNESDAY, September 4th:** Medical Society of Virginia (second day); Medical Society of the County of Richmond (Stapleton), N. Y.; Harlem Medical Association of the City of New York; Medical Microscopical Society of Brooklyn; Bridgeport, Conn., Medical Association.

**THURSDAY, September 5th:** Medical Society of Virginia (third day); New York Academy of Medicine; Society of Physicians of the Village of Canandaigua; Obstetrical Society of Philadelphia.

**FRIDAY, September 6th:** Practitioners' Society of New York (private); Baltimore Clinical Society.

**SATURDAY, September 7th:** Clinical Society of the New York Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

## Letters to the Editor.

### ROTTER'S SOLUTION.

34 EAST THIRTY-THIRD STREET, August 21, 1889.

To the Editor of the New York Medical Journal:

SIR: In a recent number of the Journal mention is made of a solution recommended by Rotter for use in operations and dressings in place of solutions of the bichloride of mercury. A brief account of my experience with it may save some of your readers from disappointment and perhaps from serious reverses.

Rotter's first publication was made in September, 1888, in the "Centralblatt für Chirurgie." I made a note of it, and laid it aside for corroboration. In January, 1889, he printed in the same journal a second paper, stating that the solutions, the "weak" and the "strong," had proved so successful clinically and so powerful that the "strong" had been entirely abandoned in favor of the "weak," which contained neither carbolic acid nor corrosive sublimate. In June I learned that Schede was using the weak solution and was satisfied with it. Thereupon I abandoned the use of carbolic-acid and sublimate solutions (to which there are certain theoretical and practical objections) at the Chambers Street and New York Hospitals, and for the past six weeks have used in their place the weak Rotter solution. It has brought disappointment; suppuration has been more frequent, sponges are more difficult to clean during an operation, and instruments have been discolored. Finally, experiments made by Dr. Ferguson at the laboratory of the New York Hospital to determine its antiseptic power indicate that it is far weaker than is maintained by Dr. Rotter. I can explain Schede's success with it only on the supposition that his associated antiseptic measures are so efficient that the strength of the solution used for irrigation is unimportant.

After this short flight afiel in the company of an attractive but deceitful stranger, I have gladly returned to the quiet and security of old acquaintance. LEWIS A. STIMSON, M. D.

## Proceedings of Societies.

### NEW YORK ACADEMY OF MEDICINE.

#### SECTION IN ORTHOPEDIC SURGERY.

Meeting of March 15, 1889.

Dr. A. B. JUDSON in the Chair.

**Cicatricial Contraction of the Fingers.**—Dr. A. M. PHELPS presented a patient on whom he had operated four weeks before for restoration of motion to the fingers, which had been flexed in the palm by a cicatrix in the wrist of eight years' standing. He had freed each tendon from the cicatricial tissue and had secured healing by blood-clot, with the hope that new sheaths would be formed in the clot. The wound had been dressed antiseptically, and the first dressing had been changed at the end of three weeks. The prospect of recovery of motion was good.

Dr. R. H. SAYRE said that Paget had long ago recognized the organization of blood-clot after subcutaneous tenotomy. The case presented by Dr. Phelps showed that advantage could be taken of it after open incision under antisepsis.

**Hysterical Equino-varus.**—Dr. N. M. SNAPPER presented a patient, a girl of twelve years, who had been affected for ten

weeks with hysterical equino-varus and rhythmical movements of the left foot. The talipes had been reducible manually, but the motions had been persistent. There was inability to walk, the result of the disability of the quadriceps extensor group. Before she had come under Dr. Shaffer's observation, plaster of Paris had been applied to the limb for several weeks, but without benefit.

The CHAIRMAN thought that choreic elements were seen when the patient attempted to walk. He recalled a case of rhythmical myoclonus reported by Dr. Peckham in the "Archives of Medicine" in 1883, in which the patient had been subjected to a great variety of treatment, and had finally recovered after the hypodermatic use of atropine.

Dr. S. KETOU suggested treatment by hypnotism.

Dr. R. H. SAYRE thought that the case illustrated the fact that abnormal muscular contraction would produce degrees of deformity as marked as those caused by bony distortion.

Dr. L. W. HUBBARD thought the case allied to chorea, being the result of nerve irritation or exhaustion. He suggested absolute rest or recumbency for a long period with efforts to improve the nutrition.

Dr. A. S. HUNTER had treated with success a case of hysterical hip by the administration of ignatia. The use of this drug in a number of cases of the kind had led him to value it highly when the disturbance was limited to groups of muscles only; but he thought it was of little value in the treatment of general choreic conditions.

Dr. V. P. GIBNEY had had a favorable effect in a case of rotary spasm of the neck from the use of the fluid extract of gelsemium, given in five-minim doses and pushed almost to toxic effects.

Dr. H. W. BERG said that the contraction in the case shown could not be due to nerve lesion, because it yielded so readily to manual replacement. Where there was irritation of motor nerves, as in spastic paralysis, it was extremely difficult to reduce the limb to a proper position. He suggested the ordinary treatment of chorea with electricity to make an impression on the mind rather than on the nerves.

**The Management of Hip-joint Disease from an Anatomical Basis.**—The paper of the evening was read by Dr. PHELPS, who believed, in regard to the pathology of hip disease, that it was a local tuberculous affection, due to accidental inoculation, and not to a constitutional or strumous condition. Following Volkmann, Albert, and König, he believed that the inflammation, at first simple, became tubercular by inoculation, and then purulent. The irritation of the peripheral extremities of the nerves in or about the joint produced muscular spasm, which in turn distorted the joint by trauma, aided by the bacilli of tuberculosis. In regard to treatment, he relied on mechanical treatment, believing that if we immobilized a joint and removed the intra-articular pressure, Nature would take care of the tuberculous material. His experiments on dogs had convinced him that immobilization of healthy joints did not produce ankylosis. Encouraging motion in an inflamed joint was a violation of the surgical law that an inflamed part required rest. He believed that the muscular spasm, which was a most serious element of destruction, should be overcome by extension, and that, while extension was necessary to secure immobilization, it was not sufficient by itself. He therefore resorted to a combination of extension and fixation, the extension always to be in a line corresponding to the axis of the neck of the femur.

Treatment, as a rule, should be begun in bed, extension being made in two directions—*i. e.*, toward the foot-board and laterally, the body and the sound leg being fixed to a long splint extending to the axilla. If the deformity did not yield to exten-

sion properly applied, the tissues at fault should be divided subcutaneously or by open incision. Abscesses were to be incised through their entire length, and thoroughly scooped out and washed, strict antiseptic precautions being observed. Distension of the capsule should be relieved by aspiration or incision; then traction would not produce pain.

He exhibited a patient in a portable bed, which was an ingenious substitute for the wire cuirass, made with a board cut in an outline of the body and plaster of Paris. The child was laid on the board, and then the whole was enveloped with plaster-of-Paris bandages from the foot to the axilla. The plaster was then cut away in front, the interior comfortably padded, and the patient held in place by lacings or bandages. Extension and fixation in bed were to be continued until the active symptoms and the deformity had entirely disappeared, and the spasm of the muscles was no longer present. Adults were then given crutches, and a portable splint which had a perineal crutch, extension by adhesive plaster, an abduction bar, and an upper (thoracic) ring to prevent flexion and extension at the hip. Children, after treatment in bed, were to have the portable bed, and then the portable splint, with or without the high shoe and crutches.

Dr. J. RIDLON was much pleased to hear the author of the paper take the ground that hip cases should be cured without deformity. He recalled the case of a patient in whom the muscular spasm had been relieved by pinching the muscle. The child had been very thin, and it had been found that, when the adductors were separated from the other muscles and the belly of the muscle was pinched, without any attempt at fixation, there had been as much relief as could have been afforded by lateral traction.

Dr. SHAFFER said that the paper had suggested to him the importance of separating in our minds the disease from the deformity. It was a question how far we were justified in meddling with the deformity, which was simply an expression or, so to speak, a symptom of the disease. In his experience, attempts at speedy reduction of the deformity had been followed by disastrous results. Nature gave a very positive indication in the acquired position of the thigh—that in which the immobilization reached its maximum, and the diseased parts received the greatest relief from reflex muscular spasm. If we forcibly interfered with this effort on the part of Nature, we inflicted a distinct traumatism.

On the threshold of treatment the important question was, not whether traction was to be made in the line of the shaft or the neck, but how to secure an artificial immobilization in the position Nature assumed as the one that afforded the most protection to the inflamed parts. He believed that if the joint were protected from traumatism—in other words, if traumatic contact of the inflamed joint surfaces was removed, and this could readily be done by the use of portative apparatus without entailing immobilization of the entire body from the head down—the joint was placed in the best known local condition. The portative-traction treatment was compatible with fresh air, sunlight, and moderate exercise, which were the best means of combating the tubercular disease and the tubercular diathesis. More lives had been saved and better results had been thus secured than by any other method which had been thoroughly tested.

Dr. R. H. SAYRE agreed with Dr. Shaffer as to the importance of maintaining the general health and the inadvisability of general immobilization of the body if the diseased joint could be controlled without it. He thought that complete immobilization of the hip joint in young children was very difficult to secure, and that the movement that stopped short of producing muscular spasm and pain was not harmful. For poor children

particularly he thought the portable bed was an admirable contrivance. The relief obtained in some cases by pinching the muscle could be explained on the supposition that it stopped the reflex action of the muscle. It was known that firm constriction of the belly of a muscle would, in certain cases, abolish spasm.

Dr. CHARLES L. SCUDDER, of Boston, advocated a more frequent resort to the results of experiment on the cadaver. He recalled Dr. Bradford's experiments made in 1880, in which it had been found that in an adult a force of one hundred pounds had not been sufficient to separate the head of the femur from the socket, while in the shallow and not yet completely ossified acetabulum of a young child a moderate force had caused separation, and still less force had been required in the fetus. Dr. Scudder believed that in hip disease of children a tractive force of from three to five pounds would separate the joint surfaces, as had been illustrated at the Children's Hospital in Boston in the case of a young boy who had had hip disease and night cries. The joint cavity was opened and a small quantity of pus let out. While the boy was under ether, it was found that traction made with the hand separated the joint surfaces to such an extent that the finger could be placed between the head of the femur and the acetabulum.

Dr. HUBBARD thought that no one at the present time held the opinion that ankylosis was caused by immobilizing a joint affected with chronic inflammation. He had found it difficult to get ankylosis in cases where it was desirable, as in disease of the knee. The first object was to give rest to the joint, which was best done by traction; not to separate the surfaces, but to overcome articular pressure which led to muscular spasm. He believed the long hip splint gave sufficient immobilization for all practical purposes. It was more easily managed than the portable bed of Dr. Phelps, which from neglect would be likely to cause excoriations. As the disease seemed to be a struggle between the tubercle bacilli and the vitality of the organism, he thought it especially important to place the system in the best possible condition to resist attack. He had rarely seen constitutional disturbance from abscesses which had been left alone, although in exceptional cases acute and painful conditions were certainly greatly relieved by surgical interference.

The CHAIRMAN commended the title of the paper. It was an admission that hip disease was not to be cured by treatment, but so managed that the almost inevitable recovery by natural processes should be with the minimum of disability and deformity. He thought that more emphasis should be placed on the importance of protecting the joint from the traumatisms of standing and walking, as was done by the use of Hutchison's extra long crutches and high sole on the sound foot. But in every case there were long periods of exemption from pain, when this simple apparatus could be discarded. The ischiadic or perineal crutch of the hip splint, however, could not be willfully discarded; and when it was seen that the rack and pinion not only furnished traction, but also a convenient means of adjusting the length of the upright, the hip splint appeared to come very near perfection as an instrument for the management of hip disease. He had never recognized either the trauma said to be caused by reflex muscular contraction or the alleged mechanical counteraction of the muscles by traction. He believed, and had always held, that the hip splint mitigated reflex muscular contraction by allaying the inflammation which gave rise to it. This it did by arrest of motion and prevention of pressure—motion being arrested by traction brought about by the use of the key, and pressure being averted by the perineal or ischiadic crutch, which made the limb a pendent member. As the inflammation was resolved, the reflex muscular contraction ceased.

The last annual report of one of our orthopaedic institutions contained a table from which it appeared that there had been under treatment 371 cases of disease in the hip, 6 in the shoulder, 85 in the knee, 3 in the elbow, 27 in the ankle, and 5 in the wrist—an aggregate of 483 in the lower and 14 in the upper extremity. Should we draw the inference that the incipient osteitic focus was found only or chiefly in the cancellous tissue of the lower extremity, or that a focus in the upper extremity more readily underwent resolution by reason of its comparative exemption from violence? If the latter view was correct, it followed that the limb was to be made a pendent member by the persistent use of the axillary or ischiadic crutch at the earliest recognition of the disease. In some cases an early diagnosis might be facilitated by the following simple method: Let the patient sit on a table, with the legs hanging and the knees separated; in this position, swinging the leg laterally was possible only with rotation of the femur; and if one leg oscillated in a smaller arc than the other it induced or confirmed a suspicion of the integrity of the joint.

He did not believe in treating abscesses and sinuses excepting indirectly through the general and local management of the bone disease in which they had their origin.

Dr. GIBNEY was in favor of securing absolute immobilization, but sometimes he would rather have less perfect immobilization, if by so doing he could secure a change of air and climate, with the consequent improvement in the general nutrition. Ordinary hip disease was managed satisfactorily with the portable traction splint, with or without the rack and pinion; and he had been agreeably surprised at the facility with which these patients ran around in the tenement houses. They came to his clinic only every three or four weeks for adjustment of the apparatus, and during the intervals engaged in the most active sports; they certainly did not lie in bed in dark rooms and die of pyæmia. It was unsafe to put these children in an appliance like a cuirass or the portable bed, unless one was certain of being able to see and attend to them at short intervals. It had been his lot to see cases in which he had been unable at times to obtain proper co-operation on the part of the patient's family. He had often seen abscesses burrowing up to the spinal column and down to the knee, and such cases seemed to baffle even attempts at surgical interference. We must be guided a good deal by circumstances, and if we could protect the hips from trauma and give the patient the benefit of outdoor exercise, abscesses would generally be insignificant. He believed in correcting the deformity speedily, if necessary by dividing tendons and bone under an anaesthetic, for by so doing we saved much time and lost nothing. In regard to aspirating a joint overdistended with fluid, it was almost impossible to diagnosticate an overdistended hip joint. The position of the limb did not depend on the quantity of fluid in the joint, but was due to reflex spasm and the efforts made by the child and Nature to secure fixation.

Dr. J. H. GIRDNER described an experiment on the cadaver in which great force had been applied without separating the surfaces of the hip joint. He also cited a case in which it had been necessary to keep the hand applied to the face for nine weeks in the course of healing after a plastic operation on the nose. At the end of this time there had been no limitation in the motions of the elbow and wrist.

Dr. KETCH believed that hip disease was so often characterized by exacerbations that all attempts at a division into stages were of no practical value. He thought that the hip splint could often be of use for the reduction of deformities, even in those periods when the patient was confined to his bed. In general, he believed it was a great mistake to make use of any apparatus which could be entirely left to the care of the patient

or family for long periods. The explanation of the relief of pain by compression of muscles was to be found in an involuntary action on the part of the patient which secured fixation and traction at the same time.

Dr. BERG, speaking from the standpoint of the general practitioner, who frequently saw children in the very beginning of hip disease, related the histories of three patients who had presented the symptoms of early hip-joint disease, and yet had recovered perfectly after rest in bed for a few weeks. He now insisted on all such patients remaining in bed for several weeks before commencing any other treatment.

Dr. PHELPS, in closing the discussion, said that many cases in tenement houses, whether treated by the long traction splint or by the portable bed, were deplorably neglected; but this did not argue against the use of either apparatus; it simply illustrated one of the difficulties with which all practitioners had to contend. He valued the portable bed because he desired immobilization of the affected joint, and this could not be obtained with splints having joints in them and not including the trunk. He could relieve his patients better in bed during the period of deformity, and so adopted this method of treatment. He had seen patients in England who had been in bed for several years, and were still in excellent health. He did not, however, advocate prolonged bed treatment. Believing that the cases in question were inoculations of the *Bacillus tuberculosis* on a previously inflamed surface, and not instances of constitutional tuberculosis, he explained the frequency of tubercular joint diseases in the lower extremity by the statement that the joints of the lower extremities, being more subject to traumatic inflammation, furnished good ground in which the bacillus of tuberculosis could more readily reproduce itself. He had presented his honest convictions, and hoped to report his cases hereafter in such a way that others could disprove his statements or he could substantiate his views.

## Book Notices.

*Cyclopaedia of the Diseases of Children, Medical and Surgical.* The Articles written especially for the Work by American, British, and Canadian Authors. Edited by JOHN M. KEATING, M. D. Vol. I. Illustrated. Philadelphia: J. B. Lippincott Company, 1889. Pp. xiii-992. [Price, \$5.]

If the first volume is to be regarded as an earnest of the general character of the complete work, the subscriber for the "Cyclopaedia" need entertain no misgivings as to the wisdom of his investment. The plan of the work is to combine in a systematic treatise the medicine and surgery of paediatrics as well as certain specialties and general subjects relative to the conditions of childhood and adolescence. This is accomplished by collecting a number of monographs by authors well known as teachers and as contributors to the literature of paediatrics. Also it is proposed that these articles shall reflect the views of the authors, in order that many confusing elements may be eliminated, and that the discussion of mooted points may not interfere with the practical treatment of the subject in hand.

The first volume affords a good example of the excellence of this plan. The several articles treating of the anatomy, physiology, and hygiene of infancy, childhood, and puberty, and of the fevers, miasmatic diseases, diagnosis, and therapeutics of the same periods of life, are concise, practical, and brief. Embryology and bacteriology, as well as the relation of race

and maternal impressions on the foetus, are among the subjects included in its contents as collateral to the main subject. The condensed character of the several articles is truly refreshing to the reader when he is engaged in prospecting for a little information as to a minor point of diagnostic value or one of treatment. He has been accustomed to force his way through a thick chaparral of tangled verbosity which deals with ancient history, unimportant discussions of immaterial questions, and the relation of jejune theories, in his search for the location of the places he hopes to find—but never succeeds in the finding—when he has consulted one of the ordinary medical cyclopædias; and the marked departure from the conventional type presented by this work will, in itself, entitle it to the highest degree *cum summa laude* as a work of reference, as far as his estimation is concerned.

The individual articles present but little that deserves criticism; and even that is so effectually sheltered by the protecting wing of the general good character of the book that carping comment is unable to reach it. The task which has been undertaken by the editor and his collaborators is no light one, but they have made a beginning that is indicative of a brilliant success, and the prediction that a valuable addition to medical literature will crown their efforts in this instance requires no exercise or possession of occult power. With no desire to bestow fulsome praise, we pronounce it to be the best work of its kind we have ever seen.

*The Diagnosis and Treatment of Extra-uterine Pregnancy.* By JOHN STRAHAN, M. D., M. Ch., M. A. O. (Royal University of Ireland), etc. Jenks Prize Essay of the College of Physicians of Philadelphia. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. 134. [Price, \$1.50.]

THERE is no subject which has so engrossed the minds of gynaecologists and obstetricians during the past two or three years as this one has, and it is safe to say that no pathological problem is more formidable as to its results and its complications. It was to be expected that the Jenks prize essay committee, in giving out this subject, would elicit much valuable information, and the author of this essay is to be congratulated that his was found the most worthy of the seven which were offered in competition. We should criticise its repetitions and its want of finish but for the statement that is made that there was no opportunity for revision of proof, but even with this allowance we feel that it should have been reviewed with more care before it was sent to the committee. As a matter of fact, while the literature of the subject has been searched with commendable thoroughness, nothing new or original is offered as to either diagnosis or treatment. Tait's views, as expressed in his recent work on "Ectopic Pregnancy," are accepted almost without question, although the author states (p. 24) that he "does not slavishly follow whatever he (Tait) may say, unless he is well supported by himself or others," and his views are based almost entirely upon his own experience and practice (large, it is true) upon this subject. But even so extensive an experience as that of seventy-nine cases can not prove everything in regard to the pathology of this condition, or at least we believe it does not, as Tait with no little dogmatism would seem to insist.

Take, for example, the point which Tait insists upon—that all extra-uterine pregnancies must be primarily tubal (with the bare possibility only of ovario-tubal pregnancy); the cases of Chambers and Maticki (and we know of one other), in which the tubes showed no evidence of rupture by scar or otherwise—and it is hardly a satisfactory statement which the author, following Tait, adduces, that "either the tubes were not properly examined, or, if they really were intact, rupture must have occurred very early and contraction and healing had been very

complete" (p. 40). Why should the Fallopian tubes form an exception to the fact that nature leaves the traces of repair in injured tissues? Again, why should we be expected to believe that a foetus is so quickly *digested* after tubal rupture has taken place that an operation within a few days or hours of the accident reveals nothing but a mass of blood clots? We do not wish to detract from Tait's transcendent ability as an operator, nor from the enormous impetus which his work has given to abdominal surgery, but we are unwilling to accept without question his line of reasoning in some particulars, notably in the foregoing, and to the same extent must differ with his disciple whose essay is under consideration. It is one thing to have a theory; it is another to bend observations to fit that theory; and more than one brilliant man has perpetrated this fallacy.

Though the essay contains no original suggestions, it is not without merit and is to be recommended for consultation to those who wish to become acquainted with the present status of the subject as it is viewed by Tait. It is needless to say that no sympathy is expressed with the electrical treatment of extra-uterine gestation, and with good reason, we believe.

With all deference to the high authorities who advocate this treatment, it is not improbable that the day is near when it will become obsolete.

*Outlines of Lectures on Physiology*, with an Introductory Chapter on General Biology, and an Appendix containing Laboratory Exercises in Practical Physiology. By T. WESLEY MILLS, M. A., M. D., L. R. C. P. Eng., Professor of Physiology, McGill University, Montreal. Montreal: W. Drysdale & Co., 1886. Pp. 5 to 200.

"Do not step into the domain of one's soul" is a common Russian expression, hinting at the fact that there is always something that one is desirous to keep for himself. This is the thought brought forth by reading this valuable and original little book, proving an exception to the saying mentioned. While it is in the main a skeleton of lectures on physiology, the book contains some paragraphs of full definitions and explanations, thus showing where difficulty arises for even competent and eminent lecturers—a point that one is not always willing to display. The author fully deserves, on the part of advanced students and especially on the part of those whose work it is to teach students, the most profound thanks for his liberal views in publishing the outlines of his lectures. It is much to be desired that other lecturers should follow the same example.

*Hand-book of Physiology*. By W. MORRANT BAKER, F. R. C. S., Surgeon to St. Bartholomew's Hospital, etc., and VINCENT DORMER HARRIS, M. D. Lond., Fellow of the Royal College of Physicians, etc. Twelfth Edition. Rearranged, revised, and rewritten, and with Five Hundred Illustrations. New York: William Wood & Company, 1889. Pp. xi-784. [Kirke's "Hand-book of Physiology."]

IT is much to convince beginners in physiology of the complexity of the physiology of the human organism, and, by bringing face to face the physiology of such an organism and that of simple protoplasm, to demonstrate that there is no more mystery in the former than in the latter. For the scope of a text-book this object is fully accomplished in the work. The first chapter, treating of the phenomena of light, is of necessity followed by the study of the structure of the elementary tissues, and the structure and function of the blood, and the succeeding chapters are elaborately arranged in such a manner as to present a continuous and rational study of the various physiological phenomena as they are dependent upon each other. While it is sprinkled with the numerous new facts and theories of the last few years,

the text retains the character of having been written by a faithful and devoted teacher. The section on the blood is most fully dwelt upon and in accordance with the latest knowledge; and among the numerous illustrations in the text those of Gowers's haematoctometer and Ludwig's mercurial pump are worthy of notice. The text is closed by a very readable section "On the Relation of Life to Other Forces," revised by Mr. Baker.

*Materia Medica and Therapeutics*, for Physicians and Students.

By JOHN B. BIDDLE, M. D., late Professor of Materia Medica and General Therapeutics in the Jefferson Medical College. Eleventh Edition, revised and enlarged, with Special Reference to Therapeutics and to the Physiological Action of Medicines. By CLEMENT BIDDLE, M. D., U. S. Navy, and HENRY MORRIS, M. D., Fellow of the College of Physicians of Philadelphia, etc. With numerous Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. xix-33 to 607. [Price, \$4.25.]

THE most noteworthy of the changes introduced into the present edition of this work are the addition of new articles regarding the action of a considerable number of new drugs which have come into general use since the last edition was issued, and of practically new articles on the antiseptic use of mercuric chloride and iodide, and on electricity, and the omission of useless botanical descriptions. Twenty-one new cuts have been added. The revision has been thorough, and the high standard of excellence so long accorded to this work is ably maintained.

*A Text-book of Pathology*, Systematic and Practical. By D. J. HAMILTON, M. B., F. R. C. S. E., F. R. S. E., Professor of Pathological Anatomy, University of Aberdeen. Copiously illustrated. Vol. I. London and New York: Macmillan & Co., 1889. Pp. xx-736.

It is not safe to express a decided opinion upon the merits of a work of which only one volume has appeared, but, if the second volume of this book is as good as the one before us, it will prove a very valuable contribution to pathology. Even if the work should never be completed, the present volume would be well worth having. The subject is treated as being one link of the chain beginning with morbid anatomy and ending with clinical medicine, and not as an independent branch of medical science. Sufficient space is devoted to the technique of the microscope to enable the student to dispense with a special treatise on the subject. Bacteriology receives adequate treatment, and the bibliography of each subject is large. The cuts are good and the index is full.

*The Student's Text-book of the Practice of Medicine*. By ANGEL MONEY, M. D. Lond., Assistant Physician to University College Hospital, etc. London: H. K. Lewis, 1889. Pp. xiv-458.

THE first impression made by this book—that it is inadequate—is not lessened by a careful examination. It purports to be for "those who are beginning the study of medicine, those who are preparing for examination, and practitioners who have no time or inclination to peruse treatises."

Possibly it may be of advantage to these persons, but we incline to the contrary opinion. Young men beginning the study of the practice of medicine need a work which presents the subject to their minds as concisely as is compatible with perfect clearness and reasonable fullness. A work which passes rapidly from one disease to another, devoting on the average less than a page to each, does little more than indicate that such

diseases exist, can be of no service to the student, and may do him harm by accustoming him to a superficial consideration of a subject. It may be of some value to the student after he has mastered a good text-book and is cramming for examination. Regarding the practitioner who has neither time nor inclination to read treatises we have only to say that probably he will not read this book either.

*Elements of Histology*. By E. KLEIN, M. D., F. R. S., Lecturer on General Anatomy and Physiology in the Medical School of St. Bartholomew's Hospital, London. Illustrated with 194 Engravings. New and enlarged Edition. Philadelphia: Lea Brothers & Co., 1889. Pp. xii-368. [Price, \$1.75.]

A VERY handy treatise, which presents the main points of histology in small space and in a pleasing form. Although nominally intended for students, it will be found useful to any one who has not the time to go through the larger works upon the subject. The illustrations are good, particularly the microphotographs.

*Transactions of the American Association of Obstetricians and Gynaecologists*. Vol. I. For the Year 1888. Philadelphia: W. J. Dornan, 1888. Pp. xxxviii-347.

This new society has every reason for satisfaction as to both the matter and the manner in the first volume of its transactions. With the array of distinguished names in the list of fellows and the good work with which its career has been inaugurated, the society has reason to expect a useful and creditable future. We might select a number of papers or discussions from the volume and label them classical. The amplest justification for the existence of any society is furnished by work such as this.

#### BOOKS AND PAMPHLETS RECEIVED.

Congrès pour l'étude de la tuberculose chez l'homme et chez les animaux, 1er session—1888. President : M. le Professeur Chauveau (de l'institut). Comptes rendus et mémoires. Publié sous la direction de M. le Dr. L. H. Petit, secrétaire général. Paris : G. Masson, 1889. Pp. 760.

Anatomie topographique du duodénum et hernies duodénales. Par Jonnesco, prosecuteur provisoire de la Faculté, interne des hôpitaux. Avec 18 planches (21 figures) hors texte. Paris : Lecrosnier et Babé. [Publications du "Progrès médical."]

Recherches cliniques et thérapeutiques sur l'épilepsie, l'hystérie et l'idiotie. Compte rendu du service des enfants idiots, épileptiques et arriérés de Bicêtre pendant l'année 1888. Par Bourneville, médecin de Bicêtre, Courbarien, Raoult, Sollier, internes du service. Volume IX, avec 25 figures dans le texte. Paris : Lecrosnier et Babé, 1889. [Publications du "Progrès médical."]

A Laboratory Guide in Urinalysis and Toxicology. By R. A. Witt-haus, A. M., M. D., Professor of Chemistry and Physics in the Medical Department, University of the City of New York, etc. Second Edition. New York : William Wood & Co., 1889. Pp. iv-75.

The Treatment of Syphilis at the Present Time. By Dr. Maximilian von Zeissl. The Treatment of Inebriety in the Higher and Educated Classes. By James Stewart, B. A. Manual of Hypodermic Medication. By Dr. Bourneville and Dr. Bricon. Vol. iii, No. 2. New York : William Wood & Co. [Wood's Medical and Surgical Monographs.]

Transactions of the Michigan State Medical Society. Twenty-fourth Annual Meeting, held in Kalamazoo, June 9 and 10, 1889.

On the Diagnosis of Pregnancy in the Early Months. By Llewellyn Eliot, M. D., of Washington, D. C. [Reprinted from the "Journal of the American Medical Association."]

Electrical Distribution of Heat, Light, and Power. By Harold P. Brown, Electrical Engineer. With Partial List of Deaths from Electrical Lighting Apparatus, and Address by John Murray Mitchell, Coun-

selor-at-Law, on Legislative Control of Dangerous Electrical Currents. New York : J. W. Pratt & Son, 1889.

Distended Gall-bladder simulating Floating Kidney. Cholecystotomy by the Lumbar Incision. By J. Ewing Mears, M. D., of Philadelphia. [Reprinted from the "Transactions of the American Surgical Association."]

## Reports on the Progress of Medicine.

### ANATOMY.

BY MATTHIAS L. FOSTER, M. D.

**Supernumerary Mamæ and Nipples.**—Sutton ("Am. Jour. of the Med. Sci.", March, 1889) tells us that supernumerary mamæ and nipples are more common in men than in women, are usually single, on the left side and on the thoracic wall. Occasionally they are arranged symmetrically and may be found on the abdomen as well as the thorax, following the course of the superior and deep epigastric, an anastomosis which has a close if not direct relation to the mammary gland. This is the primitive arrangement in mammals, and when supernumerary glands appear along this line they may be considered atavistic or reversionary; but when they are found elsewhere there must be some other explanation of their appearance. Sometimes in women we see a bifid nipple; at other times two mamæ coalesced, but with separate nipples. Such a condition is due to dichotomy, or abnormal division of the gland germ. Intermediate stages between two separate glands and a bifid nipple have been recorded. These are not reversions.

Aberrant mamæ are most frequently found in the axilla, where they may be found either with or without nipples. Champneys has found that the skin of parturient women often presents nippleless lumps in the axilla which may attain the size of a hen's egg. They do not possess any ducts or pores, and, though they may be noticed during pregnancy, more commonly attract attention on the third day after delivery. They enlarge with the breasts and, as a rule, decline on the fourteenth day after delivery. They may occasionally be made to furnish a milk-like secretion on pressure, but not spontaneously. He has also found mamæ with nipples, containing ducts and pores, lodged in the apex of the axilla, from which, after delivery, milk and colostrum could be expressed. Very rarely similar mamæ have been found on the acromion and thigh. In Ahfeld's "Missbildungen des Menschen" is mentioned a case in which a mamma occupied the labium majus. Bain has given an account of a nipple which grew on the face. It was just in front of the right ear and surrounded by an areola and pigmented skin. When handled it grew harder and gave rise to sensations similar to those produced by handling the true nipple. It was removed and it was found microscopically to conform to the structure of the true nipple, and that glandular tissue existed beneath it.

Supernumerary mamæ usually appear in situations which possess a goodly crop of hairs, large sebaceous glands, or both. If the milk gland is regarded as a modified sebaceous gland, these aberrant mamæ may be regarded as "sports" due to excessive development of the sebaceous glands. This assumption is supported by the discovery of very large sebaceous cysts in dermoid tumors of the ovary. The author has traced in these dermoids every stage from a nipple-like tag to a well-developed mamma with glandular tissue, ducts, and a nipple filled with a fluid microscopically identical with milk and containing colostrum corpuscles.

A careful analysis of the evidence seems to show that accessory mamæ may arise in three ways—viz., by atavism, by "sports," and very rarely, by dichotomy.

**The Vocal Cords and the Hyo-epiglottidean Ligament.**—Sutton ("Jour. of Anat. and Phys.", Jan., 1889) concludes, from an extensive comparison of the larynx of man with that of a number of lower animals, that "the false vocal cords, with the cuneiform cartilages, are the degenerate representatives of the piece of cartilage by means of which the epiglottis and cornicula laryngis were originally united, and with the cornicula must be regarded as vestigial structures."

The true vocal cords he regards "as arising from the tendinous metamorphosis of those fibers of the thyro-arytænoideus muscle subjacent to the laryngeal mucous membrane." To make the latter hypothesis complete it is necessary to find a case in which the vocal cords in man are composed in part or wholly of muscular tissue. No such specimen has yet been found, but the author does not despair of eventually finding one, especially as a patch of striated muscle has been detected in at least one case in the anterior flaps of the mitral valve in the adult.

The hyo-epiglottidean ligament is the fibrous representative of a well-formed muscle in many mammals. He has twice seen it replaced by a distinct muscle.

The objection that it is not likely that muscular tissue should metamorphose into such highly elastic tissue as is found in the true vocal cord he meets by quoting certain muscles in the wings of birds, some of which are entirely replaced by exceedingly elastic tendon—perhaps even more elastic than the true vocal cords of man.

**The Angle of the Neck with the Shaft of the Femur.**—Professor Humphrey ("Jour. of Anat. and Phys.", January, 1889), being in doubt in regard to the correctness of the generally accepted statement that the angle of the neck with the shaft of the femur becomes lessened and the level of the head of the bone consequently lowered in advancing years, undertook the examination of a large number of femora of subjects of various and known ages. His conclusions he formulates thus :

1. That the angle formed by the neck of the thigh bone with the shaft varies considerably in different persons at any given period of life.

2. That it is smaller in short bones than in long bones, and that it is also most likely to be small when the pelvis is wide, the combination of these two conditions rendering it usually smaller in women than in men.

3. That the angle decreases during the period of growth, but that after growth has been completed it does not usually undergo any change, even if life is continued to extreme old age. Some change may take place in exceptional cases, but, as a rule, the angle remains the same from the adult period till death, at whatever age that may occur.

4. That if during growth the limb be relieved of the weight of the body, as in the bedridden state in paralysis or in a stump, the angle of the neck with the shaft usually retains the open form of early life, or even may become wider.

**The Musculus Sternalis.**—Shepherd (*ibid.*) has traced the nerve-supply to ten of these muscles which occurred in anencephalous foetuses with the following result:

All were supplied by the anterior thoracic; two received an additional supply from the intercostals. The latter were the only cases in which the great pectoral was not deficient. This would seem to indicate that there are two kinds of sternalis muscles. When the great pectoral is deficient it seems clear, even without regard to the nerve-supply, that the sternalis is the missing portion of that muscle, but when there is no such deficiency the homology of the sternalis is not so clear. Bardeleben describes what he calls the "typical sternalis," which extends from the sheath of the rectus abdominis to the sternomastoid, belongs to the muscular system of the rectus abdominis and pubo-hyoides, and derives its nerve-supply from the intercostals. Shepherd is inclined to think that if the branch from the anterior thoracic were carefully searched for in these cases it would always be found.

The occurrence of this muscle so commonly in anencephalous monsters would rather point to its being a reversion rather than a new muscle appearing in man.

**An Abnormal Arrangement of the Kidney and its Vessels.**—Dr. Mahon describes the following anomaly (*ibid.*): The right kidney was small, lying in the right iliac fossa, its lower end over the right common iliac artery. In form it resembled a flattened oval and retained nothing of the characteristic uniform shape. The ureter arose from a depression on the anterior surface by four branches, which soon united and formed a single tube which descended on the anterior surface of the kidney. The organ was supplied by five arteries, thus arranged:

1. A large branch from the side of the aorta, at the usual point of origin of the renal artery, descended behind the vena cava and entered the kidney at the junction of the upper and middle thirds of its inner border.

2. A smaller branch, but larger than the remainder, from the aorta an inch and a half above the bifurcation, passed with all of the remaining branches in front of the vena cava and entered the kidney at its inner border.

3. A branch from the aorta a quarter of an inch below No. 2. This divided into two branches of equal size and entered the kidney at the depression on its anterior surface corresponding to the hilus.

4. A branch which arose from the front of the bifurcation of the aorta and entered the kidney at the lower third of its inner border.

5. This branch arose from the outer side of the commencement of the right common iliac artery, passed behind the kidney, and entered it by piercing the convex outer border.

Small veins accompanied arteries Nos. 3 and 5. What may be called the renal vein proper arose by three branches from the front surface of the kidney. They lay behind the ureter but in front of the arteries. The two lower branches quickly united to form a single trunk, which was joined by the ovarian vein of the right side. It passed upward and outward to the upper end of the kidney, then turned inward and was joined by the remaining branch. The trunk so formed entered the vena cava a little lower down than the vein of the opposite side. The renal and ovarian veins were both large and distended with blood.

The suprarenal body was attached by fibrous tissue to the under surface of the back part of the right lobe of the liver; it was hemispheroidal in shape and had no connection with the kidney.

In the same subject each common carotid artery bifurcated at the level of the cricoid cartilage, and there was a large thyreoidea ima from the innominate.

**An Accessory Phrenic Nerve.**—Larkin (*ibid.*) describes this variation. On each side there was an ordinary phrenic nerve in its usual position, with an accessory nerve, which arose from the fifth cervical. This accessory was from one fifth to one fourth the size of the normal nerve. It crossed the scalenus anticus a quarter of an inch external to and parallel with the ordinary nerve. In the chest, between the pericardium and pleura, the right accessory was from an inch to an inch and a half in front, while the left was one fourth to one half an inch behind its companion. On each side the accessory joined the phrenic just before it divided into its terminal branches. The accessory gave several branches to the pleura and pericardium, while the true nerve seemed to give none.

**The Innervation of the Bladder, Rectum, and Genital Function.**—Bernhardt ("Berliner klin. Wochenschrift," "Am. Jour. of the Med. Sci.," March, 1889) reports an accident which, although the exact pathological nature of the lesion was not determined, is of interest as contributing to our knowledge of nerve distribution.

A man fell from the second story, striking upon his buttocks. He immediately complained of pain in the back, and suffered from incontinence of faeces and inability to urinate, but not incontinence of urine. Nine days later he could stand alone, but with pain in the region of the seventh to the twelfth dorsal vertebrae, which seemed somewhat swollen and was painful on pressure. While lying in bed both legs could be moved in a normal manner without pain. The reflexes were normal; tactile sensibility, temperature, and muscle sense were undisturbed in the lower limbs, except on the inner half of the posterior surface of both thighs, beginning at the upper border of the lower third of the thigh and extending upward to those parts of the buttocks contiguous to the anal fissure. Over this area there was total anesthesia. The anus, perineum, scrotum, and penis were involved, but the inner

surface of the thighs, the sacral region, the belly, and the groins were normal. The testicles were sensitive to pressure. Erections occurred, and coitus was effected with the natural sensations, but the semen was not ejaculated from the urethra. The inability to urinate or control the sphincter ani continued. Persistent treatment with electricity for four months produced very little improvement.

This case, taken in conjunction with several similar ones, goes to prove that the function of the bladder and rectum is dependent on a normal condition of the lowest end of the spinal cord and of the nerves arising from it. The same symptoms may be produced by a disease of the nerves of the coccygeal and pudendal plexuses without any involvement of the cord itself. The case shows that the nerves controlling erection are separate from those which preside over the rectum and bladder, and also from those controlling ejaculation.

**An Amelus.**—Chalmogoroff ("Ctrlbl. f. Gyn.," No. 50, 1888) reports the still-birth of a male child which was totally wanting in limbs. There were no rudimentary legs or arms present, but it is supposed that they were amputated early in embryonic life by amniotic bands.

**Absence of the Uterus and Vagina.**—Dr. Brunes ("Ann. of Gyn.," Feb., 1889) reports two cases in which the external organs of generation were normal in appearance and the breasts well developed, but the internal organs rudimentary or absent. In one the vagina ended just behind the hymen, and no continuation could be found. By bimanual examination the broad ligament could be marked out, and indications of the uterus. Fallopian tubes and ovaries could be detected. In the other no trace could be found of vagina, uterus, broad ligament, or ovaries. Both patients suffered from cardialgia and chlorosis. Several similar cases have been reported.

**An Anomaly of the Lingual Artery.**—Shepherd ("Ann. of Surg.," May, 1889) has found in one case the lingual artery given off in common with the superior thyroïd, opposite the upper border of the thyroïd cartilage. From that point it passed upward and inward toward the median line of the neck, resting upon the thyro-hyoïd muscle. It crossed the hyoid bone internal to the lesser cornu, almost immediately pierced the hyoglossus muscle, and thence proceeded to the tip of the tongue in its normal course. At the usual origin of the lingual was a very small branch, which ended in the hyoglossus muscle. It originated probably from enlargement of the anastomotic hyoid branches of the lingual and superior thyroïd arteries, and the consequent disappearance of the main trunk of the lingual.

It is important for surgeons to be acquainted with this rare anomaly, because the artery could not have been found by means of the usual curved incision, if it had been necessary to ligate it.

**The Cranial Nerves.**—The "Journal of Physiology" for April, 1889, is wholly given up to a very valuable article, by Dr. W. H. Gaskell, on the cranial nerves and the central nervous system. He treats of the nerves seriatim, commencing with the third, as the optic and olfactory do not conform to the type of the remainder. The oculo-motor ganglion he considers to be a typical motor vagrant ganglion peculiar to this nerve, and not a posterior-root ganglion, as a number of morphologists have supposed. It is not connected with any large-fibered sensory nerves from the fifth nerve, but is connected only by very fine efferent nerve fibers mainly from the third. The fourth is very similar in structure to the third; both are efferent and divisible into a large- and a small-fibered part. The large fibers of the fourth supply the superior oblique, but the destination of the small fibers is not known. In each are strands and clumps of fibrillar tissue, which, he concludes, are the remnants of nerve fibers and cells, which were of importance in by-gone animals, but have become useless and lost their protoplasmic contents. Originally they were complete segmental nerves, with both motor and sensory roots, but the sensory portions have degenerated, and their place has been taken by the sensory elements of the fifth nerve.

The fifth and sixth nerves are really three—two efferent and one afferent. The roots of the motor part of the fifth contain the remains of nerve fibers and ganglia precisely like those in the roots of the third and fourth. In the sixth he finds no regular ganglion formations, and hence concludes that primitively the motor part of the fifth and the sixth nerves together form a complete segmental nerve. The ascending root of the fifth is independent.

The seventh, like the motor part of the fifth, is essentially a splanchnic efferent nerve, as the striated muscles it supplies are all of the visceral group, being derived from the lateral plates of the mesoblast. It is divided into groups of large and small fibers, of which the larger pass as motor nerves to the facial muscles, while the smaller enter the geniculate ganglion. The majority of these fine fibers form a separate root known in man as the intermediate nerve. In some of the lower animals this intermediate nerve can not be demonstrated, but the bundles of fine fibers are found to have a strong tendency to be grouped apart from the rootlets containing the large fibers of the seventh nerve and pass directly into the geniculate ganglion. This ganglion he considers, like the oculo-motor, a vagrant efferent ganglion. The evidence of the structure and function of the seventh nerve shows that it corresponds to a complete segmental nerve in that its efferent root contains a large-fibered non-ganglionated splanchnic portion and a small-fibered ganglionated splanchnic portion with its vagrant ganglia—viz., the geniculate ganglion and the submaxillary ganglion. There is also evidence of a degenerated ganglionic structure close to the exit of the nerve from the brain. So in this group of cranial nerves formed by the third, fourth, motor part of the fifth, sixth, and seventh nerves there are four fully formed segmental nerves which for some reason have lost a certain portion of their original components.

In the next group—those which arise from the medulla oblongata—we again find all the components which make up a fully formed spinal nerve, or rather group of nerves, but with no sign of degeneration of any special group. There is, however, a scattering of the different components, so that the nerves form parts of a number of segmental nerves instead of each one forming a single nerve. The sensory portion of the trigeminal belongs to this group. The group consists of at least five complete segmental nerves which are both cranial and spinal in origin. A characteristic of this group is the extensive peripheral distribution of its nerves.

Gaskell submits this possible explanation of the ancestral history of the spinal cord:

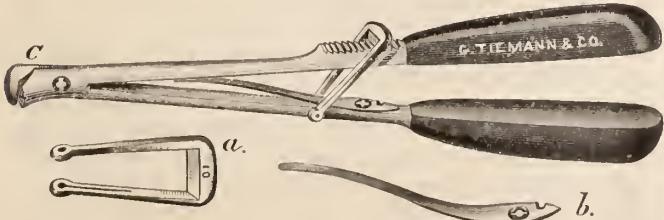

"It was originally composed of a bilateral chain of ganglia situated ventrally to a non-nervous tube, the parts of each chain being connected together by commissures also situated ventrally to the tube. By the increase and spreading round of the nerve cells and nerve fibers to the dorsal side, the original tube was so invaded by nervous elements as to have lost its original character and become the supporting structure of the spinal cord, leaving as the most marked indication of its original character the epithelial lining of the central canal and the peculiar structure of the substantia gelatinosa centralis."

## New Inventions, etc.

### THE UNIVERSAL NEEDLE-HOLDER, WITH HANDLES OF THE RUSSIAN MODEL.

BY GEORGE R. FOWLER, M. D.,  
BROOKLYN.

JUST prior to the death of my late lamented assistant at the Methodist Episcopal Hospital, Dr. W. M. Thallon, he had suggested to Tiemann & Co. that they make a needle forceps after the pattern known

as the aseptic universal, introduced by myself, substituting, however, for the ring handles those known as the Russian. He did not live to

elaborate the details of the plan, and I was requested by Mr. Julius Pfarre, of the firm, to do so. The accompanying drawing shows the result of my endeavors. The complete instrument, with the universal jaw and French lock, is shown at *c.* In order to render the forceps aseptic, it became necessary to devise some plan whereby the catch which holds the instrument while grasping a needle should be readily detached for purposes of cleaning. This was accomplished by making the space between the legs of the catch, *a*, wider at the bottom than at the top and placing a groove upon the inner surface of each leg, this groove terminating in a hole to receive the pin placed upon either side of the handle of the forceps, upon which the catch works. At the point where the groove joins the hole for the pin, the former is slightly rounded off so as to allow the pin to readily engage in the groove when the forceps is taken apart for the purpose of cleaning. To take the instrument apart the catch is thrown as far forward as possible toward the jaws of the forceps and by simply pressing upon the catch it becomes at once disengaged by its points springing apart, when it may be slipped off the forceps at its further end. To replace it, this movement is reversed; the catch is slipped on from the end of the forceps and so placed as to bring the upper limit of the grooves opposite to the pins. By simply drawing upward upon the catch the pins glide along the groove; the legs of the former spring apart, to snap together again as the holes at the end of the grooves are reached. The spring, *b*, is easily removed and replaced by means of the French lock and pin.

This necessarily extended and seemingly prolix description would make it appear as if the instrument were a very complicated piece of mechanism; in reality, however, it is a very simple affair. I have recently learned to use the instrument without the catch, relying upon the grasp to hold the needle firmly. To those who have been accustomed to rely upon a catch this is at first slightly awkward, but there are advantages in this training of the hand, not among the least of which may be mentioned the advancement of the aseptic idea, which, in my judgment, should be the leading thought in the devising of any new instrument.

## Miscellany.

**The Diagnosis and Treatment of Extra-uterine Gestation.**—At a recent meeting of the Obstetrical Society of Philadelphia Dr. William Goodell reported the history of a case of extra-uterine gestation, and exhibited the specimen. The patient had been married for a number of years without conceiving. Her catamenia had been regular up to the time when they ceased for nearly seven weeks and morning sickness set in. The next monthly period was free for a few hours, and then there was merely a show of blood which lasted several days. During this dribble severe intercostal pains, lasting two hours, followed a movement of the bowels. For several days there was great soreness of all the muscles. At irregular intervals these intercostal pains reappeared and were always followed by much muscular soreness. There were few pelvic pains, nothing like cramps, and Dr. Goodell was called in on account of a continuous dribble of blood which had lasted for three weeks. During this metrorrhaxis, membranes were twice passed, which were supposed to be fragments of an abortive ovum. Dr. Goodell found an irregular tumor to the left of the womb, closely adhering to it and pushing the fundus over to the right. In view of the history, a diagnosis of extra-uterine gestation was made, and the operation was promptly performed three months after the cessation of the last regular monthly period. There was no appearance of old or of fresh blood in the abdominal cavity, such as is found in many such cases when rupture has taken place. But blood escaped during the breaking up of numerous adhesions to the rectum and the broad ligament. The specimen showed the left ovary and the corresponding Fallopian tube greatly enlarged by a deposit of placental tissue. Dr. Osler, who had examined the specimen, had stated that the chorionic villi were unmistakably present. No fetus was discovered, but it might have perished and become absorbed, or possibly it had escaped into the abdominal cavity through an opening made accidentally into the sac during the

process of enucleation. So vascular was the sac that a stream of blood spurted out from this tear as if it came from a large vessel. Apart from a nervous attack of vomiting, which lasted nearly twenty-four hours, the woman's convalescence was uninterrupted.

Dr. J. Price said that he was satisfied that Dr. Goodell's explanation of the absence of the fetus was correct. He could cite two or three cases and an experience of his own which supported this view. Mr. Tait's first two patients had made tedious recoveries, and in both cases he had failed to find the fetus. Some time ago the speaker had opened the abdomen in a case of doubtful diagnosis. Some one standing by asked him what he expected to find. He replied, "One of twelve things." He went on and removed a large adherent tube, ruptured, the abdomen being pretty well filled with clot. He then irrigated the abdomen. After using one pitcherful, the water returned perfectly clear. To make the toilet thoroughly satisfactory, he used the second pitcherful of water, and, in finishing the second toilet, washed out a little boy. In this case he was satisfied that the peritonæum could have taken care of the fetus by digestion, as had probably occurred in Mr. Tait's cases.

Dr. Howard A. Kelly thought that this case illustrated how readily one could make a satisfactory diagnosis, given symptoms being present. With a certain order of symptoms and signs we could with the utmost certainty diagnosticate extra-uterine pregnancy in a certain proportion of cases. In another large proportion of cases it was a matter of mere conjecture until the abdomen was opened. He had operated recently in such a problematical case, one of the two possibilities being extra-uterine pregnancy. Such proved to be the condition, although no fetus was found. He found the sac and the placenta within the ruptured tube. In a recent book on this subject, by Strahan, the author had unfortunately failed to notice some experiments on the disappearance of the fetus after its expulsion into the abdominal cavity. Leopold had experimented by introducing fetuses into the abdominal cavity of dogs. These had been digested, provided the period of the more distinct development of the bony tissues had not been reached. After that period they became sources of irritation and were cast off by suppuration.

Dr. M. Price did not think that a study of the cases on record would make a man perfectly satisfied that he could say when he had a case of extra-uterine pregnancy. The ablest men throughout the world had satisfactorily decided that question. They had made mistakes time and time again. They had cut for supposed extra-uterine pregnancy and found something else; they had cut for something else and found extra-uterine pregnancy. It was very difficult to decide until the abdomen was opened. A ruptured extra-uterine gestation sac could only develop in the broad ligament. If it ruptured into the peritonæum, there was not a single case on record where, if the operation was delayed a number of days, the fetus had not disappeared. Hundreds of cases were on record. He had himself seen eight or ten where the fetus could not be found, where the microscope positively showed the presence of extra-uterine pregnancy. The cases that went on to development were those in which there had been first a rupture into the broad ligament, and then development up to a certain time when the child could resist the digestive action of the peritonæum. There was no question in his mind that in these cases electricity had done a vast deal of harm, had aggravated symptoms already existing, and had imperiled the woman's life to a greater extent than if she had been left entirely to nature. The knife, as Dr. Goodell had used it, was the only means of treatment. Delay was not justifiable at any period, unless, when the case came into the hands of the surgeon, the child had passed to that degree of development that warranted its being left to the period of viability. All these cases demanded operative procedure at an early period, if they came into the hands of the operator.

Dr. Goodell agreed with those who held to the uselessness of electricity. He thought that there was only a single class of cases of extra-uterine gestation in which electricity might be valuable, and that was in the early weeks, before hemorrhages had occurred. An examination of the specimen shown by him made it clear to his mind that hemorrhages must have taken place in the tube, forming layers of organized clot. In such cases he did not see how it was possible for electricity to do anything but harm. In those occasional rare specimens in which the chorion had remained intact, as in an abortion without rupture, the ovum being nothing more than a delicate but shaggy blad-

der, with the fetus inside, he could understand how electricity could do good by destroying the life of the fetus. Then everything might readily become absorbed; but, as we could never know positively beforehand whether or not hemorrhage had occurred, his own feelings were in favor of immediate section. While the difficulties of diagnosis were undoubtedly very great, this need not interfere with the treatment. We found a woman suffering from certain pelvic symptoms and we discovered an extra-uterine tumor of some kind. Now a painful pelvic tumor must be removed, whatever it was. The only change in the treatment would be to hasten on the operation were the symptoms pointing in the direction of extra-uterine gestation.

#### ANSWERS TO CORRESPONDENTS.

No. 284.—See our notice of the work, in this issue.

No. 285.—In regard to your first question, you had better write to the company, the address of which, according to the latest advertisement that we have seen, is No. 252 Madison Avenue, New York. Our impression is that the apparatus is still regarded with favor here.

No. 286.—See our issue for July 6th, page 12.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

THE OLFACTORY NERVE:  
ITS QUANTITATIVE AND QUALITATIVE TESTS AND ITS  
PHYSIOLOGICAL IMPORTANCE;  
ITS INTRACRANIAL COURSE AND DISEASES.\*

By CHARLES L. DANA, M.D.,

PROFESSOR OF NERVOUS AND MENTAL DISEASES, NEW YORK POST-GRADUATE SCHOOL; VISITING PHYSICIAN TO BELLEVUE HOSPITAL.

**INTRODUCTORY AND PHYSIOLOGICAL.**—The rhinologist must be looked upon as the particular guardian of the first cranial nerve. It is the only organ of special sense which, in the division of medical labor, he may call his own. He must naturally regard it with more than ordinary interest, and may properly feel toward it a sense of proprietorship and special expertness. He has dealt chiefly, however, heretofore, with its peripheral portion, and I shall venture now to call attention to some points connected with its general functions and its deeper anatomy, which will, I trust, possess some novelty and interest.

Physician and patient are both apt to disregard disturbances of the sense of smell. These are only discomforts or deprivations of a minor kind. The rhinologist, besides, sees in the nose mainly a respiratory organ and treats it for its fluxions, its pathological incumbrances, and other interesting disorders. The subjects of anosmia, parosmia, and hyperosmia very naturally are regarded as of minor importance, and cut but a small figure in rhinological literature.

The sense of smell is one, however, that still subserves much useful purpose, and is as yet by far the most delicate means we possess of appreciating attenuated matter. The nose does, in fact, bring us closer to the spirit world than any other organ, for the trillionth of a grain of mercaptan, which awakens a sensation in the mind, has weight and dimensions so infinitely minute as to be quite beyond the power of the imagination to grasp.†

The sense of smell, or something akin to it, is well developed in fishes; it is fairly developed in reptiles; it sinks almost to nothing in birds, while in mammals it finds its highest development. Nearly all mammals have a keen sense of smell, except those which have acquired aquatic habits, like the whale, seal, dolphin, etc., in some of which the organs of smell are entirely absent. The sense of smell is much diminished in the anthropoid apes. In man it is a rudimentary sense, but still it shows a higher development than in the apes.

Some writers have asserted that the sense of smell is keener in savage races than in the civilized, and that olfaction is less perfect as racial types become higher. This is not

the case. The negro or the Indian may cultivate the nose to a high degree of acuteness in certain directions, but in discrimination of odors, in appreciation of flavors, in æsthetic associations aroused by the stimulus of the cranial nerve, the civilized man is as far ahead of the savage as the latter is in advance of the anthropoid ape.\*

Olfaction includes not only the sense of smell, but, in conjunction with the nerve of taste, the appreciation of flavor. It is a function that in times past served various types of animals—

1. For sexual purposes.
2. For selecting food.
3. For hunting prey.
4. For avoiding enemies.

In man it serves—

1. For selecting food and drink.
2. For arousing the sense of hunger.
3. For protection against injurious vapors.
4. For æsthetic and, in a measure, sexual purposes.

The tendency of modern civilization is to cultivate the æsthetic function of the olfactory nerve and bring it as much as possible into close association with pleasurable states of mind. A well-developed olfactory sense is thus part of a thoroughly cultured man's equipment. A diminution in the keenness of olfaction is found to be present in the criminal, lunatic, idiotic, and degenerate classes (Lombrosi, Ottolenghi).

The olfactory sense in man is, therefore, growing, and fortunately so. Every avenue to the brain which carries to it new impressions helps to develop that organ. The cultivation of the eye, the hand, the ear, all promote and enlarge mental activity. I feel very sure that by and by there will come educators and trainers of the sense of smell and taste in children by which greater keenness, power of discrimination, and capacity for æsthetic enjoyment shall be gained. The sense of smell has always been appealed to in religious rites, and women instinctively learn that to exhale a delicate perfume adds to sexual attraction.

**CLINICAL.**—The works on rhinology and neurology have quite exhausted the subject of the clinical disorders of the sense of smell. I do not propose to enter upon this subject except very incidentally.

In the last few years my attention has been struck by the frequency with which certain neurasthenic patients have complained of deficient sense of smell. Some of these had a moderate degree of nasal catarrh, but in other cases I could not satisfy myself that this was the sole cause.

I believe, however, that there is a neurasthenic anosmia and a hysterical anosmia, just as there are similar forms of asthenopia. A more careful and routine testing of patients

\* Civilized man, when through deprivation of other senses he is led to cultivate that of olfaction, often shows capacities more marvelous than any recorded of savage races.

I might instance those cited by Professor Stanley Hall in his account of the case of Laura Bridgman ("Mind," April, 1879, p. 149). He says: "Julia Brace and other blind deaf-mutes have been able to sort the freshly washed clothes of the inmates of a large asylum, and to select and give to their owners several dozen pairs of gloves thrown promiscuously upon a table, solely or mainly by the sense of smell."

\* Read before the Section in Neurology of the New York Academy of Medicine.

† According to Valentin, we can perceive  $\frac{1}{1200000}$ , of a grain of oil of roses. According to Fischer and Penzoldt, one can perceive  $\frac{1}{2760000000}$  of a grain of mercaptan.

I have found that one can perceive the odor from 4 c. em. of a solution of oil of cloves 1 to 100,000.

might bring greater proof of this than I am able to present now.

*Frequency of Anosmia.*—I have had the sense of smell tested in one hundred adults, eighty of whom were patients in the wards at Bellevue Hospital. There were fifty men and fifty women. Among these I found two cases of anosmia—one in a man, from syphilitic disease of the nose; one in a woman who had suffered for years from menorrhagia, and who was ill-nourished, anaemic, and nervous, but had no catarrhal trouble, so far as I could learn. It would hardly be safe to infer that anosmia was present in one per cent. of adults, but it certainly is not infrequent.

*Anatomical.—General Arrangement of Sensory Nerve Tracts.*—Every sensory nerve, unless we have to except the olfactory, in entering the nerve-centers has to make certain connections with nerve ganglia before it reaches the cerebral cortex. All sensory nerves below the first and second (olfactory and optic) meet first with bipolar cells, as in the intervertebral ganglia; then with plexiform-process cells, such as are in the posterior horns of the spinal cord; then with still other collections of cells in the basal ganglia; finally, the fibers run up to the cortex. Some fibers do not make all these stops, but such is the general arrangement. No sensory impulse goes straight to the cortical cells.

The olfactory and optic nerves are somewhat differently arranged. They are both developed from the forebrain, which is embryologically pretty sharply distinguished from the mid-brain and hind-brain, out of which the other cranial nerves are developed. Still, both these nerves are developed as prolongations of the primary and secondary forebrain. They have analogous modes of development, and if the olfactory-nerve impulses passed directly to the cortex, it would be at least a unique physiological arrangement.\*

Let us see if the olfactory apparatus can be put in the same category with that of other sensory nerves. We will take up its different parts in turn.

*1. The Peripheral End-organ.*—This is usually described as consisting of certain cells in the mucous membrane of the olfactory region. The nerve filaments here, however, are non-medullated and more like nerve processes, which I believe they are, arising from nerve cells in the olfactory bulb. The olfactory bulb and its nerve process (olfactory nerves), constitute, it seems most probable, a single end-organ,† which is comparable to the nervous structure of the retina. In some fishes, indeed, the olfactory bulb is, like the eyeball, outside the cranium. The peculiar structure of the bulb, its analogy to that of the retina (as will be shown later), and its entire dissimilarity to that of any cor-

tical or basal nervous centers, are strong arguments for this view.

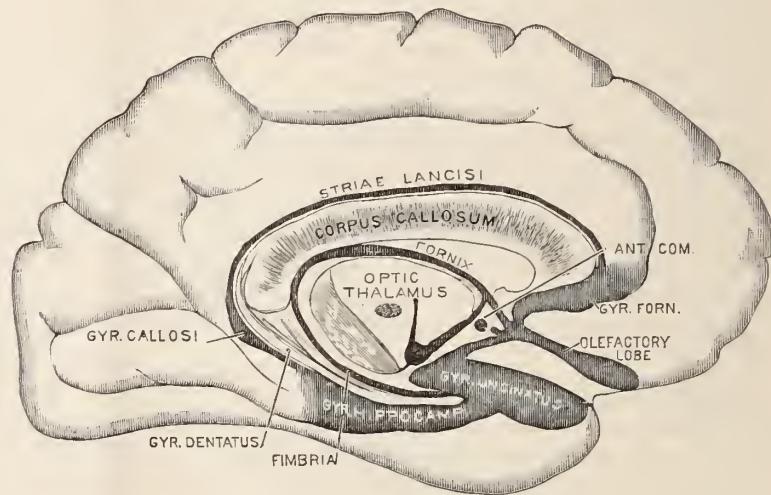

2. The second part of the olfactory apparatus consists of nerve fibers connecting the nerve cells of the olfactory bulb with those of the olfactory tract and olfactory areas in the temporal lobe, to be described below.

3. The third part consists of the cells in the olfactory tract, which is not so much a nerve strand as it is a modification of brain cortex and of other cortical areas.

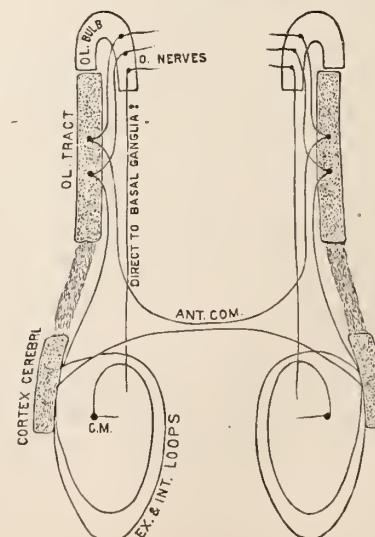

Then, cortical areas are widely distributed in the lower mammals. They are much atrophied in man. My description of them is based largely upon the descriptions of Broca and the recent elaborate monograph of Zuckerkandl.

They consist of the uncinate gyrus, hippocampus, and cornu Ammonis—all of which are parts usually described as belonging to the inner and lower part of the temporo-sphenoidal lobe.

There are still other olfactory areas, however, in the lower

animals; in man they are rudimentary. These are the anterior end of the gyrus forniciatus, which is connected to

the olfactory tract by the inner root of the olfactory nerve. From this part their strands of gray matter pass up (gyrus

\* Von Monakow ("Archiv f. Psych.", Bd. ii, Heft 3) shows that the afferent fibers of the optic nerve take their origin peripherally in the multipolar cells of the retina; thence they pass to plexiform-process cells in the external geniculate body, then to large multipolar cells in the same ganglion and the pulvinar, thence to the cortex.

† Alex. Hill, "Plan of the Nervous System."

geniculi) and over the upper surface of the corpus callosum. These are known as the *striae mediales* and *laterales* of Lancisi. They end posteriorly in a small convolution, described by Zuckerkandl as the *Balkenwindung* or callosal gyrus, and in the *fascia dentata*, which latter is itself intimately related to the *cornu Ammonis*.

Another strand of olfactory tissue—but in this case mostly composed of fibers—starts from the *cornu Ammonis* as the *fimbria*; it passes back up under the corpus callosum, when it is known as the *fornix*. It passes forward till it reaches the anterior part of the corpus callosum, when it descends as the pillars of the *fornix*, forming here boundaries of the fifth ventricle. Some fibers pass forward over the anterior commissure and connect with the outer root of the olfactory tract. But others probably continue with the *fornix* pillars, and pass down to end with them in the *corpora mamillaria*. From there fibers apparently pass up into the optic thalamus.

Both from the outer root and from the hippocampal region fibers bend inward and pass through the anterior commissure, which is in part an olfactory commissure.

It will thus be seen that the olfactory cortex consists of three deposits of gray matter in (1) the olfactory tract, (2) the hippocampus and adjacent parts, (3) the anterior end of the gyrus *fornicatus*. These parts are united by two loops, one passing outside and over the corpus callosum, the other beneath it. The parts on each side are united by the anterior commissure. There is between the two olfactory areas on each side of the brain but a commissural connection, no decussation of fibers as yet, and, unlike the optic chiasm, impulses excited in the nose on one side pass directly to the cortical areas described on the same side.

In man the outer root of the olfactory tract is the only one that practically exists. The center in the gyrus *fornicatus* and the connecting loops of gray matter (stripes of Lancisi) are rudimentary. The olfactory area in the human brain, then, is practically (1) the olfactory lobe and tract, (2) the outer root of this tract, (3) the hippocampus, uncus, and *cornu Ammonis*. It has a commissural union by the anterior commissure, and further connections by the *fornix* and association fibers in the temporal lobe.

Now, so far, the olfactory impulses have reached but two collections of ganglionic cells—those of the bulb and those of the lobe, tract, and hippocampus, uncus, and Ammon's horn. These centers are also on the same side as that of the peripheral nerve. But there are many facts in pathology which compel us to believe that olfactory sensations, like other special sensations, cross.

In addition, it is, as we have shown, contrary to physiological homologies to suppose that a sensory-nerve impulse can pass directly from the periphery to the cortex. It would be like supposing that a nerve from the retina passed without break in continuity to the occipital lobe.

Finally, the cell structure of the cortical areas referred to seems inadequate to the demands of a highly specialized and extraordinarily delicate sense-organ.\*

\* "The gyrus *uncinatus* and the *cornu Ammonis* are peculiarly constructed and show but a meager variety of cortical nerve-forms. The *cornu Ammonis* contains principally cortical elements of the pyra-

The problem of olfaction is not, then, satisfactorily settled by finding a center in the hippocampus and its adjacent areas. Nor does it explain some curious facts in comparative anatomy. The question might be left as it is; but, following the ingenious suggestions of Dr. Hill (*loc. cit.*), I would propose some such explanation as this:

The olfactory tract, hippocampus, and uncus are not really parts of the temporal lobe, but are atrophied remnants of a special lobe, the *lobus limbicus*, which at one time held an equal prominence functionally with other cerebral lobes. As the olfactory nerve declined in importance, the lobe became atrophied and finally rudimentary; just as the optic lobes, so large and visually important in birds, have become atrophied till they are the *corpora quadrigemina* in man.

The gray matter of the hippocampal region and olfactory tract is decidedly different from that in the rest of the cerebral areas (see note). It resembles a rudimentary and atrophied cerebral cortex. These regions, therefore, are imperfectly developed centers. They may be the seat of the sense of smell, but not of ideas of odor or flavor; just as there are lower visual centers.

All the special senses have, it is believed, some kind of representation in the optic thalamus.\* If this is so for olfaction, it must be through the lateral or outer root of the olfactory tract, the *fimbria*, *fornix*, and *corpus mamillare*, as suggested by Hill. It is certain that the *fornix* is connected with the carrying of olfactory impulses, for it is atrophic in animals like the dolphin that have no olfactory organs, and it is hypertrophied in those animals which have a keen sense of smell (Broca, Hill). Furthermore, the atrophy experiments of Gudden show that it carries impulses from the hippocampus and uncus and not to it.

Having got the fibers to the optic thalamus, we must suppose that they pass to the cortex in the radiations from that ganglion.†

mid type. Essentially the same is true of the olfactory lobes. The olfactory bulb exhibits a special kind of cortical stratification."—Meynert, "Psychiatry," p. 70. Meynert thinks that the olfactory nerves pass directly to the cortex.

*Structure of the Olfactory Centers in Detail*—From without inward one finds in the *cornu Ammonis*—

1. A molecular layer.
2. A reticular layer somewhat like the small pyramidal cell-layer of the cortex elsewhere.
3. A radiate layer containing the processes of the large pyramidal cells of the next deeper layer and some pyramidal cells.
4. The pyramidal cell layer, containing cells measuring about one six hundredth of an inch in diameter.
5. The stratum orieus, containing some spindle-cells, like the corresponding layer of the cortex elsewhere.
6. The alveus or *Muldenblatt* layer.
7. The ependyma of the descending horn of the lateral ventricle.

The hippocampus and olfactory tracts resemble the foregoing very much in their cortical structure.

\* Luys collects four cases—one by Hunter, three by Voisin—in which anosmia was caused by focal lesions of the thalamus.

† The connection can not be by the *tænia semicircularis*, as stated by Luys, for that goes to the caudate nucleus (Meynert).

C. Winkler and J. Timmer have recently reported the case of an idiot with atrophy of the left occipital and posterior part of the temporal lobe and partial atrophy of the *fornix* and *corpus mamillare* and Vieq-

I will conclude this anatomical discussion by referring in some detail to the histological analogies between the layers of the olfactory bulb and nerve and the four outer layers of the retina:

1. In the mucous membrane of the nose we have olfactory cells and pigment, and even a limiting membrane, all of which resemble the pigment, rods and cones, and limiting membrane of the outer layer of the retina.

2. The next or second layer of the olfactory bulb (*stratum glomerulosum*) contains groups of nucleolated nuclei with nerve fibers running among them, the whole forming "glomeruli." The nuclei of these glomeruli resemble closely those of the inner nuclear layer (fifth layer) of the retina.

3. The third layer of the bulb (*stratum gelatinosum*) consists of a very fine felt-work of fibers with small stellate cells. This resembles the inner granular layer (sixth) of the retina.

4. The layer of ganglion cells in the bulb resembles the ganglion-cell layer of the retina (seventh).

#### 5. The layer of nerve fibers.\*

This similarity has been noted by several observers (Babuchin, Meynert, Obersteiner). It tends to show that the retina, like the olfactory bulb, is like a modified spinal ganglion.

*Bibliographical.*—The anatomy of the olfactory tracts has been studied by von Gudden by the atrophy method; by Broca, Zuckerkandl, and Alexander Hill, by the comparative anatomical method; by Ferrier, Lnciani, and Sappilli, by the experimental method; and by various other anatomists (Meynert, Ferrier, and Obersteiner), to whose works I am indebted.

The views of Luys and others that the olfactory nerve is connected with the amygdala, and those of Meynert which connect it with the caudate nucleus, seem disproved by the researches of Zuckerkandl.

The descriptions of von Gudden apply to the rabbit, and it does not seem to me that his scheme of the internal relations of the nerve is carefully worked out or can be applied to the human brain.

*The Examination of the Olfactory Sense.*—An interesting fact in connection with this comparison are the investigations of Professor Haycraft upon the sense of smell ("Brain," July, 1888).

He finds that there is a similarity between the molecular weight and vibration of bodies and the odor they exhale, and he shows that probably the sense of smell as well as that of taste must depend upon the rate of vibration of gaseous particles, just as the variations in color depend upon the

d'Azry's bundle on the same side ("Neurol. Centralblatt," 1889, p. 362). This looks against an olfactory function for the fornix; but it shows that it carries impulses to the thalamus and that the corpora mamillaria are connected with the thalamus. Meynert indeed considers them as belonging to that ganglion.

\* Summarized, the arrangement is as follows:

The 1st layer of the olfactory bulb, including cells, etc., of mucous membrane = 1st (outer) layer of retina.

2d layer, strat. glomer. = 5th layer of retina, int. nuclear.

3d layer, strat. gelatin. = 6th layer of retina, int. gran.

4th layer, ganglionic = 7th layer of retina, gangl.

5th layer, nerve fiber = 8th layer of retina, nerve fiber.

vibration rate of the ether. It may yet be possible, therefore, to construct scientifically harmonies and discords of smell and to produce actual symphonies in odor which shall awaken as deep emotion as the music of Beethoven or the paintings of Corot.

As a preliminary and very remote approach to this, I have constructed a qualitative olfactometer by which the quality of the sense of smell can be tested just as we test the sight for color-sense or the hearing for musical pitch. It consists simply of two sets of phials:

The first contains monatomic alcohols of gradually increasing molecular weight—viz.:

1. Methyl alcohol ( $\text{CH}_3\text{OH}$ ), faint alcoholic odor.
2. Ethyl alcohol ( $\text{C}_2\text{H}_5\text{OH}$ ), faint alcoholic odor.
3. Propyl alcohol ( $\text{C}_3\text{H}_7\text{OH}$ ), alcoholic odor, with flavor.
4. Amyl alcohol ( $\text{C}_5\text{H}_{11}\text{OH}$ ), less alcoholic odor and more flavor.

The second set is like the first, but contains another group of bodies—viz., the fatty acids:

1. Formic acid ( $\text{CHO}.\text{OH}$ ), acetic odor.
2. Acetic acid ( $\text{C}_2\text{H}_4\text{O}.\text{OH}$ ), acetic odor.
3. Propionic acid ( $\text{C}_3\text{H}_6\text{O}.\text{OH}$ ), acetic odor, with flavor.
4. Butyric acid ( $\text{C}_4\text{H}_8\text{O}.\text{OH}$ ), slightly acetic, with well-marked flavor.
5. Valeric acid ( $\text{C}_5\text{H}_{10}\text{O}.\text{OH}$ ), no longer acetic, the flavor alone present.

These solutions must be diluted considerably.

Now, a person with a normal sense of smell should be able not only to smell all these substances, but distinguish them and their relations, just as a person with normal vision should not only see forms but distinguish colors.

It is probable that the investigation of the sense of olfaction by this means will show that there are persons whose sense of smell is keen but who are odor-blind, just as there are persons with keen vision who are color-blind. And it is in this qualitative perception of odors that the human odor-sense is developing.

For quantitative tests of the sense of smell I have an instrument devised by Zwaarback, which is satisfactory enough, but which is expensive and is constantly breaking.

For ordinary use, I prefer this collection of six phials containing + oil of cloves, + in purity and in watery solution or mixture of 1 to 10, 1 to 100, 1 to 1,000, 1 to 10,000, and 1 to 100,000. These proportions are used in accordance with the Weber-Fechner psycho-physical law that a sensation increases in accordance with the logarithm of the stimulus. The law is approximately true for sensations of low and medium intensities at least, and it may be applied in a measure to the sense of smell.

We have, therefore, qualitative and quantitative olfactometers. In testing, the phials in each set should be mixed up and the patient should be made to sort them and make his own discoveries regarding their intensity and quality.

It may be remembered that the sense of smell is exhausted in about three minutes for a single odor, but returns in a measure after one minute's rest (Aronsohn, "Arch. f. Anat. u. Phys.," 1886, 321).

*PATHOLOGICAL.*—I have left but little space to consider the subject of the pathology of the olfactory tracts. Fortunately there is no need of saying much, for our present knowledge is sufficiently summarized in standard works.

The intracranial olfactory tracts and centers are affected *primarily* by—

1. Degenerations in locomotor ataxia and general paresis and in the course of senile decay.

2. Inflammation. Very rarely there is actual olfactory neuritis (Althans).

3. Functional paralysis and irritations, as in hysteria.

*Secondarily* by—

4. Injuries, haemorrhages, inflammations (meningitis, abscesses), and tumors.

5. Neuritic and atrophic processes, as in softening from thrombi, etc.

The location of the pathological process is usually at the base of the brain and in the anterior fossa.

Lesions causing olfactory disorder have also been found in the hippocampus, in the thalamus (four cases cited by Luys), in the posterior part of the internal capsule on the opposite side (Féré), and in the pons (one case of tumor cited by Benedict).

Syphilis is probably the most frequent of the causes of anosmia.

If careful testing of the sense of smell were made in all cases of central organic disease, it is quite likely that its disorders would furnish us more important data in diagnosis than we now gain, since the intracranial distribution of the olfactory tracts is so extensive.

As we must, however, in these cases always exclude peripheral causes, the rhinologist will be called upon to determine positively the value of the test. Hence it may be most important to be able to do this with the utmost skill, and the introduction of the qualitative olfactometer may for this reason prove of value.

In conclusion, allow me to say that I have aimed in this paper to show that the first cranial nerve is not in its senility, but is a developing sense clinically, and that there are many unsolved problems of its physiology, anatomy, and pathology which the specialist in nasal and throat disorders can do much to solve; and that an interest in these problems is justified not only by their scientific importance but by their practical value.

#### A NEW METHOD OF DRAINAGE OF THE BLADDER

##### AFTER SUPRAPUBIC CYSTOTOMY

(CAPILLARY DRAINAGE).

BY GEORGE R. FOWLER, M. D.,

SURGEON TO THE METHODIST EPISCOPAL HOSPITAL AND ST. MARY'S HOSPITAL,  
BROOKLYN.

EVERY surgeon who has attempted to maintain continuous and efficient drainage from the bladder after suprapubic cystotomy will agree with me as to the difficulties inherent to and inseparable from such attempts. It is not intended here to discuss the indications present in each case pointing to the necessity or otherwise of suturing the bladder and depending upon permanent or occasional catheterization on the one hand, or a perineal section and drainage by this means on the other. These procedures relate to cases where the surgeon may have a choice as to the method to be pursued, and in which the conditions present after a prosta-

tectomy, the removal of a calculus or a neoplasm, will guide his judgment as to which direction he shall choose for drainage, or as to whether he will drain at all or not. The present communication is intended to call attention to the inconveniences experienced by both the patient and the surgeon in carrying out drainage from the suprapubic wound itself.

In the first place, it must be admitted that there is no position in which the body can be placed, short of the knee-chest position, which will bring the site of the suprapubic wound upon a lower plane than the rest of the bladder. Unless this be accomplished, drainage by means of tubes is an impossibility. The lateral decubitus suggested by Petersen does not accomplish it, even when aided by the use of the T-shaped tube of Trendelenburg, or further facilitated by making the suprapubic incision transverse, instead of parallel to or in the median line, as suggested by the last-named surgeon. The substitution of the + -shaped tube is of very slight if any advantage over the T tube, for the reason that the projecting portion, which is intended to dip down into the bladder, if sufficiently long to reach the *bas-fond*, becomes a constant source of irritation; on the other hand, if this is not accomplished, even the advantage which is supposed theoretically to accompany this device is lost. Surely, water will not run up hill, and a siphon action can not be maintained where the source of supply to the siphon is not constant. The nearest approach to the ideal (knee-chest) position is the latero-abdominal decubitus. Experience has shown me that it is almost impossible to maintain this, even with more or less constant changes from side to side; in some cases, unless the nurse holds the patient by main force in this position, it is absolutely impossible to maintain it.

The natural position for an old person (and permanent suprapubic drainage is required oftenest in old men) confined to his bed by any illness is upon the back. Whether he is partly elevated in bed (half-sitting posture), or whether his head and shoulders are lowered almost or quite to a level with the rest of his body, the result is the same—the base of his bladder remains its lowest part. To place him in any position other than the dorsal or some of its modifications, and attempt to keep him there for any length of time, is to elicit from him constant complaint, and finally inflict upon him cruel torture if the attempt is persisted in.

The thing to be desired is a method of drainage whereby a continuous flow of the contents of the bladder may take place and the patient still maintain any position in which he may be comfortable. At the same time, this should provide against infiltration of urine into the anterior abdominal walls. If the patient lies upon his back and reliance is placed upon tube-drainage, infiltration, to a greater or less extent, will almost inevitably occur; at least, such has been my experience.

In order to overcome these objections and difficulties, I have recently pursued a plan that has given me great satisfaction. The plan is that of capillary drainage, and the method of carrying it out is simplicity itself. I select hydroscopic cheese or butter cloth, and, first sterilizing by heat, dip it in a hot milky mixture of oxide of zinc and

distilled water to which a trifle of glycerin has been added. Any sterilized gauze or cotton wicking will answer the purpose without the addition of an antiseptic if changed frequently. Either oxide of zinc, bismuth subnitrate or iodide, or even iodoform if used with caution, will answer as an antiseptic; the non-poisonous and non-irritating qualities of the two first-named, however, render them the most desirable for the purpose. The folded squares of the material selected for the purpose are placed in the hot mixture, which is kept agitated to prevent precipitation. They are then wrung out and packed in air-tight jars (fruit jars), which have likewise been sterilized by exposure to heat. Another plan, and one which I prefer, particularly when the packing is to be intrusted to a nurse, is to have the gauze prepared in strips of the proper width—say, about two inches—and rolled up as a roller-bandage. This is dipped in the zinc milk while the latter is being stirred, and then wrung out. This is then unrolled, and at the same time packed in the sterilized fruit jar.\*

Adopting the plan of Galvani, of Athens, of securing the walls of the bladder by two stout lateral ligature loops for the purpose of identifying the same during the first few days after the operation, or until the structures forming the edges of the wound in the abdominal wall have become consolidated, I retract the parts and pass the end of a strip of gauze into the bladder. By means of a dressing forceps this is carefully carried to and gently packed at the *bas-fond*. This may complete the procedure, or, in addition to this, the gauze may be fed in and loosely packed, or allowed to adapt itself rather to the cavity of the bladder. The end is allowed to project two or three inches, when the dressing is finished by laying a few folds of the gauze between the edges of the wound. The projecting end of the gauze strip is laid upon a piece of rubber macintosh, which is so disposed as to carry off the urine to a basin placed beside the bed, or a large towel, made into a compress and the end of the gauze drain allowed to rest upon this, will answer the purpose admirably.

Should the fear arise that the suprapubic wound will close prematurely or become too small to allow the strip of gauze to pass readily, the difficulty may be obviated by using a very short rubber drain of rather larger caliber, having a flange to prevent it from slipping into the bladder, or, what answers the purpose equally well, a large safety-pin passed transversely through its walls in such a manner as not to interfere with its lumen, and thus prevent the gauze strip from passing readily through the same. This rubber simply answers the purpose of a thimble, to prevent closure of the wound. The drainage strip is passed through this into the bladder, a towel folded, with a square of macintosh in its folds, and placed in position, the whole being secured in place by means of a binder such as the obstetrician uses after child-birth. With the dressings so arranged the patient may assume any position or even walk about without much inconvenience.

It is useless to attempt to prevent the contact of the

\* This zinc gauze, prepared in the manner described, I have used for a long time as a general surgical dressing, when such a one is required, in which any antiseptic substance has been incorporated.

urine with the wound in the abdominal wall. It is far better to neutralize the evil effects of this contact by providing uninterrupted drainage and keeping the urine free from irritating qualities by means of an efficient antiseptic than to attempt to place a rubber tube in position and depend upon packing between its outside walls and the wound edges to prevent contact or infiltration. In fact, the latter condition would be somewhat favored by pursuing such a course.

To sum up, therefore, the method of capillary drainage of the bladder offers the following advantages:

1. It allows the patient to assume any position most comfortable to him.
2. It is not easily displaced, and its action is not interrupted or interfered with by any accidental circumstance, such as sudden movements on the part of the patient, etc.
3. It furnishes an antiseptic to the urine, thereby lessening its irritating qualities, and an antiseptic dressing to the bladder walls and edges of the wound at the same time.
4. It is simple, requiring no elaborate preparations and not depending upon the art of the mechanic. It is effective, as I have proved to my own satisfaction by actual experience. And, above all things in importance, it is conducive to cleanliness in a class of cases in which sensitive patients constantly complain of what they consider a deplorable condition.

## THE INFLUENCE OF MUSIC AND ITS THERAPEUTIC VALUE.

BY SEBASTIAN J. WIMMER, M. A., M. D.,  
ST. MARY'S, PA.

FROM the earliest days—the very beginning of society—men, even in their savage state, signalized themselves on great occasions by a recourse to music; in songs they celebrated their various religious rites, lamented their public and private sorrows, expressed their great joy and grief, or excited one another to perform noble deeds. Simple as was this melody, it nevertheless possessed the power and expression necessary to call forth strong emotions, as a result of the wonderful influence it exerted on the mind. The Hindoos attributed supernatural power to its workings, and among the ancient Hebrews there was hardly an occasion arising above commonplace events of every-day life when they did not resort to it, even recognizing its therapeutic value. Man is a musician by nature, his emotions having created him such; and the power manifested in sound, partly from nature, partly from habit and association, so influences the fancy by pathetic impressions as to delight even those people of the most barbaric races. The marvelous powers of this soothing "language" upon the human family are at the present time even greater and more beneficial, because their effects are more thoroughly appreciated by the masses than formerly, and so great and rapid have been the strides made within recent years, comparatively speaking, that not only have the public generally noted it and commented thereon, but it has elicited the investigation by medical men as to its value as an auxiliary in the treatment or management of certain nervous complaints.

Music has indeed great power in influencing the habits of people; it soothes the wrinkles of a hard life of business, elevates our minds from thoughts of money, enterprises, anxieties, intrigue, hatred, weaning us from low and demoralizing pleasures. It is an educator; its subtle pleasures can impart only good impulses, which, causing an appreciation of its effects, can not be otherwise than at once beneficial and lasting. I firmly believe that the taste for music is inherent in every child born. Was there ever yet a babe which could not be sung to sleep? The domestic history of every family attests that. How, then, can we account for these phenomena? In very sensitive nervous centers, which are readily impressionable, located either in the cerebrum or spinal cord, the effect is discernible; and in those who are readily susceptible to all its power we find it principally manifested, for it acts with great effect on the majority of nervous systems. The brain is not alone affected, although direct impressions are powerfully transmitted through the auditory center. Slow, monotonous music, provided it is not too sluggish, has a calming influence over the individual, because it is then in accord and harmony with the nerve habit of the person who listens; if these essentials are wanting, it then may do more harm than good by causing irritation. Again, it is also essential to the ultimate success of any endeavor to bring the brain under this control that it should first arrest the attention, either by its power or sweetness, and then gradually conduct the organism into harmony with itself. Unless, say, a measured cadence begins with a powerful appeal to the brain in a key which accords with that in which the cerebrum is at the moment itself working, the sort likely to calm the mind, a negative result ensues, and, instead of allaying irritation, we find it to be more likely augmented. To arouse the spirits by music, plaintive sound is required, and this must be in the key of melancholy, which blends in harmony with the brain state of the person. The so-called brain state may be immediately changed by the attention being arrested and the cerebrum reached through the auditory center, the key being gradually and surely modulated.

On July 18, 1877, the "Lancet" states that M. J. Rambossum read a paper before the *Académie des sciences morales et politiques*, at Paris, on this very subject, and he attempted a new application of the theory of the transformation of mechanical movement into psychological and psychical movement, with the idea of securing music as a means of curing, or at least assuaging, disease, both of body and mind. Rambossum then mentions some maladies or affections which can be alleviated by this influence, explaining the action scientifically, together with its power on the development and functional play of the moral and intellectual faculties, and on the physiological state of individuals. His conclusions are as follows: (1) That there is a music which has a special action on the intelligence and on the motor nerves; (2) a music which influences specially the nerves of sensibility and the sentiments; (3) a music which acts all at once on the motor nerves and on the sensitive nerves, on the intelligence and on the sentiments. He further believes that between the effects of music and those of the aliments which modify the nervous system there are such analogies

that the laws which regulate the one and the other may be arranged in the same terms. We might assuredly profit by these musical effects in the treatment of mental and nervous affections, for they certainly have a marked influence on the sympathetic nervous system—namely, by producing a soothing effect; and this great influence exercises its power over all, whether of the educated or uneducated class, for a fine appreciation of even the grandest and noblest music is by no means a criterion of mental activity or elevation, it being enjoyed alike by all individuals. The relative and specific effects of rhythm, melody, and harmony upon persons suffering from certain maladies, such as melancholia and acute and chronic mania, have been noted, and with beneficial results in many cases; but different modes and various kinds of music have affected individuals and groups of individuals in peculiar and different ways.

In 1878 some very curious and interesting experiments were carried on in New York city, at the Randall's Island Asylum. Fourteen hundred females (insane) were congregated in the large entertainment hall of the institution and subjected to a strain of piano music for half an hour, when the general effects were noted as follows: the pulse was raised, the patients became restless, and there was a marked desire to keep time with the music. They were all susceptible to the rhythm, and its effect was decidedly stimulating. Melody without any very decided or certain tempo was without effect excepting in those cases where the force of association was still active. In a case of chronic melancholia the playing of "Home, Sweet Home" invariably brought the patient to her knees, where she began to recite the Lord's Prayer in an apparent ecstasy of devotion. In another case—one of acute mania—the patient's pulse was elevated from 78 to 106 beats, the patient not showing any other signs of excitation save the involuntary twitching of the facial muscles. Cantabile music seemed to have an effect, in the worst cases, similar to that which it exercises upon certain animals, the person being disposed to lie down and go to sleep under its influence. The results of all these experiments were markedly beneficial, and, by frequent repetitions, many of the patients showed great improvement. The effects, in almost every instance, of the pronounced rhythm were involuntary, the movements of the limbs and facial muscles being attributed to reflex action. It seems plausible to me that music can exert a wonderful influence over an individual whose nervous system has been shattered in any way by gradually soothing that system and bringing it into harmonious accord with the spirit of the composition interpreted.

Many persons, to worry off the cares and anxieties of this life, seek succor and renewed life in the concert hall, where harmony reigns supreme and stamps its individuality indelibly upon the sensitive nerve organism of the individual, refreshing and stimulating it, and thus paving the way to mollifying the effects of many complaints. Music seems to quiet the sympathetic nervous system, and by so doing penetrates the soul and brings the relief which is lasting. Some authorities go so far as to suggest a place in the *materia medica* for music, for it certainly is a remedy for such complaints as neurasthenia, insomnia, nervous prostration,

and other diseases. There is indeed solace in music, for this world has its work and troubles made pleasant by the cheerful notes which emanate from harmonious compositions laden with the fragrance which permeates the very recesses of the soul with all its curative effects, for upon the mind does the responsibility of the rest of the organism depend for its support and existence—*mens sana in corpore sano*. The sounds produced by various harmonies blend so readily with the human organism that their effects are readily appreciated by all, for few people are altogether devoid of a capacity for appreciating good music, even when not gifted with any great natural taste. Work, which sooner or later becomes mental strain, finds relief in an atmosphere impregnated with music, for it vibrates the nervous fibers of the listener in sweet sounds, resulting in anything but evil. It is the one art alone which can afford peace and joy to the heart where *medicine* can not, for sorrowful anxieties and restless troubles flee before the sweet harmonious tones, and many a heart, full to overflowing, has been refreshed by music when sick and weary.

"Music exalts each joy, allays each grief,  
Expels diseases, softens every pain,  
Subdues the rage of poison and of plague."

**Spontaneous Rupture of the Heart.**—Dr. Mallet, of Paris, described before the *Société anatomique* of that city a case of this accident which occurred last May in the Hôpital Tenon. The patient was a man, aged seventy-nine, with pulmonary disease. He died suddenly after rising to micturate. A rent, almost vertical and over two inches long, was discovered in the anterior aspect of the wall of the left ventricle. The pericardium was full of blood, the aorta atheromatous, and the left coronary artery nearly obliterated. All the valves were normal. Dr. Mallet quotes Odriozola's statistics of spontaneous rupture of the heart. That observer could only collect one hundred and seventy-six authentic cases. In many instances the patient was old, being between sixty and seventy in thirty-six, and between seventy and eighty in forty-five. The accident appears most frequent in women. As a rule, the escape of blood into the pericardium is considerable. The rent in the wall was unusually large in Dr. Mallet's case. In nearly every instance in Odriozola's statistics the rupture was in the anterior part of the left ventricle. The original report of the case deserves study. The rupture apparently took place fifty-three hours before death, when the patient was seized with dyspnea and epileptiform convulsions marked in the upper extremities; his face turned pale. The exertion of rising to micturate caused immediate death, probably by sudden escape of blood into the pericardium. A similar history has been recorded in other cases of spontaneous rupture of the heart.—*Brit. Med. Jour.*

**The Tendon Reflexes in Leprosy.**—S. M. Suzuki, M. R. C. S., L. R. C. P., contributes a paper to the "Sei-i-Kwai" (May) upon the "Tendon Reflexes in Leprosy." His attention was called to this subject by finding to his surprise that the reflex was increased in a case of anaesthetic leprosy. In five other cases since observed by him, including both the anaesthetic and tubercular forms, the reflex was similarly exaggerated. A like result appeared from the examination of seventeen cases from a leper asylum and among Mr. Suzuki's out-patients at the Tokio Charity Hospital. He remarks that the change in leprosy is that of interstitial neuritis, and that the bacillus of leprosy has been found in the new-formed connective tissue. Yet in other forms of multiple neuritis the tendon reflex is abolished. Moreover, in leprosy muscular strength is well preserved, paralysis being of rare occurrence, even in advanced cases. He concludes, therefore, that in this disease there must be other changes in the nervous system besides multiple neuritis, and intends to report at a future date upon the electrical reactions.—*Lancet*.

## THE ASEPTIC SUIT.

BY J. L. ROLLINS, M. D.,  
AUBURN, CAL.

An aseptic suit, so far as the writer is aware, has hitherto been unknown to the medical world.

In presenting this article, the new application of an old truth, viz., that cotton is impervious to germs, is all that is attempted. Without entering into details of the evolution of this idea, I will proceed at once to a brief description of it.

This invention consists of an aseptic suit or dress, the object being to provide means of protection to physicians and others against contagium while attending persons afflicted with contagious diseases.

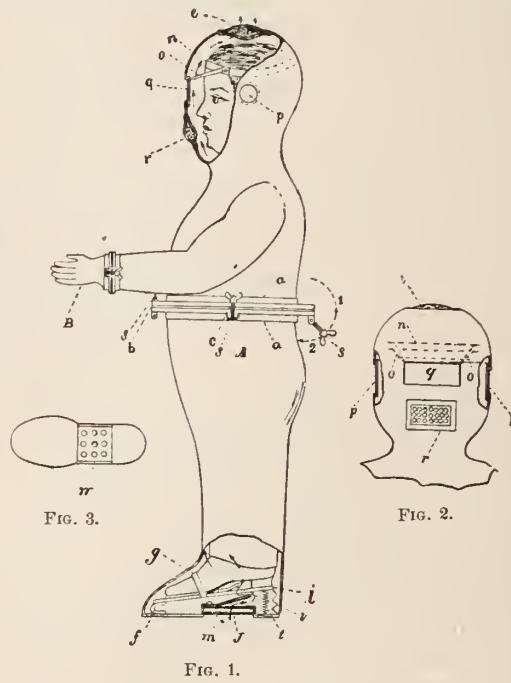

FIG. 3.

FIG. 2.

FIG. 1.

The device consists essentially of a suit or dress adapted to be readily adjusted over the ordinary clothing, so as to entirely cover the wearer, said dress being made almost entirely of material impervious to atmospheric air, such parts as do admit the passage of atmospheric air consisting of germ-proof material.

A further object of this device is to provide said dress with mechanism adapted to be actuated by the wearer for supplying an ample quantity of filtered air for respiration, and to provide said dress with the necessary facilities for using the stethoscope and laryngoscope, and also with removable gloves, in addition to a suitable glass-protected opening in the front part of the head-covering, so that while protecting the wearer against contagium he may have the use of his eyes, ears, and hands.

With these ends in view, this invention consists in certain details of constructions and combinations of parts as illustrated in the drawings.

Fig. 1 is a side elevation of the suit or dress, showing the foot and face parts in section. Fig. 2 is a front elevation of the head part of the dress, and Fig. 3 is a plan view of the under side of the foot part of the dress.

Referring to the drawings, *A* represents the dress, which is preferably made of rubber goods and in two parts, joined together at the waist by flanges *a a'*, one of which is secured to the upper part of the dress and the other to the lower part thereof, said flanges being secured to the dress by cement or otherwise and clamped together, preferably by swing-bolts *S*, pivotally secured to the under side of the lower flange *a'*, and provided with thumb-nuts as shown, said bolts being adapted to swing upon their pivots, as indicated by the arrows 1 and 2, into slots provided for their reception in both flanges, as shown at *c*, Fig. 1, thus affording a ready means for clamping together or separating the two parts of the dress. (For the thumb-nut, an eccentric is substituted, which admits of a more rapid adjustment of the suit.) A flat rubber or other elastic band, *b*, is interposed between the two flanges for the purpose of making an air-tight or germ-proof joint.

Each hand of the wearer of the dress is protected by a removable covering or glove, *B*, secured to the sleeve of the dress by means analogous to that employed for securing together the two parts of the dress at the waist.

On the crown of the head-piece is secured a disc, *e*, consisting of two perforated metallic plates, made slightly concave toward each other for the purpose of securing in position between them a wadding of cotton or other germ-proof material, a similar disc being secured opposite the mouth in the face part of the head-piece, as shown at *r* in Figs. 1 and 2.

Near the ear is a circular opening, *p*, over which is cemented a very thin disc of rubber, backed, for the purpose of giving the requisite strength, with a piece of woven linen. This thin but air-tight disc, one of which is located on each side of the head-piece, as shown in Fig. 2, is to afford the required facility for using the ear and stethoscope, which is done by simply pressing the latter against the disc and the disc against the ear.

For the purpose of admitting light to the interior of the head-piece, the upper front part thereof is provided with a glass-covered opening, *g* (shown in Figs. 1 and 2), said glass cover being supported at the required distance from the face by a light metallic frame, *o*, secured to a brow-band *n*, which fits the upper part of the head like a hat, of which the crown is the germ-proof disc *e* (see Fig. 1).

It will be observed that the part of the dress below the waist is formed like a pair of trowsers and boots combined—that is to say, all in one piece. In each foot part is a bellows, of which the upper movable board *i* is adapted to receive the foot of the operator, which is secured thereto by an instep-strap, *g*. Said board, *i*, is hinged at *f* to the toe part of the dress, the rear part being free to vibrate upon said hinge in a vertical plane, the heel part resting upon the upper end of a spiral spring, *t*, of which the lower end rests upon the internal heel part of the foot of the dress, a little in advance of which is a germ-proof disc, *m*, similar to that in the crown of the head-piece and secured in the hollow of the foot part of the dress, as shown in Figs. 1 and 3. On the upper side of the germ-proof disc, *m*, is an inlet check valve, *J*, as shown in Fig. 1, and there is also a similar but smaller valve, *v*, on the upper side of the

movable board *i*, just beneath the hollow of the foot of the operator.

Matters being thus, the wearer of the dress can supply himself, by an easy treading motion of the feet, with an ample quantity of filtered air, drawn in from beneath the feet and forced upward, thus maintaining an upward current of purified air for respiration, as indicated by arrows, and also driving out through the discs *r* and *e* the air that becomes vitiated in the head part of the dress. The movable upper bellows-board *i* needs only to be pressed downward, the upward stroke being accomplished by the resilient action of the spring *t*.

The mouthpiece of a funnel-shaped rubber tube, attached to a portion of the disc *r* (Figs. 1 and 2), may be placed in the mouth during any necessary inaction of the bellows, temporary respiration being conducted through the disc *r*, thus avoiding any condensation of pulmonary vapor on the glass-covered opening *q*, that might occur.

To the frame of the glass-covered opening *q* is attached a device to support an ordinary head mirror, for otoscopic, rhinoscopic, and laryngoscopic examinations and minor operations.

A pair of suspenders are attached to the trowsers within and supported by the upper flange *a* (Fig. 1). For ladies a rubber skirt may be provided.

The discs are composed of cotton treated antiseptically, and may be removed at will and sterilized by heating in an oven.

The aseptic suit in the treatment of isolated cases of contagious disease is designed to be transported in a convenient casing to within safe limits, when the dress is adjusted, the patient visited, and the exterior of the suit disinfected by the atomizer, when it is removed after having left the premises.

In epidemics, such as yellow fever, that scourged the Southern States in 1888, the residence of the physician may be subjected to sanitary measures, the aseptic suit adjusted on issuing therefrom, and the exterior disinfected on returning.

The aseptic suit, it is believed, offers to the wearer immunity from all specific causative agencies productive of contagious disease.

It will be observed that the end for which this invention is designed is secured by the exclusion of specific contagium, thus placing the operator in effectual insulation, regaling his being in atmospheric air as pure as that of the Alpine heights, safe behind the barrier of impregnable cotton that repels the attack of miasmata and cannon-ball alike.

The aseptic suit, while preserving every sense for accurately diagnostinating and treating all contagious diseases, and offering positive immunity to the wearer and to transportation of infecting germs to others, may it not be reasonably expected that in this invention is found a device which in the hands of intelligent physicians will absolutely stay the spread of contagion?

**The Paris International Congress of Dermatology and Syphilography.**—Dr. A. R. Robinson, of New York, has been appointed by the committee on organization to open a discussion on the subject of lichen.

FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, SEPTEMBER 7, 1889.

CERTAIN CAUSES OF ILL-HEALTH AMONG WOMEN.

CORSETS, high-heeled shoes, late hours, irrational eating, a deficiency in mental discipline, the absence of sufficient individuality, the want of some object of vital interest in life, together with the carking cares of our cruel American house-keeping—what the Indian called “too much house”—have each, in turn, served as texts for preachers many and fierce concerning the alleged physical degeneracy of women. While it is painfully true that the present system of domestic life is in many particulars defective, it is impossible to specialize and indicate any given point as the weakest in a chain that is pretty generally open to criticism. The physical degeneracy of American woman—if it exists—is due to causes quite outside the pale of heels, corsets, or even mince pie.

The dissipations of the grandmothers in the matter of household prowess and the general hardships of life in a new country are responsible, to a certain extent, for the bodily frailties of our girls. Superhuman and inhuman tasks are the sour grapes that our feminine ancestors did eat, and they have set on edge the teeth of modern young women. Though home life to-day too often is a tyrannous, heart-breaking affair, in comparison with that of Puritan womanhood in colonial times it appears a sea of heavenly rest. The only superiority of that age over our own is to be found in the firm conviction in the minds of Puritan matron and maid that life was really worth living. Now there is doubt upon that point, not loud but deep, among an overstrained and always tired latter-day femininity. The condition known as being “half dead” engenders narrow views.

But to return to our muttons—those hitherto unrecognized causes of feminine insufficiency in the matter of health. A prolific source of overstrain, with its consequent weakness, and, possibly, disease, is the size and weight of all household appliances. They are invariably too big for women to use with ease and comfort. Pots, pans, brushes, brooms, coal-scuttles, etc., are all too large and too heavy for the ordinary woman. Every household article is of the pattern best suited to the strength and inclination of the average man. The flat-iron, the ironing-table, and the clothes-basket were made for man; also the wash-boiler and the stationary tub. There is seldom any hint in point of size and weight that scrubbing-brushes and mops are feminine weapons. In the house and out of it, this is a man’s world. His dominion includes not only the beasts of the field, but also the host of inanimate objects that pertain to civilization. Desks and stools in offices, seats in cars, theatres, ferry-boats, churches, everywhere, were designed exclusively for men. Women can not even fill the chairs at home, and, at best, only rattle around in them with

more or less discomfort. Occasionally a chair is encountered that fits—not too high, too deep, or too broad. Then the spirit of peace dwells for a time in that reposeful structure.

Here is certainly a state of things. Who is to blame for all this? The manufacturers? Ourselves? Our neighbors? Our friends? Our enemies? Who is responsible, and with whom does the fault lie? Painful as it is to speak the truth, let every man nerve himself for the ordeal. Women themselves are to blame. Persistent hints from household workers would have revolutionized their tools long ago. Women’s burdens are for the most part self-imposed. They exist because of tradition, want of thought, and a deficiency of inventive faculty. The feminine mind is apt to find expression in tenderness, encouragement, sympathy, and that heavenly patience which makes it possible to do the petty tasks of daily drudgery unflinchingly and persistently. The world can ill afford to lose even the minutest fraction of these divine gifts. The joy of life is by no means an exhaustless store. There is every reason to protect women from unnecessary wear and tear. The tyranny of things presses so heavily upon the better sex that looking on the world with level eyelids is too often an utter impossibility. The machinery of home could be made simpler and better suited to the requirements of the situation; and the gain would be an all-round affair, preserving beauty, maintaining health, and bringing about an increase of sweetness and light. Self-interest is a good enough incentive for instituting domestic reforms; and generosity is not a bad motive, either, after the fashion of Pepys, who gravely records, in the immortal “Diary,” that he presented a new gown to his wife on Christmas day, in order to give the poor wretch pleasure! There is a sure reward for the hero who brings about a harmony of size, weight, and fitness between household appliances and the modern woman. The gratitude of the poor wretch is certain to equal the measure of her intelligence.

*MINOR PARAGRAPHS.*

DR. OLIVER WENDELL HOLMES AT EIGHTY.

DR. HOLMES celebrated his eightieth birthday recently. His house was filled with children and flowers and the mementoes of friends. He was serene and happy, with just a slight infirmity in respect of his organs of hearing. He was able to illustrate, in his own person, his dictum made some months before, that it was “better to be eighty years young than forty years old.”

The year 1809 was no mean year, for it gave us Holmes, Gladstone, Tennyson, Lincoln, and Darwin. A newspaper paragraph has appeared stating that Holmes, the genial, has grown cynical in his eightieth year, and the writer sees fit to offer Dr. Holmes the suggestion that he should take up his own early writings and thus revert to his original type of thought. In the first place, we beg to doubt the allegation concerning Dr. Holmes’s cynicism, unless, perchance, he had been reading some of his own books and then reading some of those “just out”; almost anybody would feel like uttering a caustic word or two under those circumstances. In the second place, the advice to him to read his own books has no sting in it, as it might have to some authors who began by writing in a cynical vein and

repented of it afterward. A characteristic little story about Holmes's early days at the Harvard Medical School has found its way into print lately. Holmes, it is said, was about to give one of his anatomical demonstrations—he had only recently come from the Dartmouth school to take his professorship—and he was surrounded by a small company of his colleagues, most of them of great stature in comparison with him; and he seemed for the moment or two at a loss for words. But finally he said: "Why, gentlemen, do you know that I feel a little strange here? I feel like a small silver coin rattling round among just so many great big coppers." That broke the ice, the constraint was dismissed, and the lecture went smoothly on. Holmes had no fear of giants, as was seen when he measured foils with Hodge and Meigs regarding puerperal fever as an infectious disease. As he himself has said, "I had a savage pleasure, I confess, in handling those two professors—learned men both of them—skilled experts, but babes as it seemed to me in their capacity of reasoning and arguing."

#### THE SAMUEL D. GROSS PRIZE.

In a recent issue of the Journal appeared the advertisement of the first competition for the Samuel D. Gross Prize, the value of which is \$1,000. The will of Dr. Gross provides that there shall be an award of this amount every five years for the best essay in surgical pathology or practice. The Philadelphia Academy of Surgery will have charge of the conditions and terms of the competition. The successful competitor must be an American citizen. All essays, in the first contest, must be forwarded to the Academy before June 1, 1893.

#### A NEW "TRI-STATE" MEDICAL ASSOCIATION.

A CALL has been issued for a meeting of the physicians of Alabama, Georgia, and Tennessee, to be held in Chattanooga on the third Tuesday in October and the following day, for the purpose of forming an association. The call is signed by committees from the Jackson County (Alabama) Medical Society, the Chattanooga (Tennessee) Medical Society, the Cleveland (Tennessee) Medical Society, the Cartersville (Georgia) Medical Society, and the Dalton (Georgia) Medical Society. The membership is to be restricted to graduates of regular medical colleges in good standing, and it is announced that papers of interest have already been promised by prominent men.

#### THE AMERICAN SOCIAL SCIENCE ASSOCIATION.

THE proceedings of the association's meetings have generally included papers and discussions having more or less to do with medicine. There is now a Department of Health, of which Dr. H. Holbrook Curtis, of New York, is the chairman. At the recent annual meeting, held at Saratoga, the programme of the department included papers by Dr. Pliny Earle, of Northampton, Mass., and Dr. Stephen Smith, Dr. Louise Fiske Bryson, Dr. Frederick Peterson, the Rev. Charles R. Treat, and Dr. Charles A. Harvey, of New York.

#### ST. MARY'S HOSPITAL, BROOKLYN.

WE learn that this institution must very soon make an increase in its accommodations in order to keep pace with the demands made upon it. Although it already has nearly two hundred beds, a new ward will soon be arranged for and added. An out-patient department has been established near the hospital during the past year.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 3, 1889:

DISEASES.	Week ending Aug. 27.		Week ending Sept. 3.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	91	16	112	19
Scarlet fever.....	28	1	21	2
Cerebro-spinal meningitis.....	2	2	3	2
Measles.....	17	3	21	1
Diphtheria.....	70	19	66	22

The American Gynæcological Society will hold its fourteenth annual meeting in Boston, at the Massachusetts Institute of Technology, on Tuesday, Wednesday, and Thursday, the 17th, 18th, and 19th inst., under the presidency of Dr. H. P. C. Wilson, of Baltimore. Besides the president's address and an address of welcome by Dr. J. P. Reynolds, of Boston, the programme includes the following titles: "A Case of Interstitial Pregnancy—Rupture of the Uterus and Laparotomy," by Dr. R. Stansbury Sutton, of Pittsburgh; "The Use and Abuse of Antiseptic Injections in Obstetric Practice," by Dr. H. J. Garrigues, of New York; "A Digest of Twenty Years' Experience in the Treatment of Cancer of the Uterus by Galvano-cautery," by Dr. John Byrne, of Brooklyn; "The Nature and Limitation of Operative Treatment for Uterine Fibroids," by Dr. Paul F. Mundé, of New York; "The Diagnosis and Treatment of Fibroid Tumors," by Dr. W. Gill Wylie, of New York; "A Case of Sloughing Intra-uterine Fibroid," by Dr. Ely Van de Warker, of Syracuse; "A Case of Abdominal Lipoma simulating Ovarian Tumor," by Dr. Reeves Jackson, of Chicago; "Electro-therapeutics in Gynaecology," by Dr. G. Apostoli, of Paris; "Death from Visceral Lesions following Ovariectomy," by Dr. Henry C. Coe, of New York; "Renal Disease caused by Disease of the Pelvic Viscera," by Dr. George J. Engelmann, of St. Louis; "Pelvic Congestions *versus* Pelvic Inflammations," by Dr. S. C. Gordon, of Portland, Me.; "The Relation of Uterine Retro-deviation to Pregnancy," by Dr. A. Martin, of Berlin; "Nephro-lithotomy," by Dr. James R. Chadwick, of Boston; "Results of Repression of Menstruation," by Dr. E. C. Gehrung, of St. Louis; "Intermediate Trachelorrhaphy," by Dr. H. J. Boldt, of New York; "A Contribution to the Clinical History of Cystic Degeneration of the Ovaries, with a Report of Cases and Specimens," by Dr. R. B. Maury, of Memphis; "Partial Rotation of the Ovum in Early Pregnancy as a Cause of Placenta Praevia, suggested by Two Cases in Practice," by Dr. Edward Warren Sawyer, of Chicago; "The Protective Influence of Vaccination during the Intra-uterine Existence of the Fœtus," by Dr. Cornelius Kollock, of Cheraw, S. C.; "The Value of Laparotomy in the Diagnosis and Treatment of Minor Forms of Intra-abdominal and Intra-pelvic Disease," by Dr. T. A. Ashby, of Baltimore; "A Brief Report of my own Abdominal Work for the Year ending September 1, 1889," by Dr. R. Stansbury Sutton, of Pittsburgh; "The Surgical Treatment of Posterior Displacements of the Uterus," by Dr. W. M. Polk, of New York; and "The Effect of Ergot upon the Parturient Uterus," by Dr. John Goodman, of Louisville.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 11 to August 31, 1889:*

By direction of the Secretary of War, a board of medical officers—to consist of NEGER, ANTHONY, Lieutenant-Colonel and Surgeon; SKINNER, JOHN O., and MORRILL, JAMES C., Cap-

tains and Assistant Surgeons—will assemble at the U. S. Military Academy, West Point, N. Y., on August 25, 1889, or as soon thereafter as practicable, to examine into the physical qualifications of the candidates for admission to the Academy. Par. 9, S. O. 185, A. G. O., Augnst 12, 1889.

GARDNER, WILLIAM H., Major and Surgeon, Washington Barracks. Leave of absence for one month is hereby granted. Par. 1, S. O. 183, Headquarters Division of the Atlantic, Governor's Island, New York city, August 13, 1889.

MATTHEWS, WASHINGTON, Major and Surgeon. Promoted to Surgeon, with rank of Major, to take effect from the tenth day of July, 1889, *vice* Town, promoted. War Department, Washington, D. C., August 14, 1889.

HAVARD, VALERY, Captain and Assistant Surgeon. Leave of absence for one month, to take effect about October 1, 1889, with permission to apply to Division Headquarters for an extension of one month, is granted. Par. 3, S. O. 86, Department of Dakota, St. Paul, August 10, 1889.

PORTER, JOSEPH Y., Captain and Assistant Surgeon, now at Jacksonville, Fla., will, if the state of his health will permit, proceed to Jackson Barracks, Louisiana, by direction of the Secretary of War, and report to the commanding officer of that post for temporary duty and by letter to the commanding general, Division of the Atlantic. Par. 16, S. O. 186, A. G. O., August 13, 1889.

BAILY, JOSEPH C., Lieutenant-Colonel and Surgeon, Medical Director, Headquarters Department of Texas, San Antonio, is granted leave of absence for one month. August 17, 1889. S. O. 54, Headquarters Department of Texas.

POPE, BENJAMIN F., Major and Surgeon, is granted leave of absence for one month, with permission to apply through Division Headquarters for an extension of two months. Par. 7, S. O. 54, Department of Texas, August 17, 1889.

The commanding officer at Jackson Barracks, New Orleans, La., telegraphs the Adjutant-General of the Army that BROWN, HARVEY E., Major and Surgeon, died at Jackson Barracks on August 20th at 1.40 P. M.

TREMAINE, WILLIAM S., Major and Surgeon, now on sick leave of absence at Buffalo, N. Y., will, by direction of the Acting Secretary of War, report in person to the commanding general, Department of the Missouri, for assignment to temporary duty at the post of Fort Leavenworth, Kansas. Par. 4, S. O. 198, A. G. O., August 27, 1889.

The resignation of PORTER, JOSEPH Y., Captain and Assistant Surgeon, has been accepted by the President, to take effect August 29, 1889. Par. 11, S. O. 200, Headquarters of the Army, A. G. O., August 29, 1889.

#### Promotions.

MATTHEWS, WASHINGTON, Captain and Assistant Surgeon, to be surgeon, with the rank of major, July 10, 1889, *vice* Town, promoted.

To be assistant surgeons with rank of captain, after five years' service, in accordance with act of June 23, 1874:

EWING, CHARLES B., Assistant Surgeon, July 5, 1889.

McCaw, WALTER D., Assistant Surgeon, August 20, 1889.

#### Society Meetings for the Coming Week:

MONDAY, September 9th: New York Academy of Medicine (Section in Surgery); New York Ophthalmological Society (private); New York Medico-historical Society (private); Boston Society for Medical Improvement; Gynaecological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private); Baltimore Medical Association.

TUESDAY, September 10th: Mississippi Valley Medical Association (first day, Evansville, Ind.); New York Medical Union (private); Medical Societies of the Counties of Chemung (quarterly—Elmira) and Rensselaer, N. Y.; Newark, N. J., and Trenton (private), N. J., Medical Associations; Baltimore Gynaecological and Obstetrical Society.

WEDNESDAY, September 11th: Mississippi Valley Medical Association (second day); New York Pathological Society; American Microscopical Society of the City of New York; Medico-legal Society; Medical Societies of the Counties of Albany and Montgomery (quarterly), N. Y.; Worcester, Mass., District Medical Society (Worcester); Philadelphia County Medical Society.

THURSDAY, September 12th: Mississippi Valley Medical Association (third day); Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society; Medical Society of the County of Cayuga, N. Y.; South Boston, Mass., Medical Club; Pathological Society of Philadelphia.

FRIDAY, September 13th: New York Academy of Medicine (Section in Neurology); Yorkville Medical Association (private); Medical Society of the Town of Saugerties.

## Proceedings of Societies.

### AMERICAN LARYNGOLOGICAL ASSOCIATION.

(Continued from page 191.)

**Dysphonia Spastica.**—Dr. F. I. KNIGHT, of Boston, read a paper on this subject. (To be published.)

Dr. G. W. MAJOR, of Montreal: I have had one case of aphonia spastica and two of dysphonia spastica. The case of aphonia occurred in a boy of fourteen years of age with a well-marked history of hereditary syphilis. The two cases of dysphonia spastica were met with in adult young men, and in both Hutchinson's teeth were observed. In the case of aphonia the vocal cords closed spasmodically on phonation, and altogether acted much in the same manner as in defecation. I noticed in this case also a spasmodic action of the diaphragm synchronous with the closure of the cords. Under treatment no satisfactory improvement occurred. The thought has more than once suggested itself to me that there may be some relation between syphilis and spastic aphonia.

Dr. S. W. LANGMAID, of Boston: I reported one case fifteen or sixteen years ago, and in that case everything I tried was unsuccessful. The patient always prescribed for himself a little whisky when he had to use the voice, and that answered for the time being. The condition seems to be about the same as at that time.

Dr. D. BRYSON DELAVAN, of New York: In one of the cases referred to by Dr. Knight the same phenomena were observable as in the case mentioned by the last speaker. The patient, after fortifying himself with a stimulant, would talk tolerably well. I had him under treatment for two months, and he seemed to improve under local applications to the larynx and vocal training, especially directed to the management of the breathing, and it seemed that if the training could have been continued long enough the trouble might have been done away with.

Dr. F. I. KNIGHT: I really believe that more cases have been seen than have been reported. I should like to have had some opinion upon the idea of Lennox Browne that these cases are not infrequent.

Dr. C. E. BEAN, of St. Paul: About two years ago a case was

referred to me by a physician in St. Paul. The patient was a man, twenty-five years of age, with a syphilitic history, suffering with aphonia spastica. I had him under observation two months, using galvanism, faradism, strychnine, etc., without the slightest benefit. He is now in about the same condition as at that time.

**Some of the Manifestations of Syphilis of the Upper Air-Passages.**—Dr. T. A. DE BLOIS, of Boston, read a paper with this title. (To be published.)

Dr. F. H. BOSWORTH, of New York: I am sorry that the speaker did not touch more upon bone lesions, which I consider the more important feature of the tertiary syphilitic manifestations in this portion of the air-tract. There is still one question undecided, and that an exceedingly important one, and that is, How far is the bone involved in these deep ulcerations of syphilis? Of course the ulcerative process means ultimately a necrosis of the bones to a great degree covered by the original gumma, and the question is not only how far is the bone involved, but also what is the ultimate tendency? My own view is that the syphilitic manifestation in the deep layers of the periosteum of the hard palate expends its virulence in the primary deposit of the gummatous material, and that the morbid process now becomes mainly a local one, which consists in the development of an endarteritis, as has been shown so clearly by Schüster and Sänger, under the action of which localized necrosis or ulceration of the soft parts ensues, purely as the result of a shutting off of the normal blood-supply. As a final result, the nutrition of the bone is interfered with and bony necrosis takes place. The primary deposit of gummatous material limits the extent of the necrosis, so that the idea of the extension of the ulceration is not correct.

Taking this view, I think that the ulceration is not the important thing; it is the bone. Deal with the bone and the ulceration will take care of itself. After the primary breaking down of the gummatous material, the maintenance of the ulceration is dependent upon the necrosis of the bone, so that removal of the diseased bone is an important part of the treatment.

The point which I desire to make here is that the original gummy deposit occurs as the result of the constitutional disease; the ulceration is a local process, the necessary result of the pathological features of the gummatous material causing an endarteritis; furthermore, the ulceration is limited by the original gummy deposits, and no new gummy matter is deposited later, except as a new explosion of the disease, as it were; a gummy deposit occurs suddenly, and is not progressive. Bony necrosis results from the gumma, and, a bony sequestrum being formed, this becomes the prominent feature of the local disease in that it keeps up the ulceration by its mere presence, as of a foreign body.

I indorse Dr. De Blois as regards the treatment in the administration of potassic iodide and not the use of mercury until the lesion has disappeared. After the syphilitic lesion has disappeared, then mercury should be given for the removal of the syphilitic virus. As regards operative treatment, it had better be let alone until the syphilitic virus is thoroughly under control.

Dr. C. C. RICE, of New York: In regard to operation in cases of adhesion of the soft palate to the posterior wall of the pharynx, one point must not be forgotten—viz., that in some of these cases there is extensive cicatrization and contraction in the post-nasal pharynx above the line of adhesion; consequently, after the lower adhesions have been separated, we do not get the good results, so far as nasal respiration is concerned, that we should expect. The reason of this failure is that the cicatrization in the post-nasal pharynx still remains. This part of the operation should be attended to, and is as important as

the freeing of the lower adhesions. It has been said that we should not operate until the "force of the specific disease has spent itself," but it is difficult to determine when this point has been reached. I have had a case within a year where there was complete adhesion and in which there had been no manifestation of a syphilitic process for many years. The patient had taken medicines, and was apparently cured. I separated the adhesions with the galvano-cautery, but the ulceration produced by the operation refused to heal kindly, and extended somewhat, in spite of all that I could do in the way of constitutional and local treatment. I have found that there was less tendency to readhesion where the galvano-cautery was used with a low grade of heat than when cutting instruments were employed. I have lately heard of an operation which has been tried in New York for the relief of these adhesions. An ingenious physician has made a perforation through the line of adhesion with the galvano-cautery, and a ring has been passed through this and worn until cicatrization has taken place, and then he has freed the adhesions in the circle of the ring. This, it is maintained, will prevent readhesion.

Dr. J. N. MACKENZIE, of Baltimore: Dr. De Blois has referred to the dangerous symptoms from the extension of the ulceration into the accessory sinuses, principally the antrum. I would like to caution the members of the association, if they have not had a similar experience, against the too vigorous removal of diseased bone from the nasal passages. You frequently pull out more than you want, and from dangerous regions. I have not had this occur in my own practice, but I have seen it in that of others. I have seen a portion of bone drawn out, and some of the brain membranes with it.

I had a very sad case on my hands a few years ago—that of a lady who had acquired or inherited syphilis. I removed nearly everything in the nose—the turbinated bones and the sides of the antrum of Highmore, and finally the perpendicular plate of the ethmoid became so loose that I removed it. The plate of the ethmoid which had been removed had attached to its upper surface a portion of membrane, but I am in doubt as to its nature. I placed her on the use of iodide of potassium and stimulating and nutritive treatment, and she remained well for two years. She was then taken with a violent headache and a profuse fetid discharge from the nose. This headache passed off in a few days, and she did not consult me until two weeks after the headache had first appeared. I found that the process had broken out again and had invaded both antra. Offensive pus was discharged through the mouth and throat and every possible way of escape. I began vigorous antisyphilitic treatment, and did everything that I knew of to relieve her, but she finally went into a state of coma, and had general convulsions. Symptoms of meningitis set in, from which she died. I am of the opinion, from my examination and digital exploration of the case, that the process extended to the brain, not through the nasal passages, but that ulceration had penetrated through some other avenue. A post-mortem examination was not allowed, so that I can not prove this point.

I fail to comprehend the point made by Dr. Bosworth. Do you leave the ulceration alone and just pay attention to the bone?

Dr. BOSWORTH: The original deposit of gummatous material limits the extent of the ulceration. The ulceration does not extend beyond. I do not believe that it invades the antrum unless there has been a primary deposit in the antrum. Of course, the ulcer is to be treated, but it can not be cured until the prominent perpetuating cause has been removed—viz., the necrosed bone.

Dr. MACKENZIE: What are the clinical facts to support this view?

**Dr. BOSWORTH:** Syphilis shows a tendency not to transgress anatomical boundaries. It extends only so far as the original deposit of gummatous material. The syphilitic ulceration does not extend from one place to another. Furthermore, I believe that clinically the extent of the swelling, tumefaction, and redness indicates the extent of the gummatous deposit.

**Dr. MACKENZIE:** I am not prepared to accept or deny this view, which, if it can be proved, marks a decided advance. It would almost revolutionize our treatment.

**Dr. W. H. DALY,** of Pittsburgh: I am somewhat surprised at the statement of my friend, Dr. Rice, that he, a man of acknowledged ability, had used the galvano-cautery knife in freeing the adhesions of syphilis. I am very glad that he has brought this up as a warning to others. I should consider it a very bad method of practice to use the galvano-cautery on any adhesions of such low vitality as syphilitic tissues. There is also a great tendency to the readhesion of cauterized tissues. I believe that the galvano-cautery is a very much abused instrument, but abused by its friends. I believe that it is often used by skillful practitioners from an unfounded fear of hemorrhage in the use of the knife. I feel satisfied that we can always obtain better results in the fauces, in the nose, in the larynx, and, in fact, in any operation anywhere, if we do it with a sharp cutting instrument and allow as free hemorrhage as is consistent with good judgment and safety. In other words, the freer the hemorrhage within certain limits, the more certain are we to have immunity from septicæmia and the more certain to have rapid union with satisfactory results. While I think that the galvano-cautery knife is a useful instrument, I think that it is a very much abused instrument. I am glad that my eminent and able friend, Dr. Rice, has made this honest confession. It may be a warning to others less experienced than himself.

**Dr. H. L. SWAIN,** of New Haven: I should like to hear if there is any way of proving the statement that ulceration takes place only in the portion where there has previously been a gummatous deposit. It would seem that we have a contradiction of this view in the secondary ulcerations which occur in the course of treatment where everything is apparently healthy and there is no evidence of gummatous deposit. These new ulcerations come in different places from those in which ulceration first occurred.

**Dr. J. C. MULHALL,** of St. Louis: I can scarcely let the statement of Dr. Bosworth pass without question. How does he explain the cases of tertiary syphilis in which almost every portion of the bony framework of the nose is involved? Does he say that there are gummatous deposits involving the nasal cavities *en masse*? Every one of us has seen cases of tertiary syphilis where hardly any portion of the boundary of the nose was uninvolved. I therefore take issue with his assertions, first, that gummatous deposit must take place before ulceration; and, second, that the limits of the ulceration will not extend beyond the first deposit of gummatous material.

**Dr. F. H. BOSWORTH:** The investigations of various observers have shown the cause of the ulcerations of syphilis. It has been shown to be due to the gummatous deposit. That is the only explanation that we have of the ulceration. The explosion of syphilis consists in the deposit of gummatous material under the mucous membrane, and the explosion exhausts itself in that deposit, but the local process goes on. There is no subsequent deposit until there is another explosion. The thing exhausts itself for the time being. Syphilis involving the whole nasal cavity is not due to extension. I have looked for it, but I have not found it. Ulceration occurs only where the original deposit took place. Subsequent deposits may involve other portions of the nose. I think there is no clinical evidence show-

ing the extension of a syphilitic ulceration of the variety under discussion.

**Dr. A. T. DE BLOIS:** The discussion has taken so wide a field that it is difficult to touch upon the points that have been brought up. I would only say in regard to the assertion of Dr. Bosworth that we should remove the bony structures and let the ulceration take care of itself, that it is very difficult to say how far the ulcerative process in the bone has extended. I have seen these ulcerations heal after a very slight scraping, while in other cases the whole bone has had to be removed. When ulceration occurs in the soft parts, we can not let it absolutely alone. It will heal, but it will heal open, and you will have all of the distressing results which follow that condition.

#### Some Unusual Manifestations of Tuberculosis of the Larynx.—Dr. C. C. RICE, of New York, read a paper on this subject. (See page 234.)

**Dr. W. H. DALY,** of Pittsburgh: There are two points with reference to tuberculous disease of the larynx which I believe are worth noting. I have demonstrated to my own satisfaction in several cases—three or four—that tuberculous ulceration of the larynx can be cured. In these cases I could discover no syphilitic complication either inherited or acquired. I have arrived at this belief contrary to the teachings that I had received from men in whom I had confidence as teachers and authors. In so far as the treatment was concerned, it was the most approved constitutional treatment, but I do not believe that the constitutional treatment had as much influence as the persistent careful local treatment. If I were to be denied one or the other in the treatment of tuberculous ulceration of the larynx, I should certainly elect to be deprived of the constitutional treatment. The local treatment resolved itself into a question of cleanliness and antiseptics, and to this end one can use what he pleases. In the cases referred to, recovery took place under the persistent use of alkaline sprays and inhalations followed by the free use of iodoform—not iodoform modified by any medicament to correct the odor, but iodoform pure and simple.

There is another point. It may seem like rank heresy, but I believe that tuberculous ulceration of the larynx occurs as a local disease—that is to say, it may occur in patients with no evidence of tubercular deposit elsewhere. There are in Pittsburgh two such cases; one of them I saw a day or two ago. The patient is a clerk in a jeweler's store, an occupation anything but favorable to the maintenance of a cure. For over a year that young man has been working hard at long hours. The voice is somewhat affected by the diseased action and changes in laryngeal structure which took place before he came under my care, and a part of the epiglottis is gone. After he was placed under treatment there was little further destruction. He is now ten or twelve pounds heavier than before his illness and twenty or twenty-five pounds heavier than when he came under my care. I regard the case as a cure. The diagnosis was confirmed by the microscopical examination made by a competent young gentleman after the method of Koch. There was no evidence of lung disease. Being a strong believer in the theory that tuberculous, strumous, and serofulvous diseases are the offspring of syphilis, I investigated this point very closely in this case to place it where it belonged.

**Dr. J. C. MULHALL,** of St. Louis: I am glad to congratulate Dr. Daly on having cured laryngeal phthisis. I, however, think that his position is a hard one to maintain, for this reason: It is easy enough to get microscopical proof of phthisis in the presence of the bacillus without phthisis existing, for in the secretions of the mouth and throat of even healthy individuals this bacillus is sometimes found. Again, I do not doubt that there is such a thing as catarrhal ulceration of the larynx. If we take

these two facts into consideration with the fact that catarrhal ulceration can be cured, we can understand how one might readily fall into error.

That laryngeal phthisis is ever primary is also difficult to prove. That it is sometimes the first sign of the condition there can be no doubt. We also know very well that tubercular disease may exist in the lungs and not be accessible to physical examination. Post-mortem examinations have proved this. Post-mortem examinations have also proved that in every case of laryngeal phthisis there is pulmonary phthisis. It is said by experts in lung disease that unless the lung is diseased in a portion of the size of a silver dollar, its presence is readily overlooked. It is therefore easy to be deceived.

That laryngeal phthisical ulceration can be healed I have no doubt, but that it can be cured I do doubt. After our attention was called to the value of lactic acid I at once made use of it in tubercular ulceration of the larynx, and I have seen the ulceration heal on one side and appear on the other side. I went one step further than the one who recommended this agent, Krause, and applied the pure lactic acid after spraying with cocaine. Clinically I know that laryngeal ulcerations of a phthisical character will heal under the influence of pure lactic acid. I have seen them heal in the pharynx in a dying patient. I, however, can not say that I have ever seen life prolonged to any appreciable extent.

I was once a firm believer in the theory that ulceration never occurred in chronic catarrhal disease. I have had two physicians under my care. One had a terrible cough for two years, his health had run down, and he had quite a large ulceration in the larynx, which rapidly healed in the course of a month under lactic acid. The cough lessened and he improved in weight and constitutional condition and was entirely cured. This was not a tubercular ulceration.

**Dr. F. I. KNIGHT:** How do you know that it was not tubercular?

**Dr. W. H. DALY:** What are the characteristics of catarrhal ulceration?

**Dr. J. C. MULHALL:** Catarrhal ulcers occur usually in some part of the larynx where there is a great deal of friction and come on after a distinct history of severe laryngitis. The ulcer has clean-cut edges and not the creeping edges of the tubercular ulcer; is single and unaccompanied by other familiar signs of laryngeal tuberculosis.

**Dr. F. I. KNIGHT:** The first point raised by Dr. Rice is certainly interesting. I have had a great deal of trouble in the diagnosis of these cases. It is hard enough to make an accurate diagnosis where we have only one disease to deal with. In some cases where I have been almost sure enough of my diagnosis of tuberculous disease of the larynx to let the patient go without constitutional treatment, I have been happily disappointed in seeing the ulceration disappear under specific treatment. These mixed cases are certainly annoying, and the only thing that we can do in endeavoring to make a prognosis is to find out if we can which disease predominates, for, although there may be evidences of tubercular disease elsewhere, the effect of specific treatment may be very satisfactory if that element has entered into the case.

In regard to the possibility of tubercular ulceration being cured, I have not the slightest doubt that such ulceration in the larynx has got well just as in other parts. That it will heal under mild treatment I have proved by the effect of alkaline applications and iodoform. I have no question that lactic acid will heal tubercular ulcerations more quickly and certainly than anything yet proposed, but after we have them healed they do not stay healed, unless we happen upon the time when the patient is ready to recover and the ulcer of the larynx is the last

point to be cured. If the pulmonary disease is in a quiescent condition and the digestion is good, and there is this one lesion in the throat which is the particular thorn, I believe that in some cases, if we heal that, we get what is practically a cure. If the disease in the lung is active and the patient is miserable in other ways, the cure of the ulcer in the throat is not going to do much good.

I have seen what I suppose Dr. Mulhall calls catarrhal ulcerations. They are catarrhal. I should call them abrasions occurring in acute inflammatory conditions; but where there is loss of substance, as in the case referred to by Dr. Daly, I should, in considering the diagnosis, rule catarrhal ulceration out of consideration.

In regard to the occurrence of tubercular ulceration as a primary affection in the larynx, I see no reason why we should doubt that it may occur there as well as anywhere else. I think, however, that all who are familiar with this class of cases and are tolerably competent in physical diagnosis will agree that in the vast majority of cases careful examination will prove that there is disease in the lung, and in other cases, where we do not get positive physical evidence, we find rational symptoms which would lead us to infer that there is pulmonary disease. I have had many cases brought to me as illustrations of primary tubercular disease of the larynx, but, on careful examination, I have found good evidences of disease at the apices of the lungs. In other cases I have failed to get physical signs, perhaps because they did not exist. Sometimes a condition of glottic rigidity prevents us from getting the signs that may be present.

The earliest signs of tuberculosis of the lungs are by no means changes in resonance on percussion and in the respiratory murmur which many seek for, but they are localized râles which are only obtained upon coughing, and a cough properly made. In my experience this is an early sign. Many physicians examine a patient without asking him to cough. I once saw a distinguished professor of Vienna make this mistake. He examined a patient in my presence and said there was no phthisis. I asked him to try the cough, and he found an abundance of localized high-pitched râles, and corrected his diagnosis. Most patients when asked to cough take a deep inspiration, cough, and at once breathe. The deep breath which they take before may spoil the râle, or, if they breathe too soon after the cough, the râle may not be heard. The patient should cough from a rest and not breathe immediately before or immediately after he coughs. In that way in many cases we get an explosion of râles, which we should not otherwise hear. I have seen very few cases in which it seemed to me that the tubercular disease was primary in the larynx. If we get a case where the disease is primary and localized, and cure the ulceration, I do not see why it should not remain cured, unless there is subsequent infection.

The other points in the paper are interesting. I have seen anterior adhesions occur from other causes, but not from tubercular ulceration. I had recently a notable case—one of eut throat.

I have not seen an isolated tubercular tumor such as Dr. Rice describes.

**Dr. W. E. CASSELBERRY,** of Chicago: I wish to support the position of Dr. Mulhall with reference to catarrhal ulceration. A year or so ago I saw a physician of Chicago who had suffered from recurrent attacks of laryngitis, suspected to point toward tuberculosis, for which reason he had spent three winters in the South, much to the detriment of his affairs. At this time he had an elongated uvula, occasioning a good deal of cough, and the larynx and naso-pharynx were in a catarrhal state. I first excised the uvula. There were no ulcers at this time. A few weeks later he appeared with a small but pronounced superficial ulcer on the epiglottis, not much more than an abrasion,

but still with distinct loss of substance, and a smaller ulcerated spot on the false vocal cord. I told him that these were catarrhal ulcers, and did nothing for them beyond keeping the parts clean, and in a week or ten days they disappeared. He has since been perfectly well.

I am glad that Dr. Rice called attention to the rather common coexistence of tuberculosis and syphilis. It has been my conviction that the existence of either one of these diseases predisposed to the other; that one of the dyscrasiae having attacked the larynx, a favorite site for the manifestations of either, predisposed that organ more than ever to the invasion of the other disease.

**Dr. J. N. MACKENZIE**, of Baltimore: I fully indorse the statements of Dr. Knight concerning the presence of localized râles as indicative of incipient tuberculosis, and I have found that where they can not be heard over the apices they can often be heard behind the scapula. By this means I have often been able to make a very early diagnosis of tuberculosis.

The question of the existence of primary tuberculosis of the larynx has been raised. This is a question which can only be determined by the scalpel. Dr. Orth, professor of pathological anatomy in the University of Berlin, in a work published some years ago, describes such a case. All the organs of the body were examined, but the larynx was the only one in which tubercles were found. I think the patient died of the tuberculosis. Primary tuberculosis of the larynx has been demonstrated in the same way by other observers.

Dr. Mulhall has already stated what I was about to say, that while undoubtedly tubercular ulceration of the larynx will heal, yet the healing of the tubercular ulcer in the larynx by no means indicates the cure of the disease. The same thing may be said of tubercular ulcers of this region as was said of syphilis by Vidius, "They make many truces, but never peace."

As regards isolated tubercular tumors, which were first brought to the notice of the profession by myself, I should like to refer to one of the cases in which death occurred from carcinoma of the stomach and liver. At the post-mortem examination tubercular cavities were found in the lung. In the trachea there was a small tumor, which I described, and which I took to be an isolated carcinomatous nodule in the trachea, of which only a few cases had been reported. I removed the nodule carefully and submitted it to microscopical examination, and was astonished to find that it was of a tubercular nature. It presented distinct miliary tubercles in all stages of degeneration, set in a dense network of fibrous connective tissue. In this case a nodule, resembling in structure the tracheal growth, was found in the pericardium. The patient died, not of tuberculosis but of the carcinoma. The tuberculous process in the lung was, however, well marked.

I have several times seen the coexistence of syphilis and tuberculosis of the larynx, and the diagnosis is one of great difficulty. In all such cases we have to resort to the test of treatment.

With reference to catarrhal ulceration of the larynx, while I should not like to absolutely deny the existence of such a condition, I have never seen it. By ulcer I do not mean the erosion or abrasion of the larynx which results from coughing or the application of an instrument, but I mean a well-marked, distinctly excavated ulcer—a true ulcer. In my experience such an ulcer is indicative of some constitutional trouble, whether it be syphilis, tubercle, or what not; it is generally indicative of a dyscrasia.

In regard to the treatment of laryngeal tubercular ulcers by harsh methods—such as the application of lactic acid, which is, perhaps, less harsh than some others, the application of the galvano-cantery, and the treatment of Schmidt, of Frankfort-on-

the-Main, by incision of the infiltrated tissues—I am glad to say that the common-sense, conservative element of American laryngology is decidedly opposed to such measures, which I believe do more harm than good. I have never had a patient in private practice who would have allowed me to resort to such measures, even had I desired to do so.

There is a form of ulceration which occurs in the later periods of tubercular disease which is found principally in the lower part of the trachea and near its bifurcation and in the bronchi, but which may be found higher up in the larynx and in the pyriform sinus. In 1881 I published a paper in Berlin in which I dealt in an elaborate way with this question. These ulcers resemble the so-called aphthous ulceration of the old Rokitansky school, and the so-called diphtheritic ulcer. The tissue becomes invaded with a rapid cell proliferation, necrosis occurs, a slough follows, and ulceration is the result, but it presents none of the characteristics of the true tubercular ulcer. I mean by a true tubercular ulcer one that is formed by the breaking down of myriads of miliary tubercles. These ulcers may or may not contain bacilli. Orth speaks doubtfully upon the subject, but seems to regard them as tubercular. Dr. Osler has found the same ulceration in the rectum, and has been at work upon the subject, but I do not know what conclusions he has reached. It is, however, readily conceivable that these ulcers may easily heal. I have no doubt that many of the so-called healed tubercular ulcers are nothing more than healed aphthous erosions which have been produced by the corrosive action of the sputa in the later stages of the disease.

**Dr. WILLIAM C. GLASGOW**, of St. Louis: A good many years ago I stated my belief that tubercular ulceration of the larynx was never healed. My experience since then confirms me in that belief. I have heard a great deal and read a great deal about tubercular ulcerations being healed. There is a common belief that any ulceration in the larynx, not syphilitic or lupoid, is tubercular. I have seen many ulcers of the larynx heal. I have seen them heal in cases of pronounced phthisis where the physical signs demonstrated phthisis, and I have seen them heal where there were few or no physical signs of this disease. I do not consider these ulcers tubercular. They heal under the simple treatment of which Dr. Daly speaks and which I have used for fifteen years—that is, iodoform and morphine by insufflation. I recall one case in which a man in the last stages of phthisis, with large cavities in the lungs, hectic, etc., was unable to swallow on account of a large ulcer on the posterior portion of the larynx. Under the use of iodoform he was able to swallow, but died in a short time. I did not consider this a case of tubercular ulceration. I have used lactic acid, but have not found it as useful as others claim. I think that iodoform has given me better results.

One remedy that I have used with great success in the last two years is peroxide of hydrogen. I have seen these ulcers heal almost miraculously under a simple spray of peroxide of hydrogen. A case came to me last spring with two thirds of the epiglottis destroyed. The lungs were examined with negative result; no bacilli were found. Under the use of peroxide of hydrogen the ulceration or seeming ulceration, for I do not think that it was true ulceration, entirely disappeared, and the patient was able to swallow. The destructive process took a fresh start on the ventricular bands—first on one side and then on the other—and this continued until death. Repeated examination of the lungs and of the sputa developed nothing until September, when bacilli began to appear. This man died of marasmus, and at the time of his death the râles of which Dr. Knight spoke were appreciable at the apex of one lung. His death occurred within a month of their development.

I do not believe in primary tubercular disease in the larynx.

In all the cases that I have seen there has been more or less disease of the lung. In addition to true tubercular ulcers, I have seen catarrhal ulcers and others which I have not been able to define, but I do not consider them tubercular. Some of these ulcers occur in the condition of septic œdema described in my paper. In true miliary tuberculosis of the larynx I have always found some evidence of disease in the lungs, and these cases have never recovered.

**Dr. W. H. DALY:** What is the value of the tubercle bacillus as a means of diagnosis? Dr. Glasgow states that it was present in one of the cases to which he has referred.

**Dr. GLASGOW:** Its presence demonstrates tuberculosis. Its absence does not demonstrate anything.

**Dr. C. C. RICE:** The different points in the discussion have been thoroughly covered. I have been particularly impressed with one thing, and that is the radical change in the opinion expressed to-day as compared with that expressed by this association four or five years ago. If the gentlemen will take the pains to compare this discussion with that on the same subject four years ago, they will find that there has been a radical change in the opinion of this association in regard to the curability of tubercular ulceration. I refer to the discussion on Dr. Cohen's paper. The opinion expressed at that time was to the effect that these ulcerations were rarely if ever cured. The prognosis, so far as the laryngeal manifestations were concerned, was exceedingly bad. I have been surprised during this discussion to hear of the number of cases of laryngeal ulceration that have been cured. I am at a loss to understand the character of the large number of ulcerative cases referred to by Dr. Glasgow which he believes to be neither syphilitic nor tubercular. Ulcerations which belong to neither of these affections are exceedingly rare in my opinion. The catarrhal ulceration spoken of is a very uncommon manifestation. I do not refer to slight erosions. I do not believe that a catarrhal ulcer can occur unless, in addition to the acute inflammatory condition, there is a direct traumatic cause, such as friction and an explosive cough. We often see erosions. They occur on the tip of the epiglottis where it comes in contact with the tongue. They occur on the vocal bands where they rub against each other. I do not believe that catarrhal ulcers are seen on the sides of the larynx. If ulcerations of any size are found in that location, I should look upon them with suspicion. We know that primary tuberculosis of the larynx is very rare. In the treatment of laryngeal tuberculosis I think that more reliance is to be placed on milder drugs than upon the use of acids and surgical measures, etc. Cleanliness and the use of cocaine to allay irritability of the larynx is important. This, with iodoform, seems to me to furnish the best means of benefiting these patients.

**Report of Two Cases of Buccal Tuberculosis.**—**Dr. C. E. BEAN,** of St. Paul, read a paper with this title. (To be published.)

**Dr. D. BRYSON DELAVAN,** of New York: As Dr. Bean referred to a case which I reported, it may interest the fellows to know that the patient is still living. I heard from him three months ago, and there has been no recurrence of the tubercular disease. I reported my experience in the paper referred to. In regard to lactic acid I can only substantiate the statements made by Dr. Knight—that it does have a marked influence in certain of the milder ulcerations, which are neither deep nor extensive. It heals them for a time. In the more severe ulcers, while it improves, cleanses, and enlivens them for a time, it is not curative. In a case recently seen there was what appeared to be a large tubercular ulcer at the tip of the tongue of the size of a ten-cent piece. The unusual feature of this case was that pain was entirely absent. Syphilis was carefully looked for, but there was no evidence of its presence, while there was exten-

sive pulmonary disease. Microscopic examination proved that the ulcer was not tuberculous, but epitheliomatous, thus illustrating the difficulty of making a positive diagnosis in ulcerative lesions of the tongue.

**Dr. C. E. BEAN:** There is nothing more to be said. The subject has been thoroughly gone into in the previous discussion. The treatment, aside from the use of the eurette, is in no wise different from the treatment of tuberculosis of the larynx.

**The Local Treatment of Diphtheria.**—**Dr. J. C. MULHALL,** of St. Louis, read a paper on this subject. (To be published.)

**Dr. WILLIAM C. GLASGOW,** of St. Louis: I am one of those who believe that diphtheria is a blood disease rather than a local affection, and the only objects of local treatment that I see are cleanliness, disinfection, and the loosening of the membrane. There is one remedy which I have found valuable in loosening the membrane. It is the peroxide of hydrogen used as a spray. Last winter I was called in consultation to see a young girl where the membrane had invaded the larynx. The symptoms were so urgent that I advised the gentleman in charge to stay all night, and stated that I thought tracheotomy would be needed. As a preliminary, I recommended the use of the peroxide of hydrogen by the atomizer. After a few applications a large piece of membrane was thrown out. The next day the larynx was much clearer, although there were still portions left. That was the only local treatment employed in this case. Every hour a gush of the peroxide was thrown into the larynx. It produced a veil of foam, as it always does, and it seemed to lift up the membrane by the formation of gas. This patient entirely recovered. I look upon the local treatment simply as an adjuvant. I think that the constitutional treatment is the main thing. The constitutional treatment that I have found most successful is that by bichloride of mercury and benzoate of sodium. This is combined with very simple local treatment. There are cases of diphtheria where more local treatment is necessary. In these cases the method which Dr. Mulhall has described would be of value.

**Dr. D. BRYSON DELAVAN,** of New York: I think that not only the general practitioner but also a great many specialists can not receive too much warning as to the importance of the early detection of the extension of diphtheria to the nasal passages. I have seen case after case in the hands of well-known specialists where any chance that the patient may have had was lost by the neglect of reasonable precautions.

During the past ten years I have used the bichloride and the cyanide of mercury in the treatment of diphtheria, with increasing confidence in the value of these drugs. As is now well established, the bichloride of mercury is the most active destroyer of the streptococcus known.

**Dr. W. H. DALY,** of Pittsburgh: I do not know that I should transgress the bounds of this discussion if I were to allude to the treatment that I brought to the notice of this association in Philadelphia in 1887.\* I think that it is probably as active and efficient as a local remedy as it is active and efficient as a constitutional remedy. Of its constitutional action I shall not speak. I refer to large and oft-repeated doses of calomel, untriturated, unmixed with sugar. I have in my possession large numbers of personal letters, from general practitioners from distant and near parts of this country and abroad, thanking me for having given to the profession my experience in the use of calomel in the treatment of diphtheria, and I take the liberty of again bringing it to your notice in connection with this paper

\* "The Simplest and Most Efficient Treatment of Diphtheria," "Transactions of the Amer. Laryng. Assoc." 1887, read at the Philadelphia meeting.

more especially with reference to its local effect. I believe that a large part of the valuable therapeutic effect of calomel administered as I recommend it—that is, two, three, four, or five grains every two hours to a child one and a half or two years old—is due to the local action of the drug upon the diphtheria poison in the fauces. I feel sure that the gentlemen who try that treatment will not be disappointed. I presume that it is your experience, as it is my own, that many cases of diphtheria that come under our observation are in an advanced stage and are in the hands of the general practitioner, and we do not have that full control of the case that we should if it were in our own hands; but if you will investigate this treatment and try it, I promise you that you will not be disappointed. The treatment is very simple and easy—simply floating the calomel on a teaspoonful of ice-water and opening the child's mouth and putting it in. If it is swallowed, well and good; if a portion remains in the mouth and fauces, well and good. I hope that you will pardon me for again bringing this to your notice. This is a valuable and tried therapeutic measure and not a new one.

Dr. HARRISON ALLEN, of Philadelphia: I have found trypsin useful in removing the membrane. It is purely a local agent. I apply it directly to the membrane, and it is best used where you can see the membrane, but I have not hesitated to carry it by curved probes to the lower part of the pharynx and to the larynx. It is of a pasty nature when mixed with mucus and readily adheres. A piece of absorbent cotton is put on an ordinary holder, slightly moistened, and dipped in the trypsin, lying on a watch glass. A large portion adheres, and this is then carried to the affected surface. The ordinary act of deglutition will not dislodge it.

A lady, the wife of a physician, was under my care last winter. She appeared to have had an ordinary tonsillitis. I plunged a lancet into the mass but found no pus. At my next visit I found the whole tonsil covered with diphtheritic membrane. The lady was extremely ill. In this case I had the happiest effect from trypsin, and I believe that it saved her life. The membrane did not extend beyond the point first affected.

Dr. S. JOHNSTON, of Baltimore: In the discussion on Dr. Daly's paper I called attention to trypsin and stated how valuable it had been in the cases in which I had used it. I then predicted that it would be used universally as a local measure in this disease. Since then, in several instances, I have found it a most useful solvent of diphtheritic membrane. I am glad to hear Dr. Allen's remarks.

Dr. J. C. MULHALL: I am sorry that the main object of my paper has been overlooked, and that was the method of carrying out the application, not of using any particular remedy. I may therefore presume that my method is peculiar to myself.

I purposely omitted to touch upon the constitutional treatment of the disease. I am afraid that the effect obtained by Dr. Daly from calomel is a constitutional effect. Looking into the throat when the membrane is beginning to separate, we find a good deal of catarrhal secretion, and I do not see how the application of any powder could affect the tissues underneath without first the complete removal of the secretions above.

Peroxide of hydrogen is certainly a valuable local agent. I have used it as well as trypsin and other solvents extensively, but I think that I get more rapid solvent effects from papoid.

I am sorry that more was not said about getting rid of the poison in the throat. This was the prime object of the paper.

**Some Manifestations of Lithæmia in the Upper Air-Passages.**—Dr. F. W. HINKEL, of Buffalo, read a paper on this subject. (To be published.)

Dr. WILLIAM C. GLASGOW, of St. Louis: I have listened with pleasure to this paper, and I think that such papers are

what we particularly need in directing attention to the constitutional origin of local troubles. There is no doubt that a great deal of local trouble is due to constitutional changes. I have seen the cases referred to, but I have not looked upon them as lithæmic. I have not been able fully to explain them. I have understood them so far as not to use local treatment. The success that has attended remedies directed to the constitutional condition and to the stomach and digestive organs has been sufficient. These cases I have called gastric, from the occasional eructations of gas and fullness after meals; but in some of them there have been slight evidences of dyspepsia. An abnormal fermentation may be the provoking cause. In all of them I have found the use of bichloride of mercury in minute doses with bismuth and bicarbonate of sodium efficient. An old lady, who had suffered for two weeks with a trouble of this kind, recovered in a few days under this simple treatment. I have seen many such cases. Perhaps they are lithæmic, but I have looked upon them as due to a disorder of the stomach or viscera. The paper is valuable in drawing attention to the possible constitutional nature of these local disorders.

Dr. HARRISON ALLEN, of Philadelphia: This is certainly a most excellent paper. There is need of defining this notion of lithæmia more accurately. In the paper referred to as written by myself, I attempted to separate the signs by which lithæmic sore throat could be separated from the gouty. There is one phase of the subject which has not been alluded to; that is, that in adolescents you get a type of throat which is very puzzling. Young, vigorous people, especially young men, will have a lithæmic sore throat which is very puzzling. These cases resist local treatment. Reverting to the discussion of yesterday on Dr. Roe's paper, suppose such a condition existed and you used the bistoury or cautery, you would at once excite a traumatic pharyngitis. The throat is of the color of a boiled lobster. I find this condition generally in those living in luxurious homes; I believe that they are over-fed and under-exercised. In Philadelphia we have a great deal of luxury, and there is a large class that eat too much. This is a matter of common comment among school-teachers. The testimony of teachers is that many of these young persons do not get along in their studies as well as they should on account of foolish luxury in their homes. If this is the case, we can understand that in its crude form this added material is useless if not injurious. It seems to me that the use of too much sugar, starch, and rich wine would produce the condition of which Dr. Hinkel speaks. We, however, can not prove this position, for it is impossible to control the habits of these patients.

Dr. D. BRYSON DELAVAN, of New York: These cases are commonly met with among the over-indulged children of wealthy and injudicious parents. The average child will not select the most wholesome varieties of food if allowed to choose for himself, so that sweets must be interdicted. Unless we can control the diet, the management of these patients is difficult. It is valuable to have attention called to it, so that a sentiment may be excited against this over-indulgence which we find among the richer classes. Among people of more moderate means such troubles are not so common. Until these cases can be put upon a proper regimen, which it is easy to suggest but difficult to carry out, I do not think that medicine or local treatment will be of much avail.

Dr. F. I. KNIGHT, of Boston: This class of cases is familiar to most of us now. It is only recently that the peculiar irritability under the topical measures struck me very forcibly. Within the past year I have noted it particularly in a number of cases. The gentlemen may remember that a number of years ago there appeared an article in the "Popular Science Monthly" by, I think, a layman, in which catarrh was attrib-

uted to the disproportion between the amount of food ingested and the amount of exercise taken. Although the views were exaggerated, there was a good deal of truth in the article. I can say that where I have been able to make patients carry out the proper treatment I have usually been rewarded by very good results. The treatment has consisted in cutting down the diet at once, the cutting off of the excess of sugars and starch, the almost complete elimination of pastry and potatoes, and, in addition, the free use of alkaline drinks. In cases where the urine has shown a good deal of oxalate of lime, particularly where there is irritative cough, I have several times seen extraordinary results from the administration of hydrochloric acid. I have in several cases seen a cough which had persisted for several months cease in a few days under this treatment. The exercise is a part of the treatment which it is hard to induce the patient to carry out; unless you lay down some definite means, unless you insist upon a man buying a horse or a young man going to the gymnasium, it will not be done. In most large cities there are men who will take charge of such discipline. We have now a Swedish gentleman of good education who is doing a great service for some of our patients in this way.

**Dr. W. H. DALY**, of Pittsburgh: This question has been brought to our notice before by Dr. Allen and, I believe, by Dr. Ingalls, and to-day, in a very instructive manner, by Dr. Hinkel. It makes one rather proud of being a laryngologist to see these practical and substantial lines of thought branching out in various directions. It certainly promises well for the future of medicine, and especially for laryngology. I confess that my attention was first called to it by Dr. Allen's paper, and I have since read his paper once or twice, and I must further confess that I am very much at sea as to any definite belief as to the pathology of these cases, whether they are primarily a digestive disorder, or a liver disorder, or whatever else it may be.

In this connection I wish to say a word with reference to Murchison, and there never lived a higher authority on questions connected with disease of the liver and some forms of lithæmia and gout; but a man who wrote so much and taught so much could not avoid making some errors. Of these I do not intend to speak. It is not safe to follow Murchison through all the mazes of his theories. I say this with all due respect, for I enjoyed a personal acquaintance with Murchison during his life, and feel proud to have known him.

As we are, in a practical way, more interested in dealing with these patients in a curative way than any other, it may be well for me to refer to a simple method which I have resorted to with probably more satisfaction than any other. In my experience with salicylate of sodium I have never been able to get patients outside of hospitals to take it longer than twenty-four hours at a time within the past year in such cases as have been referred to by Dr. Allen and Dr. Hinkel. I have ordered equal parts of salicylic acid and bicarbonate of sodium to be mixed, and of this the patient takes from a half to a whole teaspoonful, in a small, strong lemonade, half an hour before each meal. Patients will take the drug in that way longer than in any other. I do not continue it more than four or five days at the furthest. Good results are obtained in a fair proportion of cases very quickly.

**Dr. F. W. HINKEL**: I am glad to receive the corroboration of the gentlemen present. I knew that they had all seen this condition in some form. I wanted particularly to point out the fact that there are some cases in which the digestive disturbance is not due to great excesses on the part of the patient, and also that there are a few symptoms—such as a patchy appearance of the mucous membrane—which I have seen associated with the general condition frequently enough to think that it is a local

sign of some significance, and might lead one to suspect lithæmic complications where the appearance of the patient might not suggest it. As Dr. Glasgow has said, there is frequently gastric derangement. Frequently there is a chronic gastric catarrh, which must be relieved by the physician before the laryngologist can hope to relieve the condition in the upper air-passage. Whether this gastric condition is not due to the underlying constitutional condition is a question.

When we give bicarbonate of sodium and salicylate of sodium, we are really making use of remedies which will check the fermentative action which goes on in the intestinal tract, and prevent that acidity which I am perfectly sure frequently stands in a causative relation to the nerve storms which sweep over such individuals. In this way the local conditions are relieved by removing the source of irritation from the intestinal tract.

#### NEW YORK CLINICAL SOCIETY.

*Meeting of May 23, 1889.*

The President, Dr. L. BOLTON BANGS, in the Chair.

**Diabetes of Tubercular Origin**.—**Dr. M. ALLEN STARR** presented a specimen of peculiar interest. It was the medulla oblongata of a man whose only symptom of disorder had been diabetes. A miliary tubercle about one centimetre long was situated in the medullary fibers just below the point where an experimental puncture produced diabetes, in a tract figured in Tierce's book which was supposed to take a downward direction.

**Solid Oedema of Traumatic Origin**.—**Dr. J. W. MURRAY** presented a patient of whom he gave the following account: Thirteen months previously the man, a worker in an iron foundry, had had his arm drawn through a pair of iron rollers, up to the elbow, and the skin stripped up from the hand nearly to the shoulder. Afterward the skin about the elbow had sloughed away, and, two months after the accident, there had been swellings, running into abscesses, in the hands and arms, and from one of the palmar abscesses a piece of cartilage had been discharged. After this, new skin had grown in nearly as far up as the elbow. Owing to the congestion of the injured part, and especially to the destruction of the skin and soft parts (including the lymphatics) about the elbow, the hand and forearm were in a condition nearly equivalent to elephantiasis. The whole limb was very large and heavy, and entirely useless. Judging from the deformity, it was probable that some fracture of the bones also existed. There was very slight motion in the fingers. There was no anaesthesia; on the contrary, there was marked tenderness on pressure. Dark patches of pigmentation were to be seen in different parts of the forearm. There was great and constant pain in the limb, also neuralgias, a "pins-and-needles" sensation, and flushes of heat and cold. Cellulitis was common enough after a crushing injury, but in this case, instead of gradually passing away, the swelling or growth was slowly increasing. He was about to perform amputation at or just above the elbow.

**Dr. J. W. WRIGHT** said that we might suppose it a case where there had been a nerve lesion of some obscure sort which was followed by the formation of an enormous quantity of new connective tissue. The prognosis, so far as restoration of the injured limb to a healthy or useful condition was concerned, seemed to him unfavorable, and the only treatment to be amputation. The man's hands reminded him, in their swollen appearance, of the prepucce of a man he had once seen in the early stages of a very severe attack of gonorrhœa; this patient had had an unusually long foreskin, and the inflammation had caused a degree of oedema which had disfigured the penis most

effectually. The œdema in a few such cases failed to subside with the usual promptness, and continued on a few weeks, or months, or even years. Now, in the present case, we could also assume that the condition was one of solid œdema, due to the destruction of so many of the lymph-spaces and the non-absorption of the effused products of inflammation. When one cut into such tissue it was like cutting into a bowl of very thick jelly. An incision was followed by no outpouring of fluid. The material effused had enough reparative material combined with it to become practically organized and so to remain *in situ* indefinitely without further change. In several such cases where the prepuce was involved he had been obliged to make an extensive plastic circumcision, but had never seen any fluid escape. He thought that in the case of the patient now before the society the arm would be found to be in this same condition. He had never seen any treatment succeed in restoring tissue in which this change had taken place, and did not believe anything could act on it reparatively.

Dr. R. ABBE had seen one case where such an enlargement had taken place in the foot of a man suffering from necrosis of the tibia. He should think that probably a nerve-lesion existed, although he must admit that the causation here was very obscure. The condition was not one of true elephantiasis, evidently.

The PRESIDENT had met with accounts, in his readings, of a similar condition sometimes developed in the scrotum, which some writers considered due to an increased formation of cellular tissue. Sir James Paget called it a solid œdema due to a true lymphatic obstruction and engorgement, together with a formation of new tissue by cellular hyperplasia.

Dr. MURRAY said that his study of the case had convinced him that its essential features were not the result of a nerve lesion, but arose from the destruction of the lymphatics in and above a granulating surface (in this case at the elbow), and also from the general congestion. It was not unlike a suppurative cellulitis of the arm, especially one spreading upward from the hand to the forearm, only that the latter affection slowly subsided as the lymphatics gradually came into action. Here that provision was cut off.

**A Cortical Motor Center for the Human Larynx.**—Dr. D. B. DELAVAN presented the results of observations made by him in connection with an obscure case of cerebral disease, with specimens. (See vol. xlix, p. 673.)

Dr. STARR thought it an especially interesting feature in Dr. Delavan's investigation that it tended to disprove the theory of Krause that cortical lesions, and they only, produced paralysis of one vocal cord. Krause had made his affirmation as a result of experimentation. The speaker had thought it a cortical lesion in Dr. Delavan's case until the autopsy was made. In Sims's experiments, published in 1882, the conclusion had been reached that cortical lesions produced bilateral paralyses, and that extirpation of the diseased area would not cure such paralyses entirely. The lesion in Dr. Delavan's case must have had its seat in the medulla or in the nerve itself. He had a case in his clinic illustrating the same thing—a unilateral laryngeal paralysis, with a slight paralysis of the tongue. A difference of half an inch in the position of the lesion in Dr. Delavan's patient would have been accompanied by a corresponding paralysis of the tongue.

**A Large Psoas Abscess.**—Dr. B. F. CURTIS presented four photographs of a very large psoas abscess which he had opened the week previous. It was the largest he had ever met with. About six quarts of pus had been taken away from the contents of this tumor, and about two quarts remained in. The patient had had some hectic fever for a few days, but was at the time very comfortable.

### The Surgical Treatment of Inveterate Tic Douloureux.

—Dr. R. ABBE read a paper with this title. (See p. 121.)

Dr. DELAVAN had met with one of the patients operated on by Dr. Carnochan (twenty years before), and had been assured that there had been no return of the old pain.

Dr. STARR said he had had two interesting cases of the same kind, but in neither had it been necessary to make the section at a point so deeply placed as in Dr. Abbe's cases. Dr. Hall had operated on one of these patients (an old lady) in 1885, after she had suffered intense agony in the infra-orbital branch of the fifth nerve for six years. The incision had been made parallel to the inferior orbital line, and, as the face contained many wrinkles, it had been possible to make the scar scarcely noticeable. An inch of the nerve had been excised. After three years there had been no return of the pain.

The other patient had been operated on by Dr. Hartley, the right inferior dental nerve being the one affected. A slight incision having been made, the lower jaw had been trephined over the site of the dental canal and half an inch of the nerve excised, after stretching it. There had been no pain in the nerve after the first twenty-four hours following the operation. Here were two cases in which, apparently, it had not been necessary to go so far in as Dr. Abbe had found desirable. It would be well if we found some means of determining at how deep a point the section needed to be made. This point might be somewhat elucidated by the injection of cocaine into the nerve at its point of exit from the bony canal. He had recently had two cases of *tic convulsif* in which an injection of cocaine had shown which branch of the nerve was involved. In both cases the excision of a portion of the nerve had resulted in a cure. If the injection of cocaine stopped the pain in a nerve, this showed, of course, that the lesion was peripheral. If not, then operation at that point would be a vain procedure.

Dr. WRIGHT remarked that he had met with a large number of instances in which tic douloureux had proved absolutely unmanageable by medical treatment. In attempting, before operating, to differentiate as regarded what branch of the nerve was involved, it was very important to get a careful statement from the patient as to the seat of his pain. He had seen several cases where the nerve had been taken out as far up toward the brain as it was possible to reach without any result. This indicated that the nerve was affected throughout its length. But, where the use of cocaine would tell us that some single branch of the nerve was affected, a portion of that branch could be removed and the more formidable operation not gone into. He had seen a number of cases where the partial operation had been without effect, and had done some of these operations himself. So he had come to look on the operation as one which was certainly successful if thoroughly done—*i. e.*, if Meckel's ganglion was taken out, as he had often had to do.

Dr. ABBE, in reply to a question from Dr. Emerson, said that he had found the nerve redder than was natural, and swollen, but could not say whether this had been due to the operation or not.

**Masked Perityphlitis in a Child.**—Dr. H. C. COE presented a perforated vermiform appendix and a faecal concretion which he had removed from the body of a child dying suddenly in whom no such lesion had been suspected until the autopsy. The whole history of the case had not furnished a significant symptom. The child had merely complained of constipation. There had been no pain. Vomiting had been slight; the temperature not above 102° F. The bowels had been moved freely, and the temperature had then subsided. Afterward, when looking bright and well and playing actively, the child had suddenly fallen back dead. At the autopsy he had found a perforation, an escaped faecal concretion, and a very foetid, purulent peritonitis. There

had been no tenderness over the abdomen, and yet the process must have been going on for forty-eight hours. Could such a condition be suspected with such slight symptoms?

## Book Notices.

*A Treatise on Surgery, its Principles and Practice.* By T. HOLMES, M. A. Cantab., Consulting Surgeon to St. George's Hospital, etc. With Four Hundred and Twenty-eight Illustrations. Fifth Edition. Edited by T. PIOKERING PICK, Surgeon to and Lecturer on Surgery at St. George's Hospital, etc. Philadelphia: Lea Brothers & Co., 1889. Pp. xxiii-33 to 1008. [Price, \$6.]

This work is a compendium of the author's more elaborate "System of Surgery," and appears to have been pretty thoroughly revised and brought up to the period of its issue. Though the surgery of the eye has been omitted in this edition, for reasons which seem sufficient to Mr. Holmes, the book is not reduced in size, the added matter being required in dealing with the recent advancement in operative procedures. Though excellently written and carefully compiled, the book suffers somewhat from paucity in detail. This is a shortcoming of which Mr. Holmes is fully conscious, as he touched upon the fact in his preface to the first edition. Turning to the subject of abdominal surgery, with the latest and safest methods and details of which it is the desire of every ambitious surgeon to acquaint himself, one is disappointed to find that this volume has been issued before the author had the opportunity of introducing a description of Senn's decalcified-bone plates or the ingenious "catgut-ring" modification thereof by Abbe. Devices which it is already maintained lower the mortality rate after intestinal resection from 87 to 8 per cent. must surely soon find place in surgical text-books. In the work under notice the subject is thus summarily dismissed: "Little success has as yet attended the operation of resection of a portion of the alimentary canal, but there seems no reason to doubt that, with more improved methods of operating, a great success may attend it in the future, and that in certain cases the justifiability of such operations is unquestionable." Then, again, one must take issue with the deductions of the author that amputation of limbs for extensive joint disease offers better prospects than excision. Cases, such as recently reported in this country by Dr. Wyeth and others, of resections under strict aseptic and antiseptic precautions and the use of steel drills, surely negative such conclusions. The book is profusely and creditably illustrated.

*Diseases of Women: A Manual of Non-surgical Gynaecology* designed especially for the Use of Students and General Practitioners. By E. H. DAVENPORT, A. B., M. D., Assistant in Gynaecology, Harvard Medical School, etc. With Numerous Illustrations. Philadelphia: Lea Brothers & Co., 1889. Pp. xiv-25 to 317. [Price, \$1.50.]

The absence of practical details and minor points of gynaecological manipulations in the standard text-books has induced the author to offer this work as a means by which the deficiency may be supplied. The methods of examination, the diagnostic significance of signs and symptoms, and the mode of treatment of the more common forms of pelvic disease, as well as the general principles on which the gynaecological art is based, are treated of in a clear, detailed, practical fashion, supplying to the tyro what experts have learned from experience. The author has succeeded as well as could be expected under the cir-

cumstances, if not better, but in a few instances he has been a little injudicious in recommending certain semi-operative procedures, such as digital exploration of the bladder through the urethra and dilatation of the cervical canal.

The chapter on pessaries should do much to disabuse the mind of the general practitioner of the belief that these unappreciated instruments are delusive snares in hard rubber, for it certainly explains the method of employing them in a very clear manner, and in one which should be well understood.

The chief criticism which might be made on the general character of the book is that, in portions, it savors of the style of literature now so rife in the land. We refer to the "vest-pocket" treatises and "compends" which are supposed to contain all the "essentials" of a department of medical science, and which are dear to the student's heart. When applied to such a department as that of gynaecology, this would be analogous to including stenography in the curriculum of a kindergarten, and fitting pupils for reporting speeches before they had learned how to write. No such idea could have possessed the author's mind, but a few isolated parts of the work do suggest the existence of such a vicious tendency. This is not, fortunately, a prominent feature, nor is it even apparent except when the contents are compared with the plan of the work. In other respects the author has done well.

*Exploration of the Chest in Health and Disease.* By STEPHEN SMITH BURT, M. D., Professor of Clinical Medicine and Physical Diagnosis in the New York Post-graduate Medical School and Hospital, etc. New York: D. Appleton & Co., 1889. Pp. xiii-7 to 206. [Price, \$1.50.]

The name alone of the author of this compact little volume will commend it to any who are looking for a lucid statement of the principles upon which the physical exploration of the chest in health and disease is based, or for practical directions and hints in regard to the applications of the art in clinical medicine. The style is graphic, sustained, and forcible. Facts which present a natural contrast are constantly set in apposition to each other with that skill which only long training as a teacher gives. The author's efforts to convey exact ideas are well supplemented by the exquisite paper, printing, and illustrations, which furnish a continuous satisfaction to the eye.

*Lectures on Massage and Electricity in the Treatment of Disease (Masso-electro-therapeutics).* By THOMAS STRETON DOWSE, M. D., Fellow of the College of Physicians of Edinburgh, etc. Bristol: John Wright & Co., 1889. Pp. xix-379.

INTRODUCING his subject, the author states that he has endeavored to deal with it in a spirit of scientific research, claiming no special merit for originality or the working of any "wonderful cures." Twelve lectures are devoted to teaching his methods and to the therapeutical application of massage to the innumerable diseases for which it is "an infallible cure," the allegation being vaunted in a spirit strikingly at variance with the modest terms of the preface.

Further comparative analysis demonstrates equally glaring incompatibilities, as, for instance, the following statements: "Massage is endowed with wonderful power, not only in arresting muscular, atrophic, and nerve degenerative changes, but it possesses an ability unique which no other agent does possess in restoring the nutrition and regenerating the growth of nerve and muscular fiber; and when I tell you that cases of progressive muscular atrophy which have been given up as hopeless have been cured by massage under my own daily observation, I am quite sure you will agree with me that it should receive a definite place as a therapeutic agent of the utmost value."

As an offset to this sweeping statement comes the following: "We can not hope to cure a sclerosis of the brain or cord; to think of it is utterly preposterous; but we can possibly arrest its spreading and start compensatory processes, and we can relieve nutritional and functional nerve troubles (usually peripheral), which frequently give patients much more distress, pain, and discomfort than the disease itself."

The subject of electricity is summarily dealt with in two chapters, made up largely of extracts from the writings of Dr. Watteville and Apostoli, the writer believing the value of electricity as a therapeutical agent second to that of massage. Barring the apparent incongruities, the book as a whole will be found useful to those wishing to test the merits of massage. The drawings are well done, clear, and explanatory, and add greatly to the value of the work.

#### *The Essentials of Physical Diagnosis of the Chest and Abdomen.*

By J. WALLACE ANDERSON, M. D., Physician to the Royal Infirmary, Glasgow, and Lecturer on Medicine, Royal Infirmary Medical School, etc. New York: Macmillan & Co., 1889. Pp. viii-156. [Price, 75 cents.]

ANOTHER effort to elucidate the mysteries of physical diagnosis added to the numerous treatises already before us. Dr. Anderson says in his preface, however, that he has found great difficulty in selecting for his junior students a simple, concise, and suitable text-book on the subject, and hence he was constrained to become the author of this work. While no exception can be taken to the little book, which is fairly written and accurate so far as it goes, still one is impressed with the idea that Dr. Anderson's junior students might have been supplied with books perhaps even better suited to their needs. The treatise is not illustrated. Now the junior student delights to revel in pictures of lungs, heart valves, and so on, though these may be for the most part but sorry misrepresentations.

#### *Hand-book of Materia Medica, Pharmacy, and Therapeutics.*

Compiled for the Use of Students preparing for Examination. By CUTHBERT BOWEN, M. D., B. A., etc. Philadelphia: F. A. Davis, 1888. Pp. vi-366. [Price, \$1.40.]

This little work fairly fulfills the object of its author. It contains a large amount of well-arranged and condensed information, and only that which the student or young practitioner will actually need. Being written entirely in the form of question and answer, it is particularly well adapted for those students who prepare for examination without a quiz-master. Many excellent prescriptions are incorporated.

#### GENERAL LITERARY NOTES.

AMONG recent foreign publications we note the following:

F. ALCAN, Paris.—A. Boiesco, "De l'erythème nouveau palustre." — F. Terrier, "Remarques cliniques sur une sixième série de 25 ovariomies." — Chobant, "De la tarsectomie antérieure, totale et partielle, dans les eas pathologiques." (3fr. 50.) — O. Dinstrieff, "Le képhir, boisson médicinale du lait de vache." — E. Thévenin and H. de Varigny, "Dictionnaire abrégé des sciences physiques et naturelles." — J. Boekel, "De la résection du genou, étude basée sur 64 observations personnelles." (4fr.)

ASSELIN & HOUZEAU.—D. Labbé, "De l'ozone. Aperçu physiologique et thérapeutique." (1fr. 50.) — P. Bloeq and H. Gillet, "Des eirrhoses graisseuses considérées comme hépatites infectieuses."

## Reports on the Progress of Medicine.

### GYNÆCOLOGY.

BY ANDREW F. CURRIER, M. D.

**Ligation of the Uterus per Vaginam, and its Indication in Cases of Retroflexion and Prolapsus of the Organ.**—Schücking's paper ("Anales de Obst., Gin. y Ped.," March, 1889) was read at the sixty-first Congress of German Naturalists and Physicians. The author has been contemplating for years a secure and safe method of reducing a retroflexed or prolapsed uterus, and one which should be permanent in its results. One plan which suggested itself consisted in passing a ligature from the cavity of the uterus to the abdominal wall, but this involved the danger of wounding the intestine and also the possibility of infection. Besides, if adhesion of the uterus to the abdominal wall were secured, the line of adhesion would probably be insecure by such a method. Hence, it seemed evident that the desired end could be attained only by a suture which should fix the fundus uteri to the abdominal wall at its top and sides, the peritoneal covering of the uterus being fixed to the vesico-uterine fold and to the peritoneum contiguous

to this fold. This would fix the uterus in a position of acute anteflexion. As to the danger attending the perforation of the fundus uteri through the antero-lateral portion of the vagina, the author asserted that there was no danger if all the genital tract were thoroughly disinfected and a proper needle were used. Perforation of the uterus has been done without bad results too frequently, and with instruments also which were not aseptic, to fear much from such a procedure. The bladder need not be wounded, as it can be pushed aside with a sound while the suture is being passed. In three cases in which the bladder was perforated by the author no harm followed. The intestines will not be injured, as they do not lie in the area traversed by the needle. The operation has not been tried in cases in which there were firm adhesions. The needle was made as small as possible consistently with strength—small enough to pass into the virgin uterus with the sheath which guarded it, and properly curved to pass from the fundus of the uterus to the abdominal wall.

Twelve patients with retroflexion have been operated upon, eight of them without using an anaesthetic; also three cases of prolapse have been operated upon without an anaesthetic. The operation is performed with the patient in the dorsal posture, and, after the uterus has been replaced with the sound, the ligature of carbolized silk is carefully passed, the uterus being drawn downward as near the vulva as possible before its cavity is entered. The ends of the ligature are tied with a surgeon's knot (external to the body?), and then an iodoform tampon is introduced into the bladder and another into the vagina. The ligature may be cut after six to twelve days, an iodoform tampon being again introduced into the vagina. The author says there was no rise of temperature in any of his cases, but that there were slight pains in some of them. In the three cases of prolapsus the ligature was allowed to remain three weeks. In all the author's—except the first, in which the ligature parted too soon—the retroflexion or the prolapse was cured, and not only that, but the symptoms depending thereupon were also cured.

**Affections of the Fallopian Tubes and Ovaries in their Clinical and Anatomico-pathological Aspects.**—Mignon (*ibid.*, April, 1889) gives the following conclusions as the results of his clinical and histological investigations:

1. The anatomico-pathological forms do not exactly correspond to the different clinical ones in connection with diseases of the tubes.

2. The diagnosis of tubal diseases does not offer very great difficulties. Should the tumor not present the characteristic form of the distended tube, and the bimanual exploration fail to give clear results, the diagnosis may be made from the history and the course of the disease.

3. The variation in the volume of the tumor is a matter of great importance in making a diagnosis, this condition being dependent upon the processes of ovulation and menstruation. This variability is especially characteristic of small tubo-ovarian tumors, and will assist in distinguishing them from neoplasms.

4. The tubal disease tends to propagate itself to the neighboring organs and tissues.

5. This tendency of extension of the tubal disease to the neighboring organs is very variable. In some cases the process is limited to the tubes, causing great changes, in which there may be large collections of serum or pus in the distended tubes, but no false membranes or adhesions to neighboring organs. On the other hand, there may be false membranes in abundance, agglutinating the uterine annexa together, while the organs themselves may not be much altered, or may show only secondary alterations.

6. The tubes may become diseased in different ways, either by extension from the mucous membrane of the uterus or, secondarily, in consequence of inflammatory processes in their vicinity transmitted through the lymphatics.

7. Tubal disease is usually bilateral, though it may differ in degree on the two sides.

8. The anatomo-pathological changes may be varied, depending upon the coincidence of many conditions—such as the intensity of the process, its duration, the cause, the point of departure; again, the changes may be primary or secondary, as in cases in which there is muscular hyperplasia, or atrophy of the walls in consequence of the pressure of the contained fluid.

9. The phenomena of atrophy and hypertrophy are those which ordinarily attend inflammation with such consequences. There are changes in the vessels, the emigration of white and red corpuscles, swelling of the tissues, and the new formation of connective tissue.

10. Effusions of blood sometimes take place into the tubal walls, but the presence of blood in the cavity of the tube does not necessarily indicate the existence of haemorrhagic salpingitis.

11. In many cases the tube is divided into cavities of varying capacity, lined with cylindrical epithelium. Some of these cavities may communicate with the general lumen of the tube, while others are separated from it. These cavities are sometimes found in tubes which are enlarged, and at others they are in tubes which have walls of normal dimensions.

12. The ovaries almost always participate in tubal disease, especially in cases in which there is cystic degeneration, cicatricial contraction, or atrophy of the ovary with disappearance of the glandular tissue, while they are rarely implicated in cases of abscess, follicular degeneration of the tubes, etc.

13. Atrophy of the ovaries is found in some cases in which the uterine annexa are imbedded in solid and extensive false membranes.

14. Should disease of the uterine annexa persist for a long time, it will excite certain reflex phenomena of the nervous system, the gastrointestinal tube, etc.

**Massage in the Treatment of Pelvic Disease.**—Borislavsky read a paper (*ibid.*) before the Third Congress of Russian Physicians, the conclusions being as follows:

A. In prolapse of the uterus:

1. Massage applied after Brandt's method will effect a cure in some cases.

2. It can not be decided whether such a cure will be a permanent one. In some cases recurrences have been reported.

3. The method of treatment is tiresome both for the physician and the patient, and may influence the nervous system of the patient unfavorably.

4. It is doubtful whether it will be possible for this method to supplant operative treatment for prolapse of the uterus.

B. Inflammatory exudates in the pelvic cellular tissue:

1. The results of the treatment of parametric exudates by massage are more favorable than those which have attended similar treatment of prolapse of the uterus.

2. The use of massage in the treatment of chronic exudates in the pelvic cellular tissue implies a shorter course of treatment than the means which have heretofore been in vogue.

C. Intraperitoneal exudates: With reference to intraperitoneal exudates, circumscribed haemorrhages, flexions and versions of the uterus, inflammations of the uterine parenchyma and of the ovaries, the paper reports no reliable cases. For retro-uterine hematoma massage is not indicated, as it might encourage suppuration. In general, this subject requires more extensive investigation, and, as its irrational use would result in harm, it should be studied in hospitals and clinics under the direction of one who is thoroughly acquainted with it. The following are conclusions deduced from other papers on the same subject as the foregoing, which were read at the same convention:

1. Massage is undoubtedly a powerful method for the treatment of disease of the female pelvic organs.

2. The indications and contra-indications for its use are far from being definitely settled.

3. The method can only be studied experimentally.

4. Massage irritates the nervous system only in exceptional cases of hyperesthesia of the sexual organs.

5. It is not very probable that it encourages sexual excitability.

6. It is not important that the person using this method should be of the opposite sex as regards the patient.

7. Electricity has a much more exciting effect upon the nervous system than massage.

**Salpingo-oophoritis and its Relations to Abdominal Exudate.**—Terillon ("Jour. de méd.", March 3, 1889) remarks that the history of circumuterine inflammations has made a great advance, and many points have been elucidated since surgeons began to make bold investigations concerning the ovaries and tubes by means of laparotomy. These opera-

tions have demonstrated that the tube and the ovary were the origin of those affections known under the name of parametritis. They have also supported the statement of Aran and Bernutz, that pelvic peritonitis, which is secondary to tubal and ovarian disease, is a late phenomenon of the disease, but the most important one from a clinical standpoint. From these discoveries it has resulted that the so-called phlegmon of the broad ligament is no longer recognized, or at least that it is of very rare occurrence. It is therefore reasonable that the theory concerning phlegmon of the broad ligament, and also that concerning adeno-phlegmon of the same region, should be abandoned as causes of error in the interpretation of certain symptoms. In pelvic or circumuterine inflammations one frequently finds an indurated exudate near the pubic arch and the region of the broad ligament, which is an important diagnostic and prognostic sign, and which extends to a greater or less distance from the umbilicus. This exudate indicates the extension of an inflammation deeply situated behind the pubes, and frequently starting from the vicinity of the uterus. It is the ordinary expression of the extension of the primary disease, but it is sometimes the herald of fluctuation which is the guide to the surgeon for the opening of a deeply seated abscess. This exudate has usually been misunderstood as to its origin, mechanism, and significance. Writers have always considered it an extension of a phlegmonous inflammation beginning at the base of the broad ligament, developing between its layers and reaching its upper portion. From the latter point it was supposed to infiltrate the tissue between the peritonæum and the pelvis, stripping up the peritonæum and forming a mass between the Fallopian tube and the abdominal wall. Guérin believed it was the result of an adenitis situated at the level of the obturator foramen; that the peri-adenitis developed around this point could raise the peritonæum and form a mass behind the abdominal wall, and that the peritonæum became thickened to prevent the effusion of pus into the abdominal cavity. Laparotomies upon living subjects have demonstrated the error of these views, and have given the anatomical proof of the cause of the abdominal exudate and of its practical importance. In cases in which this exudate exists, laparotomies have shown that the tubes and ovaries do not always occupy the same position in the pelvis, and that they may even be found at a great distance from their normal situation. Most frequently they are retroposed in the *cul-de-sac* of Douglas and massed at the sides of the uterus, but sometimes they are fixed by firm adhesions behind the symphysis pubis at their normal level. They may also be displaced to the level of the border of the superior strait, or even to a higher level, coming in immediate contact with the abdominal wall. In the latter position the tubes and ovaries may be firmly adherent and be inaccessible by immediate palpation. If they become much enlarged and their connection with the abdominal wall is extensive, an examination of the abdominal wall gives one the impression of an exudate. The tumor may become as large as the hand or larger if the inflammation becomes diffused and forms thick masses of false membrane. This effect is the more extensive and perceptible if the omentum becomes thickened, inflamed, and adherent, and is combined with the thick false membranes, thus adding to the thickness of the supposed abdominal exudate. Five cases are narrated in which laparotomy was performed, and the foregoing statements were verified. The author believes, therefore, that primary subperitoneal phlegmasia is very rare, and that most of the peritoneal inflammations originate from the tubes and ovaries.

**The Relations of General Paralysis in Women to Certain Disorders of Menstruation.**—Petit ("Gaz. méd.", Feb. 23, 1889) says that writers are not in accord concerning the condition of menstruation in women suffering from general paralysis. Some believe that this function is not deranged; others, among whom are the Germans and Italians, believe that the cessation of the menses is a frequent cause of general paralysis which would thus be essentially a disease of the menopause. The author thinks that menstrual troubles observed in paralytic women, instead of being always the cause of the cerebral disease, may, on the contrary, be the direct or the sympathetic consequence. Petit's investigations confirm this view. In fifty-nine paralyzed women he has observed in fifty-two of them disturbed menstruation, and in seven normal menstruation. In all cases the menstrual troubles were subsequent to the beginning of the general paralysis. In sixty-four cases of insan-

ity of different varieties he has only found disordered menstruation nine times, while it was normal in the other fifty-five. The most important of his conclusions are the following:

1. The development of general paralysis in women often leads to disorders of menstruation.

2. These disorders are characterized at times by sudden and definite arrest of the menses, at other times by marked irregularity in the menstrual epochs, though the function may have been previously performed with the greatest regularity.

3. When in the course of general paralysis in women there is a remission, the effect of this remission seems to be to restore the regularity of the catamenial function.

4. Patients who during an attack of diffuse meningo-encephalitis have developed no menstrual disorder, seem to resist such troubles longer than those who have suffered suppression or irregularity of the function.

**Uncontrollable Vomiting during Pregnancy.**—Quevedo ("Prog. Ginecol. y Ped.," Dec. 10, 1888) reports two cases in which this symptom was controlled by dilatation of the cervical canal after all other means had failed. The following conclusions are deduced:

1. In the present state of our knowledge, treatment by medicines is impotent to overcome the persistent vomiting of pregnancy.

2. The method of Copeman, which consists in the dilatation of the cervical canal by the finger, has given results which are rapidly attained, are harmless, and are easy of accomplishment.

3. Sponge may be used instead of the finger without fear of producing new complications, supposing always that the sponge is known to be free from septic elements.

4. Dilatation of the cervical canal should be performed as a last resort. If it fails in accomplishing the desired end, a miscarriage should be produced.

**Curetting the Uterus for Puerperal Septic Endometritis.**—Charpentier (*ibid.*) says that the cause of puerperal infection is an extraneous septic element which multiplies within the uterus or vagina, penetrates the blood, and produces grave or even fatal accidents. The development of this micro-organism produces a septic endometritis. General treatment in such cases is useful, but should only be auxiliary to local treatment, which is most efficacious. Intra-uterine injections are frequently useful, but they sometimes fail in producing the desired end. At such a time there is no means so efficient as curetting. The patient should be placed in the obstetric position, the vagina irrigated, and the uterus drawn down. If the cervix is not dilated, dilatation should be rapidly performed, and the uterine cavity irrigated with an antiseptic fluid. An antiseptic curette should then be applied over the entire uterine mucous membrane, the scrapings removed, the irrigation repeated, and a cauterizing antiseptic applied to the curedtted surface.

**Utero-ovarian Gout.**—Mabboux (*ibid.*, Dec. 25, 1888) says that gout may be located in the female genital apparatus during or after the existence of sexual activity. There may be inflammation of the vagina, uterus, or vulva of gouty origin. Gouty phenomena may accompany menstruation in the form of dysmenorrhœa, or may occur during the intervals of menstruation. Utero-ovarian gout is to be treated by the same means which are efficient in other varieties of the disease, whether articular or visceral—that is, with alkaline mineral waters. The concentrated bicarbonate of sodium waters are indicated for plethoric patients when the inflammatory condition is not exaggerated, but are not indicated for the anaemic. The cold calcium sulphate waters are indicated in almost all cases on account of their resolvent, sedative, and tonic properties. They may be used with advantage when the pain is acute.

**Treatment of Retroflexion of the Uterus.**—Skutsch (*ibid.*) admits that an instrument has not yet been made which is adapted to the successful treatment of all cases of retroflexion, and yet the reason why pessaries fail to do well in the practice of many is that the instrument is not properly molded for each particular case, or else that the uterus is not relieved of those conditions which prevent its restoration to proper position. In many cases it is doubtless overlooked that there are resisting peritoneal adhesions and extensive scars in the parametrium. In such cases good results can be obtained by gradual stretching and unmethodical massage of the adhesions and scars. In the author's practice, in cases in which there are peritoneal bands, good

results have been obtained by methodical attempts at bimanual reduction. In cases in which there are adhesions or considerable remnants of exudate in the parametrium, the bimanual method of massage advised by Brandt for treating chronic inflammation of the pelvic cellular tissue has achieved good results. This method will also accomplish the gradual stretching of cicatricial bands. Progress having been made by such means, the uterus can then be sustained by a pessary. Before such treatment is carried out it is presupposed that a clear and accurate diagnosis of the condition of the pelvis has been made, bimanual exploration having been practiced. A long anterior vaginal wall is necessary in order that these manipulations may be successfully carried out, and this condition may be obtained by means of transverse incisions if the natural conditions are not satisfactory. With regard to operative treatment, the author feels that laparotomy is the only means by which certain results can be assured.

**Vaginal Hysterorrhaphy.**—Candela (*ibid.*, Jan. 10, 1889) describes an operation consisting in suturing the fundus of the uterus to the abdominal walls, through the vagina, without resorting to laparotomy. The operation has been performed by the author only upon the cadaver, but no great difficulty attended it. The three considerations concerning the operation are the preliminary precautions, the operation itself, and the subsequent attention. Under the first consideration is the treatment of those conditions which have arisen from prolapsus or retroversion, including endometritis and parenchymatous or perimetral congestions. Such treatment will include rest, the horizontal position, hot vaginal douches, intra-uterine irrigation, intra-uterine applications and curetting, closure of fissures of the cervix, and amputation of the cervix when that is indicated. The author's operation should not be done until the uterus and its surroundings are in a condition of physiological integrity. A day or two before the operation the uterus should be thoroughly and antiseptically dilated. One of the important means for performing the operation is the needle, which is made after the author's plans. It consists of a cylindrical cannula of about the length and curve of a uterine sound and three to four millimetres in diameter. Within this cannula is a metallic spring, at the superior extremity of which is fixed a lance point with an eye in the middle. The spring and its needle are controlled by a button at the lower extremity of the cannula. Before the operation is performed the sound must be passed within the uterus, and it must be ascertained how nearly that organ can be brought into contact with the abdominal wall, which is to be depressed to a sufficient extent behind the pubes. If the tissues are all relaxed and the uterus is readily brought into contact with the abdominal wall, the operation may be done with the patient in the dorsal posture. Otherwise the genu-pectoral posture should be used as in operations for vesico-vaginal fistula. In the latter posture the intestines will be projected forward and upward, and will not be injured. The bladder and rectum must be empty and all the tissues in an antiseptic condition. The vagina is held open with retractors, the uterus is drawn down by means of a forceps in the lips of the os uteri, the cannula is introduced, the abdominal wall depressed, and the needle forced through the fundus and abdominal wall. It is then threaded with antiseptic silk, the needle is drawn back again through the cannula, and one end of the silk is secured at the abdominal wall, the other at the vulva. Another suture is then similarly passed, its location in the abdominal wall being three or four centimetres from the first. The bladder is avoided in these manipulations, its limits being ascertained by means of a sound within it. The sutures are tied together at each extremity, the abdominal wall being brought into contact with the fundus uteri, the vaginal ends being secured into a small plate of some suitable metal, after which the vagina is irrigated and packed with antiseptic gauze. Through the punctures in the abdominal wall two or three drops of tincture of iodine are injected in order to excite adhesive inflammation. After the operation the pain may be relieved by enemata of chloral or the suitable use of opium. Liquid food should be given for six days, and if the bowels are inclined to move, an enema of warm water should first be administered. If there is rectal or vesical tenesmus, a blister should be used over the hypogastrium. The sutures may be removed on the eighth to the tenth day. Vaginal douches should be given daily for ten days, after each of which the vagina should be retamponed.

The author believes that this operation is applicable to most cases of prolapsns, and is superior to Alexander's operation for retroflexion. The dangers of laparotomy are avoided, and it is easy of performance. [This is essentially the same operation which has been advocated for several years by Schücking, and, so far as we know, has not been accorded a very favorable reception, either in Germany or elsewhere. Wisely, too, we think.]

**Dilatation of the Cervix for Hæmorrhage from Myomas.**—Kaltenbach (*ibid.*) remarks that Baker Brown and Nélaton observed independently and about the same time that thorough curetting of the cervix would diminish or prevent the hæmorrhage from interstitial myomata. Subsequently, and in the course of some ineffective attempts at enucleation, Baker Brown found that by scraping the circular muscular fibers of the os internum he was able to set up energetic contraction in the vicinity of the myoma, which became elongated and effectually tamponed the uterus. Others have observed favorable results in cases of submucous or interstitial myoma which extended to the os internum, or were prolonged into the cervical canal, by following Spiegelberg's recommendation of incising the capsule of the tumor, thus causing retraction of the tumor and of its vessels. Quite recently Kaltenbach has seen three cases of interstitial myoma in which the hæmorrhage did not cease until the cervix had been dilated. Stenosis of the cervix really favors continuance of the haemorrhage, preventing free exit of the blood. In such cases there is pain during the first two or three days of the menstrual period, the blood accumulating in the cavity of the uterus, dilating it, and enlarging the area from which haemorrhage proceeds. Dilatation of the canal by removing the mechanical obstacle relieves the unfavorable conditions.

**Salpingitis and Castration.**—Doléris ("Bull. et mém. de la soc. obst. et gyn. de Paris," January, 1889) says that salpingitis is not a recently discovered disease. It dates from Spronius, and is mentioned by Morgagni in his thirty-eighth letter. There are many cases in which the disease can be cured without ablation of the annexa, the author's experience demonstrating that the intratubal collections can be evacuated by extensive and permanent dilatation of the uterine cavity combined with curetting and drainage of that cavity. Certain well-settled points in connection with this subject must be remembered:

1. There is frequently distension of the internal segment of the tube and its uterine orifice when there is a chronic inflammatory condition of the tubal walls, combined with an encysted exudate in its middle portion and occlusion of the pavilion.

2. There may be a spontaneous evacuation of such collections, either at the time of the monthly period or as a result of some form of traumatism.

3. Diseased tubes are frequently alternately filled and emptied during months and years, a sudden and abundant flow marking each evacuation.

4. Cure has been obtained in many cases of supposed hæmatocoele or circumuterine phlegmon which were, in fact, cases of hæmatosalpinx, hydrosalpinx, or pyosalpinx, by evacuation of the tumor *per vaginam*, by the aid of a knife, trocar, thermo-cautery, or electrolysis.

5. Some cases of tubal disease have been cured by laparotomy, with incision into the tube, evacuation, and drainage, its walls being fixed to the abdominal wound.

After reviewing the different varieties of salpingitis, with their causation, the following conclusions are offered :

1. Active means of treatment should not be used in cases of acute recent salpingitis, but one should wait several months until the existence of a tubal tumor is fairly demonstrated.

2. The ablation of the annexa should only be proposed after the failure of more conservative treatment.

3. The artificial evacuation of the tumor will suffice for the cure of the greater number of the forms of tubal cyst.

4. A hastily made diagnosis of salpingitis, followed by the removal of the annexa after a very brief delay, is the negation of every sound principle of gynaecology. The deliberate sacrifice of the essential organs of reproduction in a woman is an inexcusable fault.

The artificial dilatation of the uterus furnishes a good means for opening a passage for the secretions and assuring the permeability of the uterine and tubo-uterine canals, and this should be preceded by a

careful enretting. Nine cases were treated in this way with satisfactory results. The author's method consists :

1. In slow and progressive permanent dilatation of the uterine cavity. This may require several days, and may be accomplished with disinfected laminaria tents or with disinfected sponge. It may be desirable to use the two agents successively.

2. In careful curetting of every portion of the uterine cavity.

3. In drainage of the cavity, which is tamponed with iodoform gauze, moistened with glycerin.

**Chronic Tubercular Endometritis.**—Jouin (*ibid.*, March, 1889) says that this form of tuberculosis is more frequent than tuberculosis of the other mucous membranes of the genito-urinary apparatus. This may be due to the fact that the mucous membrane of the body of the uterus is soft, spongy, and rich in tubular glands, these conditions being favorable to the development of an anaerobic parasite. It has been observed and described to a certain extent by Louis, Aran, Bernutz and Goupil, and Verneuil, but the primary form has not been distinguished with sufficient clearness from the secondary by any one of these writers. Fernet described primary genital tuberculosis in the female, and spoke of its origin from sexual contact with a tuberculous man. Cornil and Chantemesse have also produced it artificially in rabbits by the injection of bacilli into the vagina. The author's studies included nine cases, in two of which the disease followed sexual intercourse with men suffering from genital tuberculosis. In two others the husbands were tuberculous, but had no apparent genital tuberculosis. In three others the cause could not be ascertained, and in the remaining two the cause was also uncertain. The diagnosis was verified once by the microscope and twice by the peritoneal inoculation of guinea-pigs. The disease is primarily a tubercular degeneration of the endometrium, but the uterine parenchyma and the perimetrium may also be involved. The predisposing causes may be heredity and bad general condition, also ruptures of the cervix and repeated attacks of inflammation. The determining causes are the bacilli and sputa upon soiled linen, or even upon various instruments, and especially sexual relations with a tuberculous husband. The fungosities upon the endometrium in these cases contain bacilli, with which guinea-pigs have been successfully inoculated. As to symptoms, the patient is the subject of leucorrhœa, pain in the abdomen, scanty micturition, constipation, and sterility. After a time the uterus becomes much enlarged and very sensitive to the touch, also more or less fixed. The cervix is red and perhaps ulcerated, and a sanguous matter is discharged from the canal. The patients are much more prostrated than in simple endometritis, and have emaciation, fever, sweating, and arthritic troubles. Without proper care this condition will extend to the lungs, but it may be arrested by local treatment. The diagnosis is to be made by histological and microbiological examination, but also by observing certain clinical phenomena. The disease does not begin after labor nor after hemorrhagia; the patient may not have had children, and the lungs may already present tubercular lesions. The primary form of the disease is not serious if properly cared for; the secondary form implies tubercular disease elsewhere.

In treating the disease the patient should first receive creasote. Curettage may be practiced, if thoroughly done, and the mucous membrane should then receive an application of creasote. Pencils of iodoform may also be introduced into the uterus, the organ having first been well dilated. This should be repeated every twelve days. Sexual intercourse should be abstained from as long as the disease continues. The hygienic and dietetic conditions must, of course, be as favorable as possible.

**The Treatment of Uterine Fibromata.**—Délétang ("Concours méd.," Dec. 22, 1888) states that since 1884 he has treated ninety-seven cases of uterine fibroid tumor, all of the interstitial variety, with intra-uterine electrolysis. Fibro-cystic tumors and pedunculated fibroids were considered unsuitable for this method of treatment. The immediate effects of the treatment consisted of the following :

- A. A contraction of the uterus *en masse*, including the tumor, at the beginning of the treatment. This contraction was not constant.

- B. A congestion of all the organs which were intercalated within the circuit. The congestion was nearly constant, and usually continued several hours with accompanying colic pains.

- C. At times there was immediate disappearance of pre-existing

haemorrhage. The subsequent effects usually were in the following order:

1. The haemorrhage disappeared after recurring to a slight degree in some cases.

2. The pain and the functional troubles ameliorated, the phenomena not being dependent upon the size of the tumor, but rather upon the inflammatory zone which frequently surrounds such growths.

3. There was diminution in the size of the tumors, but two phases of this were distinguishable:

a. The peripheral inflammatory zone was absorbed, and the fibroma appeared smaller and less hard, but its retraction was at first only apparent. As a result of this absorption there was a segmentation into large masses, and a condition of mobility where there had previously been adhesion and immobility. At such a time the morbid phenomena were wont to disappear and the general condition to improve. In some cases there was a temporary aggravation of all the symptoms, which was due to congestion of the inflammatory zone.

b. The retraction of the fibroma was not constant. The influence of the electric current was far more pronounced upon metritis and the accompanying symptoms than upon the fibroma itself, but this does not diminish the value of the electrolysis. Notwithstanding the persistence of a tumor which is hard but well tolerated, women will frequently declare after such treatment that they are cured, and can not be convinced to the contrary.

In some of the author's cases an atresia of the cervical canal was produced by the electrical treatment, but this yielded readily to suitable dilatation. Currents of moderate intensity were used, one hundred milliampères being the usual strength, excepting in rebellious cases. The current was used five minutes at each *séance*, and the intervals between treatments were five or six days. All necessary antiseptic and other precautions were rigorously observed. In the 1,100 *séances* in which the author used this treatment there was but one accident, that being a slight phlegmasia. If currents of higher intensity had been used, it is possible that better results might have been obtained, and that they might have been obtained more rapidly.

## Miscellany.

**The Paris Universal Exhibition.**—The "Lancet's" special correspondent writes to that journal as follows:

On Wednesday, August 7th, as announced in a previous letter, the members of the Congress were up betimes, so as to catch the special train destined to take them to Rheims. After a three hours' journey we reached the historic town. A number of brakes, vans, and carriages were waiting at the station, and we were conveyed some distance out of Rheims to view the sewage farm. This is quite a new institution, and only commenced to receive the sewage some four months ago. The town possesses 150 hectares, but can dispose, for irrigation purposes, of 500 hectares. This is amply sufficient, and when there is a storm, or when by some other cause there is more sewage than the soil under cultivation requires, the water may be thrown on some waste land. Thus the danger of flooding the ground is obviated and underground drains are not required. There is a pumping-station to send some of the water up to the higher grounds, which reach an altitude of twenty metres. Unfortunately, the chief utility of this sewage farm is to prevent the contamination of the river. It does not in any way solve the drainage problem. Rheims still drains into cesspools; the town has not water enough for water-closets, but when the water-supply has been increased then the existence of this sewage farm will enable the town to drain direct into its sewers. After duly investigating all these facts, the Congress was entertained at lunch at the Château des Maretz, which belongs to the company that has undertaken the management of the sewage farm. The lunch was served in a magnificent avenue of trees. Of course, there were some excellent speeches, notably by the director of the company, the prefect of police, the Mayor of Rheims, Dr. Napias on behalf of the French, and Mr. Adolphe Smith, who was specially re-

quested to return thanks by the Swiss, Turkish, Russian, American, and English delegations. Madame A. Tkatchef, doctor in medicine, spoke for the ladies, and the utmost enthusiasm prevailed. The Congress then visited the cathedral, the Pommery champagne cellars, and were again entertained, this time by the municipality of Rheims, at a second lunch given in the Town Hall. Here more speeches were delivered. Those who participated in this pleasant journey will recognize that the study of serious subjects does not interfere with the spirit of mirth and the sense of enjoyment.

On the following day, Thursday, the Congress set to work again in good earnest. In Section 1, M. Delvaille (Bayonne) urged that the medical inspection of schools, as prescribed by the law of 1886, should be more rigorously applied, and that medical officers should be appointed for this purpose. Dr. Sevestre, of the Paris pauper children's hospital, urged that it was in its earliest manifestation that measles was most contagious, and that children suspected of this complaint should be kept away, but that the convalescents might be allowed to return earlier than was at present the custom. Dr. Layet (Bordeaux) related that, by exceptional severity toward the "suspect," they had avoided the necessity of closing schools, while Dr. Rochard insisted that the school teachers must be instructed in these matters. It was no use relying exclusively on the medical profession, for there were 28,000 communes in France which had no doctor. With regard to shortsightedness in schools, Dr. Motais (Angers) gave the results of investigation on 6,700 children. He found that shortsightedness was much more frequent in Germany than in France, but that it was growing to an alarming extent in France. He was anxious to see the course of studies varied and children prevented from looking for too long a period at some near object.

In Section 5, Dr. Alméras (Menton) read a paper on the contagion of consumption, in which he complained that delicate persons were afraid to visit winter resorts for fear of contracting phthisis. He therefore asked that hotel keepers should take rigorous measures to disinfect rooms which had been occupied by consumptive patients. At the present time hotel keepers generally charged £12 in case of death, under the pretext that the room had to be purified; but it was rarely, if ever, properly disinfected. He proposed that the ceiling, walls, etc., should be submitted to a pulverization with a sublimated solution containing 2 of mercury per 1,000 of water and 12 in 1,000 of tartaric acid. When this was dry, then the same place should be similarly sprayed with a one-per-cent. solution of carbonate of soda. This would convert the sublimate into insoluble salts. This service of disinfection should be managed in winter health resorts by representatives of the public authority, and hotel keepers should receive written certificates from the municipalities that the work had been properly done. If this certificate could not be produced, strangers should refuse to hire the room or apartment.

Dr. de Valcour (Canues) described three cases of scarlet fever following upon each other in the same room of a hotel where disinfection had not been practiced, and called upon Mr. Adolphe Smith to describe the English law on the subject. After the Congress had heard this explanation, Senator Dr. Pacchiotti related how a lady belonging to an aristocratic and influential family was taken away by the police from an Italian hotel (though she was in a very grave condition, and subsequently died), so that she should not infect the hotel with the small-pox she had contracted. The Italian law had armed medical men with sufficient powers to see that proper precautions were taken. Dr. Felix (Bucharest), on the contrary, was loath to ask too much from the state, and more anxious to so educate the people as to make them spontaneously and willingly take the precautions judged necessary. At Bucharest they had a disinfecting stove, and he was surprised to note how many persons came of their own accord and asked to use it. The declaration of infectious diseases was not obligatory in Roumania, but the police had ample powers over hotels. A Swiss delegate explained that only in some cantons was a notification of disease obligatory. Disinfection in towns was easy, but difficult in country districts, though there were epidemics in villages as well as in towns. The section concluded that in each sanitary district a disinfecting service should be organized, and that the carding of bedding in the streets or squares of towns should be prevented.

Dr. Devillers brought forward a motion against fairs held in large

towns. He related that in 1886, in the Belleville districts of Paris, small-pox broke out immediately after such a fair, and in houses that faced the street where it was held. This present year it had been noted that there were six times as many cases of scarlet fever near one of these fairs as in other parts of Paris. In some provincial towns similar observations had been made. Apart from epidemic diseases accidents sometimes occurred, and the noise was most distressing to many persons, especially to invalids. Some speakers objected, on the other hand, that the special tax levied on these booths provided money for the elementary schools; nevertheless, the Section voted that such fairs should be held in open spaces outside large towns, and not in the streets.

Dr. Martin now read a learned dissertation on the condition of French sanitary legislation. He lamented that there was no law against infection. Theoretically the mayors had considerable powers, but, as they could not act without funds, and could not obtain funds without a vote from the municipal councils, their powers were rather nominal than real, especially in cases of emergency. Nor had the mayors received any support from the higher Courts of Appeal. For instance, during the cholera epidemic of 1885, the Mayor of Caen had suppressed a cesspool which caused a great nuisance and contaminated the subsoil. On appeal, the Higher Court, while recognizing that it might have been necessary to suppress the cesspool, decided that the mayor had no right to prescribe how this should be done, but should have left the work to the discretion of the owner. Practically, if the sanitary authority had no right of supervision, it would mean that the work would not be done, or would be done badly. Again, at Toulon, during the cholera, a man refused to whitewash his room; the municipal authorities thereupon sent their agents to do the work. The owner appealed to the local police court, and this court approved the action of the municipality, but when taken up to the Court of Cassation, this tribunal refused to confirm the decision of the Toulon police magistrate. Municipalities, after such judgments, are afraid to act. The French penal code, it is true, gives the right to sue for damages, but to apply this in cases of contagion would be so unusual that no court would grant a verdict. Yet there are laws in France that are very severe, especially against foreign epidemics, such as cholera, plague, yellow fever, and in some cases penalties of one year's imprisonment and even a sentence of death can be applied; but the utter lack of national feeling renders it impossible to apply the legislation that does exist. The French sanitary law had been justly described as the "freedom of suicide." But no one had a right to create such infection in his own house, as it was likely to travel to the houses of others. It was not always the landlord who was to blame. Often a tenant would hire a stable or coach-house and convert it into a dwelling. The text of the law was extremely vague. What constituted an unwholesome dwelling should be clearly defined, and not left to the discretion of judges, who very often were absolutely ignorant as to the rules of health. Many courts by their verdicts had set forth that they did not consider a supply of water in a house a necessity. A high court had condemned a local by-law ordering that houses should be supplied with water as an attack against individual liberty. The best method of action and of punishment was for the sanitary authority itself to effect the required improvements and charge the owner with the cost. Only this must be done promptly. As matters now stood, legal decisions sometimes were obtained months after the nuisance had ceased to exist.

The discussion on this important subject was resumed in the afternoon sitting, when the difficulty of uniting the commissions of hygiene and similar bodies composed of men technically qualified to deal with such questions, but possessing at present only the right to give advice and no executive powers whatsoever, with the mayor, the prefect, or other authorities who could act, was very fully debated. The facts also that the mayor had to consider his electors, and if it was a fashionable resort he had to be very careful not to spread alarm, were obstacles to the stringent application of prophylactic measures. Two bills had been before Parliament to create a sanitary law and a sanitary authority. The project presented by M. Siegfried was countersigned by no less than fifty deputies belonging to all parties, and yet it had fallen through, such were the purely political preoccupations of the National Assembly. Dr. Treille (Deputy of Constantine in the French Parlia-

ment) remarked that as the sanitary services had been transferred from the Ministry of Commerce to the Ministry of the Interior, and were in the hands of a man on whom sanitary reformers might rely, we could look forward to considerable improvement. Parliament would not resist a project if its necessity was clearly demonstrated, but he would suggest that the bill had better be first introduced into the Senate. Dr. Martin thought it was urgently necessary to alter the law of April 14, 1850, which had rendered the law of 1789 inoperative. The Belgians, it had been seen, had availed themselves of the law of 1789, with the most admirable results so far as Brussels was concerned. Here 12,015 lives had been saved in fifteen years. Taking the one year 1886, there were 628 deaths less than the average. Estimating every life at the modest sum of 1,000 francs, this represented a sum of 628,000 francs, and, as the Sanitary Bureau which had accomplished this result only cost 48,000 francs for the year, this was equal to an investment bearing an annual interest of 1,400 per cent. On hearing these details the Section burst into loud applause, and Dr. Janssens, the chief of the Brussels Sanitary Bureau, had to rise over and over again to bow his acknowledgments. After a few more observations from different speakers the Section adjourned.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

**Authors of articles intended for publication under the head of "original contributions"** are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

**All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication.** No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

**Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings.** Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

**Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked.** Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

**All communications intended for the editor should be addressed to him in care of the publishers.**

**All communications relating to the business of the journal should be addressed to the publishers.**

## Original Communications.

### A CASE OF RUPTURE OF THE UTERUS AND A CASE OF CÆSAREAN SECTION.\*

BY WILLIAM T. LUSK, M. D.

On this the fifth anniversary of the Fifth District Branch of the State Association it is my pleasant duty to congratulate the members present upon the prosperity of the organization they represent. The rapid growth in membership, the zeal exhibited for the principles for which the organization stands, and the scientific merit of the work performed at these annual gatherings, are all prophetic of a long and useful life. But I will not take up your time with laudations of ourselves. With the permission of the society, I wish to occupy the attention of my audience with the relation of two cases, which I have hitherto refrained from publishing, that they might have at least the merit of freshness on this occasion.

CASE I. *Labor at Full Term; Undilatable Condition of the Cervix due to Cicatricial Tissue; Spontaneous Rupture of the Uterus.*—Martha G., aged thirty-three, was brought by ambulance to the Emergency Hospital, near midnight on the 10th of November, 1888. She exhibited signs of severe suffering. Temperature, 99.5° F.; pulse, 140. The features were pinched and the face was pallid. The patient was semi-maniacal. No history was sent with her, but, so far as could be ascertained from her somewhat incoherent statements, this was her second pregnancy. Her first confinement had been a prolonged one, and had been terminated by instruments. The present labor had lasted about thirty hours.

I was hastily summoned. On my arrival I found the membranes had long ruptured, and the uterus was firmly retracted upon the child. The body was apparently situated in an oblique position, with the head directed to the left. The uterine contractions were severe and rupture was regarded as imminent. On vaginal examination, I found that no dilatation of the cervix had taken place. By pressing the index finger slowly upward, the os internum was reached. To my surprise, I discovered that the non-dilatation of the cervix was due to firm cicatricial tissue situated at the internal os and extending somewhat over the lower segment.

With the impending danger of rupture I decided upon the Cæsarean section, and, with this object in view, the woman was removed to the isolation ward in the Sturgis Pavilion at the Bellevue Hospital. At the sight of the preparations for the operation the patient began to beg and implore most piteously to be left in peace until daylight. Her cries and importunities led to hesitation, and hesitation, as the sequel shows, proved fatal, for, while the question was under debate, she called for a chamber, saying she wished to pass urine. When placed upon the vessel she began, in spite of every attempt to control her, to make violent straining efforts. Suddenly she fell back unconscious. The pulse was almost imperceptible; the entire surface was intensely pallid, and the body was covered with

clammy perspiration. It was evident that our worst forebodings had been fulfilled. Uterine rupture had taken place. The patient did not rally, and death followed in about two hours.

November 11th.—Autopsy made by Dr. T. Mitchell Prudden. In his report he says: "The body was fairly well formed and nourished; stature short; decomposition considerably advanced; abdomen much distended.

"On making the abdominal incision, the body of the child was found, corresponding to the long axis of the mother's abdomen, with the back directed to the front. The head of the child was bent sharply to the front. There was about 55 c. e. of soft red blood-clot in the abdominal cavity.

"The rent in the uterus extended obliquely across the uterus from the upper cervical portion to the right side of the fundus. The walls of the uterus were about one centimetre thick, and the ragged edges of the rent were deeply stained and infiltrated with blood.

"The placenta was firmly attached to the left upper segment of the uterus, which contained about 60 c. e. of dark, soft blood-clot.
