8. Inhalation of rarefied air with exhalation into compressed air.

If a pump and motor are substituted for the foot-bellows, the only inconvenience connected with office use of the apparatus can be obviated. The additional cost is not excessive, and it leaves the apparatus still well within the price of any other capable of doing the same work.\*

\* Mr. Metzger sells either the compression or rarefaction apparatus singly, with all necessary attachments, for \$30, and the double apparatus for \$50. With pump and electric motor, the cost would be increased from \$25 to \$35 additional. Codman & Shurtleff sell the resistance valves for \$5 a pair. Both manufacturers inform me that the time necessary to secure accurate adjustment of all parts of the appa-

My endeavor has been throughout to use the simplest and least expensive methods and mechanical devices, and I have tried to induce the manufacturers to reduce their prices to the lowest point, in order to secure the widest possible and freest possible diffusion of the method, which I look upon as one of the most valuable within the reach of the therapist. The therapeutic expedients most generally employed are inhalation of compressed air and exhalation into rarefied air, and I shall speak of these only and briefly.

In using the apparatus the patient should preferably stand, but he may sit if necessary. If a face-mask is used, it should be accurately adjusted over the nose and mouth, and made to lie close to the cheeks to prevent escape of air. A glass mouth-piece may be used instead of a face-mask in many cases; and it is unnecessary to close the nostrils, as the nose and mouth can not be conveniently employed together for forced respiration, and there will be no interference. Each patient should have his own mask or mouth-piece.

At first the smallest pressures only should be employed ( $\frac{1}{10}$  or  $\frac{1}{6}$  atmosphere), and these may be gradually increased according to indications. It is never advisable to exceed  $\frac{1}{6}$  atmosphere. From ten to fifty or even one hundred respirations, occupying from five to twenty minutes, are made continuously, beginning with the smallest number and gradually increasing. After inhaling for a while, say ten minutes, a rest of ten minutes or more is taken, after which the process is repeated. This may be gone through with once, twice, or three times daily, according to indications. Where the patient has an instrument at his home, it is employed more frequently than when it is necessary to visit the physician's office in order to obtain the facilities.

The physiological effects of these expedients are very apparent. The effect upon the circulation of increasing the pressure within the thorax, as compared with the pressure upon the periphery, by inhalation of compressed air, is, in brief, to drive the blood toward the point of least pressure—that is, out of the thorax. On the other hand, the effect of exhaling into rarefied air, thus increasing the pressure upon the periphery, as compared with that within the thorax, is to drive the blood into the heart and lungs.

The effect upon the respiratory act is equally obvious. If the pressure within the thorax be made greater than that without, expansion will be effected with less muscular effort. The air-cells are fully dilated, and occluded areas of lung tissue are forced open where the pathological process is not of such a nature as to prevent this result. There is also pressure upon the inflammatory congeries of new cells and upon congested blood-vessels, tending still further to increase the amount of available lung tissue, and to a certain extent to relieve congestion and promote resolution of inflammation. It acts as pressure by means of the bandage acts in external inflammations. The activity of the pulmonary circulation being increased, as well as the activity of the systemic circulation, a greater volume of blood passes through the pulmonary capillaries in a given time, and is

exposed to a greater amount of oxygen under pressure—conditions which slightly favor the absorption of oxygen. As the increased volume of blood carries a greater number of corpuscles, theoretically it would seem that there should be a greater activity of oxygenation, and this has been confirmed by exact investigations conducted by Waldenburg, Speck, and others, and of which a full summary is given by Oertel in his admirable treatise. Subsequent exhalations are freer and longer, and a greater amount of carbonic acid is given out, thus increasing pulmonary ventilation. Masses of desiccated secretion, desquamated epithelium, etc., are mechanically dislodged and their expulsion by cough facilitated, so that at first cough is increased. It is afterward lessened by correction of the conditions producing it. In the light of our present knowledge of auto-intoxications, the cleansing of the lungs from these decomposing masses of effete material must be considered of no little advantage.

Expiration into rarefied air facilitates emptying of the lungs, and, consequently, contraction of the chest is more complete. Subsequent inspirations are deeper.

By exhaling into rarefied air after inhaling compressed air we emphasize the difference between the two processes, and make an alternation of pressure-effects upon the vessels. All the effects before noted are thus heightened. An improved respiratory habit—that is to say, a fuller, freer, and more regular habitual respiration—is brought about, and the gain in vital capacity is very great. Not only is the exhalation of carbonic acid favored, but the subsequent absorption of oxygen is augmented on account of the greater extent to which emptying of the lungs has been secured. The alternating effects upon the alveoli increase the elasticity of the lung tissue. The alternate filling and emptying of the vessels stimulates circulation, increasing both rapidity and volume.

I am aware that doubts have been cast on the possibility of increasing the absorption of oxygen. Be this as it may, the effect clinically is to vastly stimulate and increase the nutrition of the patient. By careful observation I have been led to attribute this increase of nutrition to the ease with which the patient is able to dispose of the greater amount of nutriment which we administer. A patient overfed but not taking inhalations of compressed air, will not increase so rapidly in weight as one who is overfed and at the same time taking these inhalations. A patient taking inhalations of compressed air and not overfed will not increase in weight. I have thought that the great gain was due to the stimulation afforded to the secondary assimilation and to the general metabolism. Tissue respiration and the activity of the erythropoietic processes are increased by the increased activity of circulation, the heightened blood pressure, the augmented pulmonary gaseous exchange, and also by the pressure transmitted from the diaphragm upon the abdominal organs. Patients with pulmonary troubles who are taking iron will take larger quantities and bear it better. This is also the ease in anaemia and chlorosis. One of the earliest manifestations of improvement is promotion of sleep, due partly to relief of cough and improvement of respiration; partly, perhaps, to improvement of metabolic processes and consequent elaboration of physiological hyp-

noties. There is also an obvious gain afforded by the exercise to the chest muscles, to which a portion of the augmentation in vital capacity must be attributed. Some four or five years ago I published a number of personal observations on the increase in the chest capacity from inhalation of compressed air. The results were not so remarkable as some of those published by European observers, but they indicated a gain of from twenty to thirty cubic inches in respiratory capacity, and from half an inch to an inch and a half in chest expansion. This was in patients in whom chest expansion and respiratory activity had been impaired by condensation of the lung from phthisical or pneumonitic processes, or from the presence of pleuritic effusion. Pressure stimulates absorption of pleural effusions, and after the effusion has been absorbed the inhalation of compressed air tends to hasten the re-establishment of the normal action of the lung.

In two cases of asthma I have overcome the spasmodyc dyspnoea of the acute attacks by the inhalation of compressed air at rather great pressure ( $+ \frac{1}{30}$  to  $+ \frac{1}{20}$  atm.). I suppose that the rationale of the effect is, in part, the paralyzing of the spasmodycally contracted muscles of the bronchioles by the increased pressure of the air, and in part the relief of fluxionary congestion by direct pressure upon the engorged vessels, acting somewhat upon the principle of Monell's method of fixing the feet against the foot-board of the bed, taking a deep inspiration and holding it as long as possible.

The pneumatic expedient which has afforded the best permanent relief in asthma, especially when dependent upon emphysema, is, I think, expiration into rarefied air. This promotes collapse of the distended air vesicles and tends to relieve the lungs of the accumulation within them and, to a certain extent, to obviate paralytic distension in consequence of the presence of a greater amount of air than they should normally contain. It can not, of course, restore destroyed septa.

I have also thought, in common with those observers of largest experience in pneumotherapy, that the inhalation of compressed air had some good effect in the treatment of dilated heart from the pressure exerted upon the pulmonary vessels and cardiac chambers. Latterly I have employed in this condition expiration against pressure by means of the resistance valve, an expedient still more physiological. I have not used expiration into rarefied air in these cases, believing it to be counter-indicated, although it has been recommended by some.

There are many other obvious clinical applications of this method of treatment, but my object in bringing the subject before the college has been more particularly to show what can be done mechanically by a simple apparatus which may be placed in the patient's home, and not to refer especially to therapeutic uses. These would depend upon the views of the physician, and the experience which he obtains in the management of the method. The greater that experience, the more confidently will he extend it.

The effects are purely physical and mechanical, and easily deducible from a knowledge of the physical and mechanical effects upon normal circulation and respiration.

The one great advantage of the compressed-air machine

is that it will enable us to treat at home patients with phthisis or threatened phthisis; and especially to prevent the development of tuberculous in patients having—perhaps with an apical catarrh as well—insufficient expansion, insufficient aeration of blood, insufficient nutrition, sluggishness of circulation, and impairment of the muscular apparatus of the thorax. These patients are often sent chasing around the world in the vain search for a restorative climate, but very few receive benefit, except, of course, such good as may be incidental to an outdoor life. There are, however, a very great majority of persons whose circumstances preclude the possibility of leaving home. I have elsewhere indicated how we may by a few simple expedients imitate many of the features of special climates.\*

I have not had a wonderful number of cases under my care, so that I can not give any extended statistics. But every year I see several cases of phthisis benefited and three or four cases improved in a remarkable manner. There is one case in particular which is in my mind, because I received a letter from the patient to-day:

It is that of a Bostonian, thirty-two years of age, who spent last winter in Philadelphia and, although the weather was unfavorable and she had an intercurrent pleurisy, made a good recovery. She had a large cavity in the right lung and a smaller cavity in the left lung. All of her father's family except her father, and many of her mother's family, died of consumption. Her mother was said to have had consumption, but recovered under open-air life, forty years ago, and is hale and hearty. The father, who is some sixty-five years old, has fibroid phthisis, and is now breaking down. She was seen by Professor Da Costa at the beginning of the treatment and at the end, and he was able to verify both the pulmonary conditions and the great gain. When she began treatment her weight was 107 pounds; when she left Philadelphia in May it was 135 pounds, and in a letter received to-day she states that she now weighs 152 pounds. She had an evening temperature of 100.5° F., and all the troublesome symptoms of phthisis in the stage of softening. She went home with normal temperature and troubled only by more or less coughing, which has steadily decreased. The treatment was simply that of nutrition, overfeeding with nitrogenous and fatty aliments, whisky and hot water, aided by inhalation of compressed air, which enabled the increased quantities of food to be disposed of. The patient was kept out of doors as much as possible, and instructed to take deep and slow respirations continuously. Medication was principally symptomatic, for relief of cough, for disinfection of the alimentary tract, or for stimulation of digestion. She was given at different times creasote, iodoform, arsenic, amyl nitrite, and compound spirits of ether, with inhalations of terebene, chloroform, or ethyl iodide from the Yeo (perforated zinc) respirator, or from the Oliver nebulizer. I must not forget to add, in defense of a method of treatment now abused in neglect, as formerly in extravagant use, that the Bergeon injections of hydrogeu sulphide and carbon dioxide served a useful temporary purpose in controlling a recurrent suppuration in the partially healed cavity of the right lung, following the pleurisy.

This woman evidently inherits a consumptive diathesis—but also a good recuperative force, which only required to be put under favorable conditions. She had a machine at her hotel, and she obeyed orders as to diet with religious exactitude.

\* "Artificial Climatic Effects for 'Stay-at-Homes,'" "Philadelphia Med. Times," Feb. 6, 1886.

Patients who recover like this, stay recovered. I have two patients treated in 1883 and reported in 1885, who are still well; and some of my brother's cases referred to at the opening of these remarks have been well for twelve and thirteen years. Even patients that do not recover can be greatly improved. Life is not only prolonged, but it is made much more comfortable. And to return to what I deem the most important considerations, the treatment is essentially a home treatment, and it is within reach of those of moderate means.

### ON THE PRINCIPLES OF THE MECHANICAL TREATMENT OF HIP-JOINT DISEASE.\*

BY NEWTON M. SHAFFER, M. D.,

ATTENDING SURGEON IN CHARGE OF  
THE NEW YORK ORTHOPÆDIC DISPENSARY AND HOSPITAL;  
CONSULTING ORTHOPÆDIC SURGEON TO ST. LUKE'S HOSPITAL, NEW YORK.

HIP-JOINT disease, especially in childhood, may be described as a chronic tubercular lesion of the coxo-femoral articulation, with the major signs and symptoms in the initial stage suggesting a primary osteitis rather than a synovitis. The clinical history and the course of the disease, and the pathological conditions found both after excision of the head of the femur and after death, all tend to emphasize this statement. In discussing the principles which should govern us in the treatment of this lesion, I shall accept this as my text, for without some generally understood pathological basis it would be difficult to formulate any definite principles of treatment, either mechanical or otherwise.

Nor can we proceed intelligently without a glance, at least, at some of the more important of the signs and symptoms of the disease. And we will briefly consider some of them.

As is well known, an insidious and generally unexplained limp is almost always the first sign that claims our attention. And this very suggestive evidence of the change that is going on in the articulation is always, I think, accompanied by a still more suggestive and important indication—viz., an instinctive and involuntary muscular protection of the articulation. Long before pain or any apparent deformity appears these two important indices of hip-joint disease are present; and it is now, I think, generally accepted that the condition which accompanies these two signs, when typically expressed, is that of the first apparent stage of hip disease. My own experience has proved, and every year the proof has grown stronger and stronger, that this limp and this instinctive and involuntary muscular joint protection are necessary to establish a diagnosis of hip disease in the earliest stage. We all recognize that many other conditions may produce a limp and the muscular signs which simulate hip disease, but the differential diagnosis is not on the whole difficult, owing to the peculiar and expressive character of the involuntary muscular protection of the joint.

It is not assuming too much, I am sure, to say that these two signs—the limp and the instinctive muscular protection of the joint—have a peculiar significance. The limp may be interpreted as an instinctive effort on the part of the patient to avoid the increased inter-articular pressure produced by the simplest act of locomotion; and the second, the muscular protection, indicates that the muscles, acting upon the affected articulation, guard the joint when the joint lesion is exposed to even the slight traumatism of passive motion.

The whole expression of the articulation in the first apparent stage of hip disease is, if I may be allowed the expression, one of joint apprehension under certain tests and in certain conditions. It is very like the apprehension which accompanies the more advanced and painful stage of the disease, when any and every movement of the joint produces an agonizing pain—only the acute pain is absent, and the apprehension is less marked. In short, it is the first stage of a chronic disease, unmarked by pain or fever, and the whole expression of the affected joint under examination is that of a protest against traumatism, both the limp and the acute but slight muscular resistance crying out against the simplest functions of the normal joint—viz., gentle locomotion and a natural degree of articular mobility.

It is well known that this first stage of hip-joint disease—the stage of vulnerability—where the trouble has not fully developed, but where Nature has kindly given us ample evidence of the extensive mischief that is impending, the limp referred to as occurring in this first stage may disappear. The rest and protection which the patient instinctively gives the affected joint are sufficient in some cases to remove the limp and to modify the involuntary muscular protection. But the joint still remains vulnerable, and a major traumatism, like a fall or a blow, or even the constant repetition of the minor traumatism caused by locomotion, re-excites the latent pathological condition, and the limp returns and muscular protection again becomes pronounced. I have known this to occur seven times in one patient before the symptoms became so pronounced that a diagnosis was made, the surgeon in attendance being unfamiliar with the fact that a remission of the limp was likely to occur in the early stage. It has happened several times in my experience that the limp has disappeared without active treatment while the patient was under observation. I have watched these cases with much interest, and I have found that *the muscular protection of the joint did not wholly disappear, as the limp did*. It may be worth while to say that temporizing in these cases proved a mistake, for in every case, after a lapse of weeks or months, and in one case of two years, the symptoms reappeared with redoubled energy, and the lost time was not always wholly regained. In short, so long as there is a true pathological and involuntary muscular protection of a joint in the first stage of tubercular hip-joint disease (and also, I feel sure, in the second and third stages as well), we must imitate Nature's method and place the joint under conditions where it can receive no major or even minor traumatism.

And this, it seems to me, must be the fundamental prin-

\* Read before the American Orthopædic Association at its third annual meeting, in Boston, September, 1889.

ciple of mechanical treatment—viz., to protect the affected joint—and to secure for it that which Nature from the very beginning of the lesion attempts to secure—relief from traumatism. In the first apparent stage, that of the initial vulnerability of the joint, where the limp is slight and the muscular protection is only, perhaps, just perceptible, adequate mechanical protection of the affected articulation is just as imperative, in my experience, as it is when the disease is well defined and fully developed. All of the cases that I have watched where rest—simple rest in bed—has been pursued as the only treatment, have failed to obtain permanent relief. I have watched cases of this kind long enough to know that those which I have thought were cured, and if I had been writing an essay at the time they passed from active observation I should have reported as cured, have all, after a longer or shorter time, relapsed, if prompt relief from traumatism was not given by apparatus efficiently applied.

From a mechanical standpoint, therefore, the first object of treatment should be to modify or to absolutely remove, if possible, traumatic contact of the opposing joint surfaces in hip-joint disease; for, however much the medical profession may differ regarding the influence of traumatism as applied to the aetiology of this disease, I think none will deny its baneful influence after the lesion is once established in the joint. The second object, having placed the patient under the best possible local (joint) conditions for repair, is to surround the patient by those hygienic influences and to administer those remedies which will aid Nature in eliminating a tubercular disease. On this point I need not dwell. I think this association as a unit will agree that a patient with tubercular disease in any part of the body will do better, for example, in the pure air of the Adirondacks than in the wards of a hospital. And if the patient has hip-joint disease he will do better walking about in the fresh air in an efficient protective apparatus properly applied than if he be confined to bed with or without a protective splint.

To return to the first object—that of securing a modification of the traumatic contact between the surfaces of a tubercular hip joint. We have seen how Nature instinctively protects the diseased joint in the first stage. In dealing with the more difficult problems of the second stage (that of deformity) it will be well if we again look to Nature's methods and see what she attempts to do; and we will be wise if we imitate, if we can not always accurately follow, her example.

The first apparent stage of hip disease has been referred to. This early initial stage is one where, in my experience, it is comparatively easy to secure a perfect cure of the disease without deformity or without any serious modification of joint mobility. If the first stage, however, be permitted to go unchecked, as it usually does in the absence of any urgent symptom, the second stage, that of deformity, appears sooner or later. The signs rather than the symptoms of the stage of vulnerability have passed unnoticed, and Nature has narrowed day after day, week after week, perhaps even month after month or year after year, the arc of femoral movement in all directions, until in

many cases the results are apparent ankylosis of the articulation with a marked deformity. This deformity is apparent first as a flexion; then, as a rule, follows abduction, and this is usually accompanied by a rotation outward of the femur. After a time adduction and rotation in the opposite direction may ensue, but flexion is always present.

It is not only possible, and in many cases more than probable, that a good result may be obtained with free joint motion in the second or deformity stage. But the golden opportunity has passed when the limping gait becomes emphasized by a deformity, or, in other words, when the muscles, having placed the joint in the position of the least traumatism and of the greatest ease, instinctively and involuntarily protect, to the best of their ability, the diseased part or parts.

In the early part of the disease, and oftentimes in the second stage (before true adhesions have formed), if we administer an anaesthetic and pursue its effects until a profound narcotism is produced, we find there is little or no resistance to full and free joint motion. As soon as we temporarily interrupt the reflex arc, and relieve the muscles of their duty, we find the muscular evidence of hip-joint disease absent—*i. e.*, there is no resistance to free joint movement and there is no deformity.

Nature, in short, in hip-joint disease is producing in her own way an involuntary muscular splinting of the joint—the tense and shortened muscles, in a typical case, making an almost perfect coaptation splint. But there is this difference between the conventional coaptation splint of surgery and the involuntary muscular splint of hip disease: The force of the former is exerted, as in the treatment of a fractured thigh bone, for example, *laterally*, or in a direction which lessens the circumference of the splint. On the other hand, in hip disease the force of the muscular splint is exerted *longitudinally*—*i. e.*, in the direction of the long diameter of the contracted muscles, or in that direction which throws the head of the femur against its socket. This muscular splint in hip-joint disease simply avoids the major joint injury of motion and pressure combined by substituting for it another form of articular injury—viz., an inter-articular pressure which limits motion and retains the joint by means of this inter-articular pressure in that position which, unaided by art, inflicts the least injury to the diseased joint. The limitation of motion in the joint is accomplished only at the expense of an intensified joint pressure—a pressure which is much further increased by any form of mechanism which uses the femur as the long arm of a lever to correct the deformity.

When the second stage is reached, locomotion becomes very difficult, the whole body swaying around a deformed joint, and each successive traumatism—even that of walking with the aid of crutches, and surely that of an unscientifically applied apparatus—produces a fresh grazing field for the tubercular bacilli. The transition from the second to the third stage (that of joint disintegration) is so gradual that it is difficult to draw the line. But, sooner or later, if the disease be not arrested, a more or less rapid joint disintegration ensues. The femoral head becomes smaller and

smaller, the acetabulum becomes concentrically enlarged, perhaps perforated, abscesses may form, and finally, after the disease has run its course, the ultimate deformity and disability with which we are all familiar appear. Even in this last stage the muscles are tenacious of articular control and refuse to grant the full movement the altered joint surfaces permit. The muscles are only quiescent when in those exceptional cases, and after years of struggle, actual ankylosis occurs, or the tubercular process is wholly ended.

It seems perfectly apparent to me that the deformity of the second stage is due to an involuntary muscular action, and that the deformity of joint disease, irrespective of the question of whether there is a synovial effusion or pus within the joint capsule, represents Nature's position of greatest ease. This muscular coaptation splint is Nature's only way of modifying traumatic contact of the opposing joint surfaces, and this modification is secured by a change of position. It would seem that this muscular effort or splinting is more apparent in some cases than in others.

At the clinic of the New York Orthopædic Dispensary and Hospital we see quite often cases of very considerable and sometimes very tense accumulation of pus and tubercular material within the capsule of the knee and ankle joints where there is little or no interference with articular mobility. The deformity in these cases exists only in joint outline. The mechanical relations of the opposing joint surfaces are not interfered with and there is little or no muscular effort, either voluntary or involuntary, to control or limit the movements of the affected articulation, and pain is wholly absent. The signs of disease (there are no symptoms present at all) which present in this class of cases at the knee and ankle do not seem to indicate an osteitis; on the contrary, the synovial membrane is distinctly diseased and the lesion is probably confined to this membrane, and perhaps superficially to the cartilage also.

In this class of cases, where the synovial membrane is apparently much affected and the osseous tissues have escaped major injury, Nature makes no effort to limit joint motion by muscular action. I have attempted elsewhere to explain why this is so.\* I merely desire on this occasion to call attention to these two classes of chronic tubercular joint disease—the synovial and osteitic—and to say that where the synovial membrane is primarily and solely affected at the knee and ankle, the mechanical treatment should be different from that which will be mentioned in this paper on tubercular disease of the hip.† And I also wish to call attention to the fact that in hip-joint disease we are always met by the initial symptoms of a bone lesion rather than those of a simple synovial disease. Whether we have chronic synovial disease at the hip in the early stage of the trouble, it is impossible, from a clinical standpoint, to say. In the well-marked cases of uncomplicated synovial disease at the knee and ankle, the only evidence of the lesion, as already remarked, is an objective one—a

synovial swelling—a sign that for anatomical reasons is not always available at the hip.

The cases of synovial disease at the knee and ankle are, however, much less frequent than those which at the same articulations from a muscular standpoint are the perfect analogue of the muscular and deformity conditions found in hip disease. In these latter cases there is no essential change in joint outline, no evidence of a distended or swollen capsule or synovial change, but rather a spurious ankylosis induced by the same muscular conditions which produce the second stage of hip-joint disease. Here, in this latter or osteitic class of cases at the knee and ankle, it is easy to interpret Nature's effort to modify the traumatic contact of the opposing joint surfaces, and to understand that in the osteitic condition Nature abhors motion and uses every effort to restrain it, and to restrict it within certain limits. Within the limit set by Nature, motion I believe to be harmless, and hence it is that it seems wrong to immobilize a knee joint, for instance, with simple, uncomplicated synovial disease of the tubercular variety. But if we attempt, in the osteitic form of the disease, to pass beyond the limit set by Nature, or if we try by unscientific means to secure a better position for the distal half of the joint when Nature by her every expression says "No," we ignore the valuable lesson which she teaches us and inflict more injury, in many cases, upon the diseased articulation than all our boasted orthopædic science can relieve. And a very wide difference of opinion among both orthopædic and general surgeons would be bridged, I think, if the fact were recognized that where there is some or even a little motion at a diseased joint, true immobilization is not necessary. But motion under these circumstances should be controlled within the limit set by Nature. A joint that is practically immobilized by the muscular coaptation splint will recover motion under the absolute fixation of traction, as has been proved very many times.

I have seen on many occasions, especially in the large general hospitals of this and other countries, irreparable injury inflicted upon a slightly diseased hip joint by useless manipulations and tests, both with and without anaesthesia. I have known apparently curable cases to be rendered hopelessly incurable by an ill-advised attempt to rectify the deformity of hip disease in the second stage, when there was little or no thought bestowed upon the plain expressions, muscular and otherwise, of the pathological condition. The absence of pain is too often made the criterion of whether a patient with hip disease should be subjected to certain tests and certain forcible methods of treatment, the decision generally being that if there is no oral expression of pain the joint would stand almost any desired force without injury. My own experience leads me to say that very frequently the patient in whom there is an entire absence of the oral expression of pain is the one who should be the most carefully and conservatively treated, and about whom should be thrown the most careful safeguards against traumatism. No one, for example, would be likely to advise the use of forcible measures to remove deformity in a case of hip disease when the patient was in the exquisitely sensitive stage; and yet many patients, where this acutely

\* "The Etiology and Pathology of Chronic Joint Disease." "A Series of American Clinical Lectures," vol. iii, No. 6.

† "A Lecture on the Prognosis and Treatment of Ankle-joint Disease." "Annals of Anatomy and Surgery," May, 1882.

sensitive stage is but a step removed, are subjected to unnecessary and in many cases to unscientific measures of treatment. My experience leads me to say that if there is a condition where preventive measures can be applied, where much mischief can be prevented, where it is our duty to anticipate the next bad phase of the disease and to avoid it, it is in hip-joint disease and allied affections; and he who passes by unheeded the plain indications, or he who with a limited experience maintains that operative surgery can accomplish in the treatment of chronic joint disease more than Nature, conservatively assisted and protected, has yet to learn the pleasure that can be derived from a patient and diligent conservative treatment of a diseased joint.

If, then, we are to aid and imitate Nature, rather than to force her, in the treatment of hip-joint disease, and we have interpreted aright the various phases of this condition, there need be no hesitation as to the course to be pursued.

In the first stage—that of the earliest noticeable vulnerability of the disease—when there is a slight limp and an almost normal arc of motion, it is comparatively easy to protect the articulation from traumatism, because nature affords a wide range of movement within which, with scientific mechanical protection, it would be difficult to apply any traumatism to the joint. There is no articular deformity present and the muscles are not tense and irritable, except as the vulnerable parts are exposed to contact or pressure. While it would seem that the mechanical treatment of these cases is simple, it is best to take no risk, but to make the artificial joint protection as complete as possible. The major difference in the detail of treatment between the first and second stage is that while in the second stage we must overcome or greatly modify the deformity before permitting locomotion—and a shorter or longer period of reenbency is necessary to accomplish this—in the first stage we have no deformity and the patient can at once assume the upright position and walk about in a properly constructed apparatus. When the deformity of the second stage is removed, locomotion—also with the aid of proper apparatus—is to be advised, and within certain limits encouraged.

It is therefore the second stage of hip-joint disease that demands our principal attention, for in this stage we are met by the most expressive evidence of the disease and the most important problems of treatment, and it is in this stage that a single error may undo the work of previous weeks or months.

Let us, for example, take a case of hip-joint disease in the second stage, where there is a marked deformity and where there is a very considerable modification of articular mobility, and attempt to determine the indications for the mechanical protection of the joint. We need not stop to consider whether pain or abscess are present. The indications from a mechanical standpoint are the same whether these conditions are present or absent.

The principal apparent expression of the joint lesion is the deformity. It is so important, both to the mind of the patient and his friends and, in many instances, to the surgeon himself, that the grave lesion of which it is the simple index

is lost sight of, and the mistake is very frequently made of hastening the reduction of the deformity at the expense of the articular disease itself. It is here that errors are most frequently made, and it is here that we should be prepared to use, with all patience and diligence, the most scientific and efficient means at our disposal. I have often remarked that if hip-joint disease was unaccompanied by its expressive deformity it would lose its principal terrors for both the surgeon and patient; and he who would strive for the best attainable result in this formidable complaint must always remember that hip-joint disease is no trifling affair, and that it were better—far better—to use no mechanical treatment at all than to attack the disease by an immature and unscientific effort, by apparatus or otherwise, simply to modify one of its signs. I have no doubt at all that much irreparable mischief and that many avoidable abscesses and death itself have been occasioned by meddlesome mechanics in the treatment of hip-joint disease, and I know of no problem in orthopaedic surgery, unless it be that involved in the mechanical treatment of true lateral curvature of the spine, which requires the expenditure of more thought and effort than that which claims our attention in the treatment of hip-joint disease in the second stage.

Whatever may be the primary cause of the deformity in the second stage, no one, I think, doubts the important part assumed by the muscles in the production of the mal-position, as well as in maintaining it after it has once been produced. And no one who has examined many cases of hip-joint disease in the deformity stage can doubt that the principal resistance to the reduction of the deformity lies in the muscles, which are on guard all the time to protect the joint from undue movement, which, in joint language, is synonymous with the slightest traumatism. The first and the most important step in the treatment of the disease is to remove this element of trauma from the joint. This simple statement underlies the whole problem of the value and of the necessity of mechanical treatment, and I have no hesitation in predicting that that method which best subserves this indication is the one which will outlive all the others.

If in the second stage the thigh is flexed and abducted and we attempt by manual effort to overcome either deformity, even if guided by the intelligent hand of the most experienced orthopaedic surgeon, we find that the muscular resistance can not be overcome by any ordinary effort, and that nothing but an extreme degree of force, which inflicts intense pain, will modify the acquired position of the femur and bring it into the so-called straight position. There can be no disputing that this resistance to the reduction of the deformity, and the pain which we inflict while doing so forcibly, mean that the joint, in its sensitive and apprehensive condition, demands adequate protection, and they mean as well, also, that he who would afford his patient the most complete relief and the best attainable result will study these and other things which the joint almost talks to us about, and make available the lessons which they convey.

It seems perfectly apparent to me that a joint in the condition above described needs, as a first step toward recovery, an essential modification of the traumatic contact

between the opposing articular surfaces\*—not in the position we wish it to be in, but in the position which Nature has selected.

No one who has seen a child suffering with the agonizing pains of hip-joint disease, who has been crying night after night with the lancinating neuralgia of an inflamed hip joint, go to sleep soon after the thigh has been held quietly but firmly in the chosen position of the disease, can doubt the value of the relief afforded by manual support and protection intelligently applied to these cases. The certainty of the relief afforded by this simple test is in no way diminished by suddenly or even gently relaxing the support given by the hands of the operator. The quick and apprehensive cry that follows, and the shiver that runs through the frame of the little sufferer, give positive evidence of the value of properly applied protection in these conditions. It is, I think, our uniform experience that when pain is present in these cases it affords an infallible guide and an unerring indication as to treatment. My own experience goes still further, and I am prepared to say that if pain were present uniformly in the second (or even the first) stage of hip-joint disease, our results would be better and sooner attained. My experience further demonstrates that those who aim for the best attainable results are those who treat their patients as if there were a slight pain present all the time, and who follow them up with the same careful attention they would bestow upon a joint that is slightly sensitive; for the less sensitive joints are none the less removed from the dangers that threaten the painful ones, and the feeling of false security that comes to both the patient and the surgeon, when pain is not present, leads to many errors of treatment and to many bad results. In a well-applied portative apparatus, embodying correct principles, the patient is apt to forget that he has any joint disease, and the surgeon is prone to hope, if not to think, after a while, that the worst is over and that a favorable end of the disease is very near. It is under these circumstances when the symptoms are latent only, and when the disease, though either stationary or progressing toward recovery, is far from the desired end, that it is the duty of the surgeon to in no way relax his attention, for the period of convalescence in hip-joint disease is in many respects the most perilous.

I think I am wholly warranted in saying that, whether pain is present or absent, we should adopt from a mechanical standpoint the best-known means of modifying, as a first and as the most important of all considerations, the traumatic contact of the affected joint surfaces.

In the experiment referred to above, when manual support is given to a painful joint, it is found that simply supporting or fixing it by the hand or hands gives little or no relief. If the lever principle is added and it is attempted to fix the joint in that way, the pain is increased. But as soon as a traction force is applied—the body forming a counter-traction—relief is almost instantaneous. And it is found, in typical cases, that the pain returns just as soon as the traction is relaxed or modified. This experiment has been

made by us all, in many cases and under all kinds of circumstances, and it is among the well-demonstrated facts of orthopaedic surgery. If, now, continuing our tests, we attempt to alter the relation of the joint surfaces to each other—*i. e.*, attempt to correct the deformity even while exerting this traction or pulling force—we find that the pelvis moves with the femur, so strong, so active, and so incessant is the muscular splinting of the joint. We also find that when the change of position involving the use of a lever is attempted the pain at once returns, and the more force used in making traction, save in the position which gives the patient comfort, the more the patient complains and the greater is the pain inflicted.

Let us pursue our experiments with manual traction still further. Let us keep up the traction for an hour or two, or even longer, in the direction which brings relief, as I have done on many occasions when, with no apparatus attainable, sleep could only be purchased by manual traction. What happens? Little by little, as the trauma, which has been exerted upon the joint surfaces for the preceding weeks or months, is relieved, the muscles relax their tension and it becomes possible to obtain an increase in the joint motion without inflicting pain. After traction has been kept up persistently and intelligently for an hour or two under these circumstances, the patient will even sleep for a short time without any traction at all. But if we desist entirely and allow the limb to again resume its chosen position, the muscular tension soon returns and the joint will become as rigid and as painful as before, under the influence of the muscular splinting which is so characteristic of both the painful and non-painful conditions.

These experiments have doubtless been unconsciously made by us all, not only with the hand, but by properly constructed and applied traction apparatus. It is an almost daily experience for us all to reproduce with traction apparatus the effects of manual traction, and when traction apparatus is properly applied the joint, supported and protected in Nature's indicated position and relieved from the constant traumatism of its own effort, begins to mend. The muscles, relieved of their duty of splinting the joint, relax their grasp. The deformity soon becomes modified, and after a few days or a few weeks the deformity is removed or sufficiently modified so that the patient can walk about in the open air and gain that great advantage which properly applied portative traction apparatus gives—viz., gentle exercise and locomotion in the open air, with a minimum of restraint as applied to the general functions of the body.

We may now formulate some of the conclusions applicable to the conditions found in hip disease, and its mechanical treatment.

1. The initial signs of the first stage of hip-joint disease are, as a rule, a limp and an involuntary muscular protection of the articulation.

2. The involuntary muscular protection frequently, if not always, precedes the limp. It also precedes the pain, which is generally a very late symptom, occurring almost always in the second stage.

3. The more insidious the approach of the disease, the greater, as a rule, is the necessity for ample protection and

\* Dr. E. G. Brackett, of Boston, has proved that in childhood distraction of the hip joint is an evident fact. *Vide* "Boston Medical and Surgical Journal," vol. cxxi, No. 17, October 24, 1889.

prolonged observation. This is particularly true of an insidious and inveterate muscular protection of long duration which scarcely varies from month to month, and, while limiting the joint motions only slightly in all directions, is unaccompanied by any evidence of pain, except as the femur is used as a lever to overcome the muscular resistance.

4. The first indication from a standpoint of mechanical treatment is to remove as far as possible all traumatic influences from the diseased articulation.

5. This can best be accomplished by some form of apparatus which possesses the power to directly modify, or to wholly remove, interarticular pressure.

6. Our efforts to relieve the pain of the acute stage are abortive until a traction force is used.

7. The deformity of hip-joint disease is due to an instinctive and involuntary muscular splinting of the articulation, which muscular protection becomes modified after efficient traction is applied.

8. The presence of the muscular splinting of hip disease necessarily indicates the existence of a greater or a less degree of interarticular pressure in those positions where muscular contraction resists the reduction of the deformity.

9. This muscular splinting exists very often to a very great degree without any pain at all, and in these cases, as well as in those where pain is present, traction is necessary to adequately protect the diseased articulation.

10. The muscular signs of hip disease, especially the instinctive and involuntary muscular protection, are by far the most important, both as applied to diagnosis and prognosis in hip disease, taking precedence over pain.

11. Clinical experience proves that all the important signs and symptoms of hip disease are at once modified by intelligently and scientifically applied traction, the modification of the symptoms and signs being in almost direct ratio to the efficiency of the protection thus afforded the affected articulation.

12. Where there is no deformity present, a portative traction apparatus may be applied, and the patient may at once assume the erect position (ample protection being afforded the diseased joint) and walk about in the open air almost without restraint.

13. If the disease permits a certain amount of motion at the affected articulation, motion within the limit set by Nature is not harmful. It is only the cases that Nature attempts to immobilize by an emphasized muscular splinting that require artificial immobilization, and these latter cases acquire motion under the immobilization produced by traction applied with this end in view.

14. Where deformity is present, the patient should be placed in the recumbent position, with the affected member at rest upon an inclined plane in a proper traction apparatus. Both the traction apparatus and the inclined plane should be so constructed that any desired position may be obtained without disturbing the patient or the affected joint.

15. The deformity assumed by the involuntary muscular action indicates approximately the position in which we should make our initial mechanical traction.

16. Clinical experience proves that to make traction

"in the line of the deformity" is an error. We should rather say that traction is to be made *in the line of comfort*, and this means that the angle of traction should be less than that of the deformity—*i.e.*, the joint should be placed in a position of greater flexion than that which is the exponent of the disease. By doing this we make traction wholly in a direction which modifies interarticular pressure, and we avoid the error of the lever apparatus, which makes a fulcrum of the diseased articulation to overcome the deformity.

17. The time necessary to overcome the deformity should always be given with the patient recumbent, as above described, and the line or angle of traction should be changed, not arbitrarily from day to day, but as the relaxation of the muscular splinting allows a change of position without any injury to the joint.

18. As soon as the deformity is reduced or sufficiently modified, the traction apparatus arranged for locomotion should be applied, and the patient should be allowed to have the benefit of gentle exercise in the open air, without interfering by crutches or other unnecessary apparatus with the normal functions of the rest of the body and the unaffected members.

19. Traction during recumbency with an apparatus that has a strong pelvic band and double perineal pads is superior to the weight-and-pulley traction, inasmuch as the former gives us complete control over the pelvis as a point of counter-traction.

20. If the joint is very painful and sensitive—even if there be no deformity—the joint should be given the extra rest which recumbency, traction, and a relaxed ilio-psoas muscle bring. The presence of a cold abscess is not a contra-indication for locomotion in a proper portative traction apparatus, nor are several siusses a bar to outdoor treatment with a proper protection splint. The only contra-indications to locomotion and outdoor life are a very sensitive joint, an acute phase of the abscess, and the existence of a considerable deformity.

21. Any apparatus embodying the lever principle alone—that form or those forms of apparatus which make the femur the long arm of a lever to "pry" the joint straight—are, I believe, very strongly contra-indicated, except in those cases where the articular adhesions prevent the reduction of the deformity by traction. Luckily, these cases are rare. When met with, however, I believe that it is better to reduce the deformity at once under ether, and then to apply efficient traction, rather than to subject the diseased joint to the prolonged and irritating traumatism of a powerful and constant leverage.

After reviewing the whole field, it seems to me that we can not avoid the conclusion that we should use traction as a means of relieving the self-imposed muscular traumatism of the joint, not only to meet the very evident general mechanical conditions, but to relieve the muscles as well. The muscles were long ago tired out before the painful stage appears, and we should appreciate the constant strain the muscular tension imposes upon the central nervous system. It has been taught that we should make traction to "antagonize the muscular spasm." I think this is an error. It

seems rather that we should rest the joint by giving it immunity from the traumatism of inter-articular pressure, and then await the gradual yielding of the muscles. This will soon permit us to place the distal part of the joint in the desired position, and we need not inflict the slightest injury to the joint if we proceed carefully. I am quite sure that this object can be secured by the intelligent use of traction and counter-traction.

And the mechanism of this traction apparatus should be so arranged that it can be adjusted to any desired position without removing it from the patient. We can then cause the apparatus to follow the thigh as it falls into position and not force the thigh to follow the apparatus, as we must always do if we use the lever apparatus without the traction attachment.

The objections to any form of apparatus which embodies the principle of the lever alone are very great. It seems to me that this principle as applied to the treatment of tubercular joint disease in the light of the pathology of the disease, in the light of the muscular conditions which accompany it, and the unerring certainty with which the lever aggravates the already existing traumatism, is crude and unscientific.

Those who favor and use the lever apparatus always insist upon the necessity of removing the superineumbent weight of the body from the diseased joint. They forget or ignore the fact that the underlying articular pressure produced by the muscular splinting of the joint is just as injurious, if not more so, than the superineumbent weight. It is easy enough to remove the superineumbent weight with crutches (but this alone will not cure the disease), and it is also easy to gain position by making the femur the long arm of a lever. The muscles must yield if the lever force is sufficient, but the joint already disabled will suffer. It will be interesting in the future to see the results produced by this lever plan of treatment.\*

But if, on the other hand, we can successfully give the affected joint not a fictitious "rest," not a pseudo—"immobilization," not a fallacious "fixation," but by supplementing the artificial joint protection, be it what it may, with an additional apparatus or attachment which will imitate the action of manual traction, we shall accomplish the end that Nature seeks by her ceaseless and involuntary muscular protection in an osteitic joint disease. We must do more than "rest," "immobilization," or "fixation," as described by some writers who use these terms, can produce, because all these "methods" have for their aim, not so much the avoidance of traumatic contact between the opposing joint surfaces as the maintenance of a traumatic contact which already exists and which must necessarily be emphasized by the application of the lever principle or of any of the so-called "fixation" splints. As long as the muscles guard-

ing a diseased hip-joint are in a state of ceaseless contraction, as long as they are actively and instinctively engaged in securing for the diseased articulation the best protection they can give, our mechanism for the relief of the joint should embody some means of successfully combating the effects of their incessant action. And we should always be prepared to produce true physiological rest for the over-tired muscles and the vulnerable articulation; we should be able to secure real immobilization of the joint when it is indicated, and we should always be ready to give the joint absolute fixation when it seems necessary, just as we should permit and even encourage motion when the joint condition does not contra-indicate it.

And, as I look over the entire armament of orthopaedy, I know of no mechanical method of accomplishing all that we desire in these difficult and tedious cases of hip-joint disease except that which imitates the simplest method of relieving an inflamed joint—viz., manual traction.

And I feel that if this principle of traction be scientifically utilized and adapted to the needs of each individual case there is no doubt that we shall give to our patients suffering from hip-joint disease and allied articular affections the most perfect mechanical protection available, which is, after all, the *sine qua non* in the treatment of chronic joint disease.

## A CASE OF TUBAL PREGNANCY.

BY E. D. FERGUSON, M. D.,  
WEST TROY, N. Y.

THE following case presents some points of interest:

The patient, a woman, thirty-two years of age, nullipara, married over three years, was first seen by me in consultation with Dr. Van Vranken, of West Troy, on October 5, 1889. The following are among the facts then determined: The last menstruation was on July 12th; there had been some slight bloody discharge from the vagina recently; she regarded herself as pregnant; she was and had been without fever or notable constitutional disturbance; she had suffered somewhat from nausea; on September 15th she was suddenly seized with pain to the right of the hypogastrium, and the pain had continued with varying intensity up to the time of the examination, so that she had practically been confined to her bed; at no time had there been a condition which could properly be called shock.

Examination showed a tumor of about the size of a small orange in the right broad ligament; the uterus seemed by palpation to be about twice its normal dimensions, but was not notably displaced toward the left; there was moderate tenderness over the uterus and over the tumor in the right broad ligament. The diagnosis was right tubal pregnancy with probable rupture downward between the layers of the broad ligament, and proper explanations were made to the husband with a view to an operation. In the mean time electricity (galvanism) was directed.

I did not see the patient again until October 11th. I found but little change, though the tumor in the broad ligament was apparently somewhat larger and quite as firm. There had been two or three paroxysms of severe pain in the region of the tumor, but still no shock or collapse, and no retro-uterine mass. The patient was now informed as to her condition, and, as she accepted the advice for the removal of the tube, arrangements were accordingly made, and the operation took place on the fol-

\* In "An Analysis of Twenty-one Cases of Hip Disease treated by the Thomas Splint," by Mr. John H. Huddleston ("Boston Medical and Surgical Journal," Oct. 24, 1889), it was found (the Thomas splint being a typical "lever-fixation" splint) that the general results were as follows: "Good position with little flexion and adduction, but great shortening, great atrophy, and very constant elevation of the trochanter above Nélaton's line with a remarkable percentage of abscesses."

lowing day, Saturday, October 12th, at 11 A. M. On opening the abdomen, exit was given to a large amount of very dark clots and fluid blood. The amount could only be estimated, but there was more than two pints, probably not more than three pints, of fluid blood and clots.

The layers of the right broad ligament were separated and the space occupied by blood clots and placenta. Apparently the final rupture into the peritoneal cavity had occurred through the upper and posterior portion of the tumor. There was a broad pedicle and the cobbler's stitch was used. The foetus, which had escaped from the sac, was advanced three months in gestation.

There was considerable shock following the operation, which lasted one hour from taking her to the table till she was again in bed, but reaction was prompt, and when I saw her at 3 P. M. she was comfortable and cheerful, and everything promised a favorable progress. I had requested Dr. Rulison, who was caring for her during the absence of Dr. Van Vranken, to draw her urine at 6 P. M., and his report that he got less than a tablespoonful of urine had an ominous significance. It having been an operation of necessity, no examination of the urine had been made, but, had I known of pre-existing renal trouble, I should probably have proceeded with the operation. I saw her again at 9.30 P. M., and the catheter brought only a teaspoonful of bloody urine. Though she was free from any evidence of shock or collapse, still there was a manifest tendency to somnolence that suggested uræmia, and in fact that supervened soon after midnight, and she died about 4 A. M., about sixteen hours after the operation. An autopsy was made about eight hours after death, and some points then noted deserve attention. The peritoneal coats of the intestines were quite congested at the time of the operation, presumably from the irritating effect of the intraperitoneal blood, but at the autopsy they presented a normal color and smoothness. The stump was already covered in by firm adhesions to contiguous parts through means of plastic lymph, and the peritoneal surfaces of the incision were so adherent as to require notable force in their separation. During the operation care had been taken to avoid bringing the right ureter into the field of the ligatures, and it was found undisturbed. Both kidneys were in the congestive stage of acute nephritis and presented no evidence of chronic disease. The urine showed "blood casts" and a large amount of albumin. Whether the use of chloroform instead of ether will lessen the mortality from renal changes following abdominal operations seems to me an open question as yet. This case lacks in having no record of the state of the urine before the operation. The death was due to uræmia, more rapidly fatal, doubtless, on account of the depression due to the operation.

The points of special interest to me were the large amount of blood (and clots) in the abdominal and pelvic cavities which must have been there two or more days before the operation, and yet there was no history of notable shock, and no physical signs of its presence in Douglas's *cul-de-sac*. There was sufficient tympanites the day preceding the operation to obscure the diagnosis of its presence by abdominal palpation or percussion.

In addition, the speed with which the pedicle may be covered up and closed in by plastic material was very striking. Though the patient survived the operation only sixteen hours, the stump was so firmly closed over and shut in as to preclude any probability of haemorrhage from that source. This result, however, may have been hastened in this instance by the pre-existing state of irritation due to

the intraperitoneal blood. Fortunately, recent experience in laparotomy affords a smaller percentage of opportunities for such examinations.

The uterine walls were found over an inch in thickness.

## TWENTY-THREE CASES OF TYROTOXICON POISONING.

BY D. M. CAMMANN, B. A., M. D.

ON March 14, 1889, seven children in a large institution in this city were taken ill. In the following five days sixteen more became ill with the same symptoms. One of the children was four years old, two about six, and the others from seven to thirteen or fourteen. The cases varied in severity, but were all similar in character. The symptoms were frontal headache, nausea and vomiting, diarrhoea, and high temperature. The children were ill for two or three days and then recovered, with the exception of pallor, lasting for a variable time. Several, whose temperature was high, had four or five grains of the sulphate of quinine, but the others had no further treatment than rest.

The headache in some of the cases was severe, lasting for a day or two and then slowly passing away; others had little or no headache. With none was the vomiting severe. Some vomited once or twice and then not again; others two or three times within twelve or fifteen hours; others had nausea but no vomiting; a few had neither nausea nor vomiting. Nearly all had slight diarrhoea—from two to five or six passages within twenty-four hours. In no case did the vomiting or diarrhoea last for a longer time. The highest temperature was 105° F. in the mouth. The temperature in most of the cases ranged between 102° and 104°. It gradually declined in two or three days, being higher at night than in the morning. Two of the patients complained of pain over the stomach, but it was not severe, was not increased by pressure, and soon passed away. The pulse was rapid, small, and compressible. The skin felt as usual—neither moist nor dry. The tongue was slightly coated, and in some cases clean at the tip and sides. None of the patients showed marked prostration, and some, after lying still a few hours, were up and moving about.

The highest range of temperature was in the older children, of eleven or twelve years of age, the temperature of the younger ones not usually running quite so high. The relation between the height of the temperature and the vomiting and diarrhoea was not very evident, but, as a general rule, those who had most vomiting and diarrhoea did not have the highest temperature, and *vice versa*. In several of the cases in which an examination was made the spleen was not enlarged. At the time there were two adults in the institution with symptoms of malarial fever. One of the boys, aged twelve, who was taken with the symptoms described, developed double pleuro-pneumonia.

The system of drainage and water supply was of the most perfect description, the plumbing having been thoroughly renewed within a couple of years, and repeated examinations by experts had failed to reveal any defect. The dietary was of the simplest kind, and was nearly the

same as had been used for the last twenty-five years. During that entire period the institution had been remarkably free from diseases of the gastro-intestinal tract, and even during the summer months such cases had been extremely rare. No change in the diet had lately been made.

About one hundred and fifty children were in the institution. Those that were attacked were scattered pretty equally through the different dormitories. The attacks did not, in the majority of cases, commence immediately after a meal, but some commenced in the morning before breakfast, the patients having eaten nothing since supper the previous evening; others commenced in the middle of the night; others immediately before supper, the patients having eaten nothing since a midday dinner; others commenced almost immediately after a meal.

An examination was made by Dr. Edson, of the Board of Health, who recognized the milkman's name as one with whom the board had formerly had trouble. Thirty-six persons who received milk from the same farm had been poisoned. These cases were reported in a paper read before the Ninth International Medical Congress. Tyrotoxicon was not found in the milk at that time, but there was ample reason to infer that this substance or some other ptomaine was the cause of the poisoning. The symptoms were the same as those of the cases in our institution. After the milkman was changed no new cases occurred.

Specimens of the milk used in the institution were examined by the Board of Health, and two per cent. of water was reported in one and five per cent. in another. No tyrotoxicon was discovered. After a careful investigation no other cause for the trouble except the milk could be found. The molasses was suspected; but, besides its having been in use from the same barrel some time before the trouble began, cases occurred several days after it was stopped. On analysis, it was found to contain only a trace of copper. Other articles of diet were in a like manner excluded as a cause.

We can fairly say, I think, that these cases were caused by tyrotoxicon or some other ptomaine, although the poison was not found. It is not my purpose in this paper to consider how tyrotoxicon and other ptomaines are generated or the precautions necessary to prevent their production, but rather to glance at the clinical aspect of the cases that have come under my notice.

Many cases have been reported, both in this country and abroad, of poisoning from ice-cream, pies, puddings, etc., in which the symptoms were intense gastro-intestinal irritation, and in which elaborate chemical investigations have demonstrated the absence of metallic poisons. It was not, however, until 1885 that Dr. Vaughan found in cheese a poisonous ptomaine, tyrotoxicon, and subsequently he isolated the same substance from milk and from ice-cream which had produced poisoning in eighteen persons. Only within the past few years have compounds known as ptomaines been investigated by Bence Jones, Dupré, Marquardt, Schné, and Briger. They are alkaloid-like bases obtained from animal matter after decomposition. They are found during the earlier stages of decay, but, as putrefaction continues, rapidly disappear. The ptomaines are powerful poisons. The

poisonous effects sometimes produced by lobsters and other feeders on carrion are probably due to them.

The action of tyrotoxicon on the lower animals has been studied by Vaughan,\* and been found to produce symptoms closely resembling those of cholera infantum; indeed, he believes it to be often the cause of this disease. Ten to twenty-five milligrammes given to a cat produce in a few minutes nausea, retching, vomiting and purging, an irritable stomach, and a rapid, feeble pulse. With larger doses the severity of the symptoms is increased, and the breathing becomes shallow and labored. With doses of from seventy-five to one hundred milligrammes violent retching occurred, with a rapid and feeble pulse, but neither vomiting nor purging, and death took place within a half to three hours. The post-mortem appearances corresponded exactly with those of children after death from cholera infantum.

Carefully recorded cases of poisoning in man are lacking. It is probable that, with a fuller knowledge, we shall be able to distinguish between poisoning by ptomaines and other substances, as well as between the ptomaines themselves. In the majority of cases the usual symptoms are violent gastro-intestinal irritation, retching, vomiting, purging, rapid and feeble pulse, redness of the throat, and elevation of temperature. In fatal cases the temperature is commonly below normal. Besides these more common symptoms, in some cases have been reported dizziness, momentary loss of consciousness, constriction of the throat, a rash resembling that of scarlatina, convulsive movements of the limbs, dilatation of the pupils, and constipation. Death seems to result from heart failure.

None of my cases were severe. Evidently only a small quantity of the poison had been taken by each person. The attacks came on quite suddenly, and sometimes apparently several hours after any milk had been taken. The temperature seemed to have the highest range in those who had the least vomiting and purging. In the majority of cases prostration was not marked: the pulse was increased in frequency, small, and compressible; the skin felt as usual, or warmer; the tongue was slightly coated and in some cases red at the tip and sides; there were headache, nausea, vomiting, and purging. Some had redness of the throat. A few had a rash resembling that of scarlatina. Two had pain in the stomach, but it was not increased by pressure, and soon passed away. One was attacked with double pleuro-pneumonia, from which he recovered.

#### A CASE OF RECURRENT FIBRO-SARCOMA OF THE THIGH. AMPUTATION AT THE HIP JOINT. RECOVERY.

By JOHN A. WELLS, M.D.,  
ENGLEWOOD, N.J.

The history of this case is submitted both as a contribution to the literature of amputation at the hip joint and as illustrating the possibility of obtaining entire asepsis under the most unfavorable surroundings.

\* "Transactions of the Ninth International Medical Congress," p. 485.

J. F., colored, aged thirty-two, single, denied syphilis and injury. He had been most intemperate in the use of alcohol, but entirely free from sickness of any kind until January, 1887, when he noticed for the first time the presence of a painless new growth on the dorsum of the right foot. This growth within four months had increased to the size of an orange. It was removed at that time by dissection and found to be non-adherent to the bony structures. A microscopical examination of the tumor confirmed the impression that the growth was a simple fibroma. Contrary to expectation, however, the tumor reappeared within a few weeks in the unhealed wound, and rapidly increased to double or triple its original size, with the ultimate supervention of gangrene and septic symptoms. Amputation at the middle third of the leg was performed two months after the primary operation, and by strict antiseptic precautions the wound healed throughout the greater portion of its extent by primary union. The recurred growth was then found to be adherent to the metatarsal bones. The patient's temperature fell on the following day from 103.5° to 100° F., and rapidly sank to normal. After an interval of two years, during which he enjoyed excellent health, in spite of his intemperance, he sought my advice, and I found a dense fibrous-feeling mass measuring 16 cm. in circumference at the junction of the middle with the upper third of the right thigh on the internal aspect. He had first noticed the mass three months before. During the two weeks following his visit to me it had increased nearly one third in size. Ablation of the entire extremity was advised on account of the previous unsatisfactory attempts at excision, and was performed by the writer, with the kind assistance of Dr. Clarke, Dr. Banks, and Dr. Haring, on the 21st of August, 1889. The surroundings were so extremely unfavorable for operating that the writer may be pardoned for mentioning briefly the well-known measures for securing asepsis which were employed. All unnecessary furniture was removed and the necessary articles were covered with clean sheets. The walls and the floors were well scrubbed with soap and water, and on the morning of the operation the patient was given a warm bath and dressed in clean under-clothes. All the water used in the operation, necessarily taken from a notably contaminated well, was boiled for one hour before using. One sixth of a grain of morphine with one ninety-sixth of a grain of atropine was administered hypodermically a few minutes before commencing the ether. The latter was administered with an Allis inhaler, with little difficulty in obtaining and continuing its effects, after some preliminary excitement. This fact is only mentioned because in the previous amputation, where no morphine or atropine had been given prior to the ether, it had been found impossible to bring the patient under the influence of the anaesthetic, and it was finally necessary to substitute chloroform. During the latter half of the present operation, on the contrary, no ether whatever was necessary. The integument involved in the incisions and the adjoining portions were shaved, scrubbed with green soap, and irrigated with a solution of bichloride of mercury, 1 to 1,000. Towels soaked in a solution of the same strength covered the exposed integument contiguous to the field of operation. The instruments employed had been previously boiled and placed in a solution of carbolic acid, 1 to 30. After thorough cleansing and disinfection of the surgeon's hands, the joint was exposed by the usual incision on the outer aspect of the femur, disarticulation was effected, and the femur was stripped of its muscular attachments for about six inches down the shaft. The method of Marshall Jordan for preventing hemorrhage was found entirely effectual. A disinfected Martin's elastic bandage was doubled twice and passed around the groin above the tuber ischii posteriorly, thereby preventing downward slipping in that direction. A roller bandage

was placed over the superficial femoral as a compress, and the crossed ends of the Martin bandage were tightened over it by forcible traction on them by the hands of an assistant pulling in the direction to obtain the greatest pressure on the compress. The skin and fasciae were divided circularly, opposite the point to which the femur had been stripped, and allowed to retract. Instead of dividing the muscles at this point, as recommended by some authorities—as it was believed that the flaps so formed would be insufficient to cover the large amount of muscular tissue—the cuff was dissected upward for three inches or more, and the muscles were divided at that point circularly with a catlin. The wisdom of this procedure was demonstrated, as, on bringing the flaps together, there was no tissue to spare. There was no hemorrhage whatever on completing the section. The vessels were ligated with asepticized catgut, a drainage-tube was inserted into each of the three angles, and the wound was irrigated with bichloride of mercury, 1 to 5,000. The flaps were sutured by alternate catgut and aseptically-prepared silk sutures, the lines of incision were dusted with iodoform, and a generous dressing of creolin gauze and borated cotton was applied. At the completion of the operation there was little if any evidence of shock, the pulse being 100 and the extremities warm. On the following morning the pulse was still 100 and the temperature 99° F. The patient reported several hours of sleep, and desired permission to smoke his pipe. Whisky, in half-ounce doses, was given several times daily; the bowels were kept constipated for five days for fear of disturbing the dressings, in view of the unskilled nursing at his command, and were then moved by a laxative. On the fifth day the temperature rose to 99.4° F., falling to normal after the evacuation of the bowels. This was the highest point reached at any time, and at no other time after the first twenty-four hours did it exceed the normal. On the seventh day it was thought best to remove the drainage-tubes, one of which, that to the acetabulum, was necessarily a long one. The drainage-tubes were accordingly removed and shortened two thirds. The dressings were entirely free from pus, and there was apparent primary union throughout. Three days later the tubes were removed entirely. On the sixteenth day, at the next dressing, the silk sutures were removed, being perfectly dry. There was complete primary union throughout the long incisions. The patient was up on the twenty-first day, and out on the twenty-eighth.

It has seemed to the writer that perhaps this case deserved reporting with some detail for several reasons: For the apparent effect of the atropine in preventing the shock naturally incident to so extensive a wound, and for the assistance rendered by the morphine to the anaesthetic, as demonstrated by the previous difficulty of securing anaesthesia in the same case; for the efficiency of the Marshall Jordan method in preventing hemorrhage; for the necessity of an upward dissection of the cuff to obtain sufficient flaps; and, more important than anything else, as illustrating the fact that the surroundings of a filthy negro shanty are not insuperable obstacles to the attainment of complete asepsis.

**Sense of Taste in Criminals.**—“Dr. S. Ottolenghi, a pupil of Professor Lombroso, has studied the sense of taste in criminals compared with that of other individuals. He says that in criminals the sense of taste is manifestly weak relatively to that of ordinary individuals; there is, again, a difference less marked between occasional delinquents and those who are habitual or born delinquents. Female criminals have the sense of taste still more obtuse than men of the same category. The author concludes from these remarks that this diminution in the sense of taste in criminals depends on a defect in the cerebral cortex.”—*Medical and Surgical Reporter*.

NEW YORK, SATURDAY, NOVEMBER 23, 1889.

MEDICAL STUDENTS AND MEDICAL MINDS.

AN address to medical students, recently published in the "Lancet," speaks of certain personal qualifications essential to success in the practice of medicine. The successful practitioner must have the sympathetic temperament, tact, common sense, and the tenacity and diligence necessary to develop and improve these qualities by the discipline of constant and progressive study. The proper habit of thought is the first thing for the student to cultivate. Thinking out problems and discovering a reason for everything are the true basis of rational knowledge, and constitute the difference between the real student and the mere laborious, painstaking reader of books. Scientific discussions are valuable aids to the learner at every stage of his career. A good lecturer impresses upon the mind facts of importance that the casual student, however earnest, might easily overlook. The experience of others working along specified definite lines, yet much in advance, is of incalculable benefit to him who runs and reads. To be one of an army marching toward truth in any given direction is both a moral and an intellectual stimulus. A well-made abstract of the good things that fall from the master's table is invaluable as an exercise for the mind. Notes concerning main facts, the headings recorded in brief, and the conclusions leading up to them more fully written out, form an admirable nucleus for a medical library and an excellent guide for original investigation. Methods of study, companionship, and the choice of books have a powerful influence on any career, that of medicine not excepted. They are largely a matter of temperament, sometimes acting as cause, sometimes as effect. Good methods, good companions, and good books will discipline even a crude mind. On the other hand, a bright student secures them as a matter of course. There are books and books. It goes without saying that, if professors write books, students should have sufficient *esprit de corps* to possess them. At the same time, the real value of a book consists in its power to help and inspire the reader, to put him in a working mood. A very little book often does great things, and sometimes an old work will throw a very window of light upon a perfectly new subject. This is an affair of individuality, of temperament, of mental make-up.

While there are many things that must be dug out alone in medicine, because the mental bread of each must be eaten with his own tears, yet there are but few occasions where two heads are not better than one. Much in the way of investigation and the acquisition of knowledge is best when shared. Together, each studies for the good of all, and, because one is indispensable to the other or others, perfect individual equilibrium and independence are secured. Companions teach as

well as schools. The quizzes of Brown, Jones, and Robinson may leave an impression when that of the pure unadulterated excellence of authorities has quite faded out. Learning how to ask questions of patients as well as of medical men, and how to answer them, is an important means of getting into an exact and direct mental attitude. The best talker—*i. e.*, the one who makes the plainest and most direct statement in the fewest words—is considered the best officer, other things being equal, in large business corporations. This, in a general way, applies equally well to physicians and the practice of medicine. Exact expression—verbal, literary, graphic, or of bodily action—is an unmistakable evidence of exact thought. Still, when all preaching is done and everlasting truth has been reiterated for the hundredth time, the simple fact remains that, if the medical man has not the quality of success, he does not succeed. Men of science are born, then trained. They are not made. Methods, companionship, books, training, and all the rest, are of no avail without this subtle something that makes for success and is inherent in the individual. It is possible to be honest, industrious, faithful, and conscientious, and still miss many of the prizes of life. Industry, personal magnetism, exactness, elasticity, a good manner, and grit are the chief factors in that abstruse process known as getting on in the world of medicine. In broader terms, industry, tenacity, and imagination are the natural and chief mental endowments needed. Without these characteristics there is no such thing possible as the scientific mind.

THE TREATMENT OF PNEUMONIA.

WALTER HAYLE WALSH, in the first edition of his "Practical Treatise of the Diseases of the Lungs and Heart," published some forty years ago, speaks of pneumonia as standing high among those diseases of which "the fitting treatment has been established by scientific experience," and then he goes on to say that that treatment consists of bloodletting and the administration of tartarized antimony, and the latter he thinks the more efficacious agent. Yet how few of those who read this page have ever seen a patient bled or antimony prescribed! The mean amount of blood M. Bouillaud took from his patients was four pounds five ounces, and antimony was recommended by Walshe in doses of half a grain every hour for the first three or four hours, increasing to two grains every two hours. Since those days many fashions have come and gone, and who can say that the fitting treatment of pneumonia has been established? The administration of stimulants in large doses recommended by Todd, the nihilism of Bennett, and the antipyretic and antiseptic plans, all have had their innings, and a recent battle of statistics has shown that the mortality has at all events not undergone any appreciable reduction during the last half century.

The treatment of pneumonia by the application of the icebag has recently been under discussion at the Harveian Society in London. Dr. Lees, of St. Mary's Hospital, brought forward the record of eighteen cases of pneumonia in which a satisfactory result had followed this treatment in all but two. We

have looked into these histories, and there is no doubt that the results are very good, but we must bear in mind in pneumonia that there are cases and cases—that some cases will end in recovery in spite of any treatment, while there are others in which no treatment will save the patient. To the former class belong the large majority of the cases brought forward by Dr. Lees, if not all of them. Age and an alcoholic history are the most important factors in the prognosis of pneumonia, and it is very remarkable in connection with these cases that, of the whole number, none of the patients were older than forty. Can the cases have been taken haphazard from the last that fell to the lot of Dr. Lees as a physician to a hospital, or were they picked out from a number presenting themselves for treatment as being the most suitable for bringing out the superior advantages of a newly advocated remedy? There were no alcoholics among Dr. Lees's patients, nor were there more than three cases in which really grave symptoms were present. In two of the cases the writer acknowledges that no benefit was evident, and in two others the diagnosis of pneumonia was very doubtful.

The suggestion of a new treatment for any disease should always be favorably received and attempts made to give it a fair trial. In the case of the ice-bag treatment of pneumonia this will be done, but we venture to assert that, if any hospital physician were allowed to pick out of his case-book eighteen cases of pneumonia treated by ordinary methods, he would be able to put together quite as good a record as that published in the "Lancet" and discussed at the Harveian Society.

### MINOR PARAGRAPHS.

#### THE PHONOGRAPH AS A UNIVERSAL ACOUTEMETER.

ACCORDING to the "Deutsche Medizinal-Zeitung," Lichtwitz maintains that Edison's phonograph fills the requirements for an acoumeter. It is possible, he asserts, to arrange phonogrammes by means of which the hearing can be accurately measured. The phonograph can reproduce every sound and tone perceptible to the normal ear, including the inflexions of the voice; it repeats the sound without noticeable change, so that the acuteness of the hearing of different patients, and of the same patient at different times, can be accurately compared; it will reproduce with the same intensity and quality of sound the uniform phonogramme, so that aural surgeons of all lands can compare their observations.

The operation of the apparatus is simple. The ear-piece is applied to the ear which is to be tested, and a phonogramme which is audible to the patient is sounded. The acoumetric scale is then descended until a phonogramme is reached which can not be heard. This marks the limit of hearing for that ear. In this manner the source of sound remains always at the same distance from the ear, and only the intensity of the tone differs. If the phonograph will do all that Lichtwitz alleges, and if it is practicable to create such a graduated series of fixed phonogrammes as he suggests—and we do not now see why such a plan may not be feasible—we may look forward to a great improvement on the present rather crude means of testing the hearing. All of the methods at present employed for this purpose are objectionable in that they do not furnish a fixed volume of sound in every case. The tone and intensity of the

"tick" of various watches differ, and sometimes they vary even in the same watch. Still more unreliable for purposes of comparison is the use of the human voice, but the plan suggested is intended to furnish the same tone and intensity of sound in each case, and so to render observations more exact and permit of comparisons of observations in a manner not at present possible.

#### ANÆMIA CURED BY HYDROTHERAPY.

"LA Médecine contemporaine" records the following case of Dr. Good's: The patient, a girl of twenty, was affected with pallor, with a coppery hue, heaviness in the head, troubled sleep, bad dreams, poor appetite, painful digestion, constipation, cardiac and carotid murmurs, constant weariness, disinclination to walk, and painful menstruation, the menses being scanty and too light in color. There were also great depression of spirits, pronounced ennui, and an absence of interest in life. The treatment consisted in applying the cold douche to all parts of the body in turn, beginning and ending with the feet, and for a few seconds only, the temperature of the water being at 54° F. After the first day the douching was administered morning and evening for thirty seconds, the water being at 50° F., a shower-bath preceding the douche. Cold food and cold water as a drink constituted the diet prescribed. In three weeks the complexion had improved, digestion was less difficult, but walking was still an effort. Two weeks later the patient's condition was much improved in every way. Menstruation was absolutely painless, she had good sleep, there was less repugnance to walking, she was in better spirits, and the circulatory bruits were less pronounced. In a little over two months from the beginning of the treatment the patient began to grow stout and to walk, eat, and sleep well. The circulatory bruits were then almost imperceptible, the mental depression had disappeared, and the character of the menses was normal. After three months' treatment with the douche twice daily, from twenty to forty seconds, the patient left in perfect health. During that time there was no change in the diet, which proves that water as a drink does not retard recovery, as Fleury has affirmed. On the contrary, wine is said to impair the good effects of hydrotherapy.

#### MANIA FOLLOWING AN OPERATION FOR ENTROPION.

A CASE of this kind is mentioned in the "China Medical Missionary Journal." The patient was a woman, about thirty years of age, who had suffered from an attack of insanity eight years before. No anaesthetic, general or local, was given. The day after the operation she became restless, refused food, and was irritable on being spoken to. In a few days she had gradually become wildly maniacal and violent. A month later her mental condition, though better, was still far from satisfactory. It is going too far to say that this attack of mania was due to the operation, as it might have appeared even if nothing had been done, but it is very suggestive that the operation, through the nervous strain on the part of the patient, was the exciting cause. Frequently the occurrence of insanity after operations has been accredited to the effects of the anaesthetics employed. But in a case where there is a predisposing tendency to insanity it may be gravely considered whether the nervous expectation and excitement attendant upon an operation may not serve as an exciting cause.

#### FATAL POISONING WITH CALOMEL.

The "Deutsche Medizinal Zeitung" quotes from a Finnish journal an account, by Dr. Runeberg, of a most interesting case of the fatal termination of subcutaneous calomel injections in

a syphilitic and anaemic woman. The injections were three in number, and their administration extended over a month. Three weeks after the last injection the woman died. At the post-mortem examination an incision of the buttocks exposed two morbid foci: a smaller one, consisting of fibrous tissue, enclosing a solid, yellow, caseous mass; a larger one, containing about two tablespoonfuls of a grayish-white, thick liquid resembling pus. A comparatively large quantity of mercury was found by chemical analysis in the liquid of the second collection, while not a trace of it was to be found in the first. The poisoning was, of course, complicated by the anaemia, but was continued by the constant absorption of the injected calomel. This difficulty could only have been met by excision of the morbid mass, but an operation was contra-indicated by the patient's enfeebled condition. It seems, therefore, that, in so far as a patient's tolerance of mercury is unknown, it would be advisable to administer it either by the stomach or, if subcutaneously, in smaller doses more frequently repeated and more readily controlled.

#### PROTECTIVE INOCULATION WITH AN ANTHRAX ALBUMOSE.

ACCORDING to the "British Medical Journal," Mr. E. H. Hanhin has experimented on over a hundred mice and about fifty rabbits with an albumose that he has isolated from ordinary cultivations of anthrax. The albumose is precipitated from the cultivation liquid by the addition of a large quantity of absolute alcohol, and the washing in this liquid frees it from the soluble ptomaines; it is filtered, dried, redissolved, and filtered through a Chamberlain's filter. From one five millionth to one ten millionth of the weight of the animal was injected. If an animal was inoculated with anthrax after a large dose of the albumose, there was apparently a hastening of the fatal termination; but after inoculating a small dose of albumose, immunity seemed to be conferred; with a medium inoculation, the anthrax bacilli were able to live and produce more albumose, at length overcoming the resisting powers of the animal. The albumose seemed to be slowly excreted, and to be capable of suppressing the germicidal power of the animal. The experiments were made in Koch's laboratory, and he personally inoculated with anthrax some animals protected by the albumose, and the animals lived.

#### THE PARASITES OF THE HEALTHY SKIN.

ACCORDING to the "Journal d'hygiène," Dr. Arnaldo Maggiora has come to the following conclusions as the result of numerous experiments: Micro-organisms that may also be isolated in the ground or atmospheric air live constantly on the normal human skin. In the various parts of the body the same forms of micro-organisms are almost always found. The fetid perspiration of the feet is not due to the presence of a special form of micro-organism, but to the fact that the micro-organisms develop under special conditions of temperature and humidity presented by the feet when covered with boots. The complications of an infectious character that may present themselves in wounds of the feet probably depend on the greater or lesser facility with which such wounds may be infected by pathological organisms that are present in the soil or in the atmospheric dust deposited on the pavement.

#### TOTAL BLINDNESS AFTER EATING MUSHROOMS.

In a recent number of the "Gazette des hôpitaux," M. Fougeray and M. Fouchard report a case of total blindness in a primipara, aged thirty-one years, who had gastro-intestinal trouble, uncontrollable vomiting, and migraine, after eating

mushrooms. For thirty-six hours she was absolutely blind, and homonymous hemiopia followed. Ophthalmoscopic examination showed slight contraction of the field of vision, but no scotoma. A painful perception of blue persisted for five or six days. Twelve days after the attack the patient aborted, the foetus, of seven months, being well formed. Complete recovery followed. The authors believe the amaurosis to be hysterical, and they say that, while cases of hysterical amblyopia are not rare, only one other case of hysterical total amaurosis without ocular lesion has been reported.

#### STEAMSHIP SANITATION.

THE "British Medical Journal" makes a very pungent criticism of the ordinary methods of examining emigrants at British ports. The writer applies the word "farcical" to the work, drawing a picture of the huddling crowd, encumbered with their baggage, as they pass over the gang-plank. Suspicious cases can not be isolated or put under observation. On board the steamer there are, on crowded passages, no hospital accommodations just at the time when they are apt to be the most needed, the space belonging to the sick being absorbed by the agents for bunk-room. If the ship's surgeon makes any complaint in regard to these matters, he may expect to be snubbed or repulsed in some unpleasant way.

#### MEDICAL MATTERS IN PRINCE EDWARD ISLAND.

FROM the "Maritime Medical News" we learn that an association was organized, on October 2d, among the medical men on Prince Edward Island. There were present twenty-five registered physicians at this initial meeting. Officers were elected, Dr. R. Johnson being chosen president and Dr. S. R. Jenkins secretary, both of Charlottetown. Resolutions were adopted empowering a committee to endeavor to procure the passage of a medical act for the province, in order to "insure a high standard of professional education and of social dignity and estimation."

#### URBAN CLEANLINESS.

COMMISSIONER J. S. COLEMAN, of the New York Street-cleaning Department, will lecture, under the auspices of the American Public Health Exhibition, on the 29th inst., at the Brooklyn Institute, at eight o'clock in the evening. His subject will be "Civic Cleanliness," and he is fitted to treat clearly concerning the gradual building up of the largest plant, on this side of the Atlantic, for the collection and disposal of civic refuse.

#### THE NEW YORK ORTHOPÆDIC DISPENSARY AND HOSPITAL.

AT a recent meeting of the board of trustees it was resolved either to enlarge the present building on Fifty-ninth Street or erect a new one elsewhere. The institution, as we have before stated, has long felt the need of more extensive accommodations, and it is to be hoped that the sum now required, \$100,000, will be subscribed before the winter is over. Several large subscriptions have already been made.

#### ITEMS, ETC.

**The Red Cross at Johnstown.**—Miss Clara Barton left the field in the Conemaugh Valley on October 25th, on the termination of the greatest campaign that the Red Cross Society has hitherto enlisted in. A public reception was given Miss Barton on the evening before she left, which was attended by people of

every class, out of respect to the noble lady who had befriended them in their great calamity.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending November 19, 1889:

DISEASES.	Week ending Nov. 12.		Week ending Nov. 19.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	40	6	31	11
Scarlet fever.....	60	2	27	4
Cerebro-spinal meningitis.....	3	3	2	2
Measles.....	46	6	40	3
Diphtheria.....	89	26	84	18

**The New York Post-graduate Medical School and Hospital.**—A clinic for diseases of the rectum has been established, to be under the care of Dr. Charles B. Kelsey, who will also give clinical instruction in the school. Dr. Kelsey will be assisted by Dr. J. Blair Gibbs.

**Medical Registration in North Carolina.**—The October issue of the "Bulletin" of the State Board of Health of North Carolina contains the following semi-official announcement: "All physicians in this State must register with the Clerk of the Superior Court of their county before January 1, 1890, if they intend to practice thereafter and collect their fees for services rendered. There will be no subterfuge allowed. The law must be enforced."

**The Woman's Hospital.**—Dr. Bache McE. Emmet and Dr. Horace T. Hanks have been appointed surgeons to the hospital, to succeed Dr. James B. Hunter, deceased, and Dr. C. C. Lee, resigned.

**Trained Nurses at Bethlehem.**—The graduation of a class of four trained nurses was the occasion of a special celebration at St. Luke's Hospital, Bethlehem, Pa., on October 18th. Dr. Arpad G. Gerster, of New York, was present and delivered the address to the class.

**The Kings County Medical Association** met on November 8th, at the new rooms over the Brooklyn Post-Office. The subject before the meeting was the "Ocular Symptoms referable to Renal Disease," introduced by a paper by Dr. L. A. W. Alleman, with a discussion by Dr. Rushmore, Dr. H. R. Price, and Dr. Waterworth. The annual committee on nominations was appointed.

**The Guild of St. Luke.**—An association in London, composed entirely of medical men, whose banding together has for its object their mutual support in looking after the religious welfare of their patients, is known by the name of the Guild of Saint Luke. At a recent public meeting, held at St. Paul's Cathedral, there were present, according to the "British Medical Journal," two to three thousand persons interested in the work of the guild.

**The Middleton Goldsmith Lecture.**—Professor William Pepper, provost of the University of Pennsylvania, will deliver the Middleton Goldsmith Lecture before the New York Pathological Society in the hall of the New York Academy of Medicine on Wednesday evening, January 15, 1890. The subject of the lecture will be "Ilepatie Fever."

**The New York Polyclinic.**—Dr. Francis J. Quinlan has been appointed lecturer on diseases of the throat and nose.

**Bromidia.**—Seven Kansas City druggists were lately fined \$500 each, with costs, for counterfeiting this preparation.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 10 to November 16, 1889:* MACAULAY, C. N. B., Captain and Assistant Surgeon, is granted leave of absence for one month, to take effect about the 29th instant. Par. 2, S. O. 166, Department of the Missouri, Fort Leavenworth, Kansas, November 8, 1889.

MAUS, LOUIS M., Captain and Assistant Surgeon, having relinquished the leave of absence on surgeon's certificate of disability granted him in S. O. 249, October 25, 1889, from this office, will, by direction of the Secretary of War, upon being relieved from duty at Fort Porter, N. Y., as directed in S. O. 242, October 17, 1889, from this office, proceed without delay to Fort Stanton, N. M., and report in person to the commanding officer, Department of Arizona. Par. 8, S. O. 261, Headquarters of the Army, A. G. O., Washington, November 8, 1889.

The following changes in the stations of medical officers serving in this department are hereby made, viz.: CRAMPTON, L. W., Captain and Assistant Surgeon, from Fort Lyon, Col., to Fort Sheridan, Ill.; CORBUSIER, W. H., Captain and Assistant Surgeon, from Fort Hays, Kansas, to Fort Lewis, Col.; IVES, F. J., First Lieutenant and Assistant Surgeon, from Fort Lyon, Col., to Fort Sill, Indian Territory. Par. 3, S. O. 167, Headquarters Department of the Missouri, Fort Leavenworth, Kansas, November 9, 1889.

#### Society Meetings for the Coming Week:

**MONDAY, November 25th:** Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

**TUESDAY, November 26th:** New York Academy of Medicine (Section in Laryngology and Rhinology); New York Dermatological Society (private); Buffalo Obstetrical Society (private); Boston Society of Medical Sciences (private).

**WEDNESDAY, November 27th:** New York Surgical Society; New York Pathological Society; New York Academy of Medicine (Section in Obstetrics and Diseases of Women and Children); American Microscopical Society of the City of New York; Medical Society of the County of Albany; Auburn, N. Y., City Medical Association; Berkshire, Mass., District Medical Society (Pittsfield); Philadelphia County Medical Society.

**THURSDAY, November 28th:** New York Orthopaedic Society; Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private).

---

## Proceedings of Societies.

---

### NEW YORK SURGICAL SOCIETY.

*Meeting of October 23, 1889.*

The President, Dr. LEWIS A. STIMSON, in the Chair.

**Chopart's Amputation.**—Dr. CHARLES McBURNEY showed a patient on whom he had performed Chopart's amputation, suturing the extensor tendons to the plantar flap and keeping the foot in a state of dorsal flexion during the after-treatment, with the idea of securing better power of flexion when the foot came to be used. The result had justified his expectation, and the movements of dorsal flexion were remarkably good.

**Fracture of the Pelvis.**—Dr. McBURNEY also showed a patient who had been brought to the hospital with this injury, together with extraperitoneal haemorrhage filling the prevesical space and infiltration of urine in the same region. An incision was made exposing the prevesical space, and, as rupture of the bladder was strongly suspected, the peritoneal cavity was opened, but no intraperitoneal rupture was found. Additional drainage was provided for by way of the perineum, and the patient had made a good recovery.

Dr. C. K. BRIDDON said, in reply to a question by Dr. McBURNEY, that he had reported several cases of rupture of the bladder; that about two years before he had read the histories of three cases, two of which were associated with bad fractures of the pelvis; that in both cases the fragments were so interlocked as to be immovable. One was treated by incision of the prevesical space and perineal section, but the injury was complicated by others of a severe character, and the man died. The other was treated by suprapubic section alone; the drainage was perfect, and the patient recovered. The third was an intraperitoneal rupture not associated with fracture; the operation of suturing the bladder was done late, and the patient died. When an extraperitoneal rupture had been made out by opening the prevesical space, even with the strictest antiseptic surroundings, he did not regard it as a trivial matter to open and explore the cavity of the peritoneum in search of other suspected injuries; he would not do so without what he might regard as very sufficient reasons. He thought that in operations for extravasation of urine due to rupture of the bladder perineal drainage should not be employed.

Dr. McBURNEY thought that in extravasation of urine perineal drainage at least should be used in all cases.

Dr. J. A. WYETH thought that the question could be settled only by considering the conditions present. Perineal drainage was useful in ruptures about the urethra and the neck of the bladder, and might safely be supplemented by suprapubic drainage. In all these accidents, where the symptoms suggested intraperitoneal rupture of the bladder, it was imperative to open the peritoneal cavity to ascertain the exact condition, and necessary to disinfect that cavity.

**Wound of the Abdomen.**—Dr. FRANK HARTLEY presented a case of lacerated wound of the abdomen with protrusion of intestine and symptoms of internal haemorrhage. The patient was a boy who had fallen six feet, impaling himself on a picket of an iron fence. Laparotomy was performed, and the intestines were replaced. The peritoneal cavity was found to contain a large quantity of blood coming from a perforation of the deep epigastric artery at a point about an inch from the external iliac. The fascia had been torn from the iliac fossa except over the line of the external iliac artery. The artery having been tied, the contused intestine was placed in such a position that an artificial anus might form with safety if the intestine sloughed; the iliac fascia was sutured into position; and the lacerated portions of the muscles in the upper portion of the wound were excised and their ends brought into apposition, but in the lower half the laceration was so extensive as to render this impossible, and that part of the wound was packed with gauze. The patient had made a good recovery, and left the hospital in five weeks. At present there was no hernia, and there was no sign of weakness indicating a probability of its occurrence.

**Habitual Dislocation of the Sternal End of the Clavicle.**—The PRESIDENT presented a youth, nineteen years old, who a few months before had gradually been affected with such laxity of the ligaments of his left sterno clavicular joint that the clavicle became dislocated forward whenever he raised his elbow above his shoulder, and returned to its place when

the arm was lowered. On the right side the bone moved forward in like manner, but not to the extent of dislocation. The condition was very annoying to the patient, and he applied for treatment in the early part of August. As retention by molded splints or bandages was usually not only ineffective but also very troublesome, the president had sought to produce by subcutaneous injections of alcohol such a thickening and condensation of the circumarticular tissues as would prevent recurrence of the dislocation. He had made four injections, at intervals of a week or two, and the patient had refrained from raising the elbow during the whole time, but had worn no apparatus. He could now raise his hand high above his head without causing the bone to slip forward. To the touch the surrounding tissues seemed denser and thicker. The parts had been quite tender for a day or two after each injection. In making the injections he had thrown the alcohol, not into the joint, but into the circumarticular tissues, pushing the point of the needle close to the bone.

**Suprapubic Cystotomy.**—Dr. WYETH presented several specimens of tumors and calculi from three cases in which he had recently operated. The first case was that of a man, forty-eight years old, who had had symptoms of cystitis, with impediment to the outflow of urine, for seven or eight years. These symptoms had gradually increased until the retention of urine had rendered the constant use of the catheter necessary. A diagnosis of obstruction within the bladder having been made, suprapubic cystotomy was performed in the usual way. The bladder contained a uric-acid calculus measuring an inch by an inch and a half. This was readily removed by the wound, giving the exploring finger complete command of the bladder. A tumor, projecting about three quarters of an inch, was found situated immediately behind the outlet into the urethra. This was twisted from its base with Spencer Wells's ovarian-sac forceps, and there was little or no hemorrhage. Retractors were then introduced so as to protect the soft parts, and the surface from which the tumor had been removed was seared with the actual cautery. The ordinary Trendelenburg T-drainage-tube was introduced, iodoform gauze was packed around it, and the usual dressing was applied. The tube was removed on the fourth day, when the symptoms of obstruction and cystitis had entirely disappeared. The sinus closed in three weeks, and the patient was discharged cured, being able to pass his water without the catheter.

Another case was that of a man, forty-five years old, whose symptoms were analogous to those in the case just described. A similar operation was performed, and a tumor measuring half an inch antero-posteriorly and a quarter of an inch from side to side, with an elevation of about three quarters of an inch, was removed. The drainage-tube was taken out on the fifth day, and the sinus had closed by the end of the fourth week, a perfect cure resulting.

The third case was somewhat unusual, being one of acute cystitis and urethritis in a boy of four years, with paralysis of the bladder due to compression-myelitis. The inflammation had resulted from infection by the use of a catheter that had been employed on a patient suffering with non-specific urethritis. The boy's temperature rose as high as 103° F., and his suffering was intense. Suprapubic cystotomy was done in order to clear out the bladder and establish effectual drainage. Relief followed immediately, and now, three weeks after the operation, the tube had been removed and the sinus was closing.

Dr. McBURNEY remarked that the objection to suprapubic cystotomy was the persistent sinus in the track of the tube.

Dr. WYETH said that his experience had led him to believe that the sinuses could be healed readily. In many cases there

was no cystitis and drainage was not important. Then the wound in the bladder could be closed at once with catgut sutures, and a catheter introduced through the urethra for permanent drainage for five or six days. This allowed the bladder to be at rest and the wound in its walls to close. In other cases, where drainage was essential, the tube should be removed at the earliest possible moment, to prevent the tendency to the formation of a fistula.

**Intestinal Anastomosis.**—Dr. F. KAMMERER related the histories of two cases of gastro-enterostomy in which he had lately performed end-to-end anastomosis with catgut rings. The first was that of a woman, about sixty years old, with a tumor of the pylorus and dilatation of the stomach. After making the incision, from the ensiform cartilage to the umbilicus, the speaker divided both the upper part of the jejunum and the pyloric end of the stomach transversely to the course of the organ, and then applied Abbe's rings. The patient got along very well for the first two days, but then peritonitis developed, of which she died on the fourth day.

The second case was that of a man, twenty-nine years old, who had suffered for many years with pyloric obstruction, and came into the German Hospital in a very low condition. As a preliminary measure his stomach was washed out daily for two weeks, but even then the contents had not been entirely withdrawn, and he began to fail so rapidly that, if anything was to be done, it had to be done immediately. Gastro-enterostomy was performed. The speaker incised the viscera in the direction of their course and introduced catgut rings. In this, as well as in the first case, the Lambert suture was added as a precaution. The patient died on the second day, from shock. The speaker had not had the difficulty in finding the upper part of the jejunum that had been met with by some authors. Holding up the lower angle of the abdominal incision and drawing the gut through his fingers, he had easily recognized the duodenum by its attachment to the vertebral column. He had secured each ring with six sutures, two of which were passed laterally on both sides of the incision into the viscera. He thought it would be a good plan to pass the suture lying in the angle of the incision through the walls of the gut, for he had found a tendency of the gut to recede over the ring at that point. This had caused him a great deal of trouble. The specimen from the first case showed clearly the digestive power of the stomach, for the ring was entirely gone. In the second case, however, the ring was completely intact. This he attributed to the patient's low condition. The speaker had had no experience in the use of Senn's plates, but he thought he should use them in his next case, although he must admit that in his second case, in which water had been forced into the jejunum as a test, not a drop escaped at the line of sutures. The sutures were of silk.

Dr. B. F. CURTIS thought it was customary to use six threads with the catgut rings, and always to pass the end threads through the wall of the bowel, and not through the incision. Six Lambert sutures should be added for greater security.

The PRESIDENT said that the use of catgut rings in end-to-end union was not novel; French surgeons had so employed them for over three years.

Dr. McBURNEY said he always passed the end suture through the wall of the bowel, about a quarter of an inch beyond the end of the incision. This he considered safer than to pass it through the angle of the incision itself. He thought there was not much danger of infection through the tissue of the wall of the gut, and silk had the advantage of not being liable to slip and was always soft, whereas catgut was taken out of a liquid that had of necessity rendered it hard and unyielding.

Dr. McBURNEY thought there was very little likelihood of harm being done if the rings were well applied. Peritoneal

adhesion would take place and cover the sutures in. He would ask why Dr. Kammerer had concluded to use Senn's plates in any future case.

Dr. KAMMERER would do so in the hope of avoiding every chance of infection. When catgut rings were employed, many sutures were necessary—at least six or eight or more, for he believed that, when only four were used, there was no absolute guarantee that the parts of the rings between the sutures were in close approximation. Only very little fecal matter would have to find its way between the sutures to cause peritonitis. And any hard material would always make a better approximation of the two surfaces. In his second case the result had been good, however, so far as the anastomosis was concerned.

Dr. BRIDDON said that one of the gentlemen of the house staff of the Presbyterian Hospital, Dr. Shively, had been experimenting with chromicized gelatin as a substitute for the catgut rings. It could be molded into any shape, and could thus be placed in accurate position.

Dr. WYETH asked what the size of the aperture in Dr. Kammerer's specimen had been when it was fresh.

Dr. KAMMERER said that the openings had measured about an inch in length. As to its being the usual practice to pass the end sutures through the wall of the gut, he had not been able to gather from Dr. Abbe's address, in Philadelphia, that he invariably did so. It was known that, when Senn's plates were used, two sutures lay in the angles of the intestinal wound. When the gut was transfixed with sutures in the entire circumference of the catgut rings, the tension on the different parts of the gut lying between the individual sutures after they were tied was probably often unequal. On this account also he believed that the ideal ring was one of unyielding material and armed with few sutures.

Dr. CURTIS repeated that the suture at each end of the oval catgut ring should always be passed through the wall of the intestine in exactly the same manner as those at the side. Unless this was done there was nothing to hinder the intestinal wall at the end of the wound from slipping over the ring.

The PRESIDENT believed that a fatal issue in these cases was due to the escape of the contents of the bowel along the side of the silk ligatures. He thought there would be a manifest advantage in using catgut for sutures as well as rings.

Dr. WYETH thought the greatest danger lay in the possibility of failure to establish thorough communication. The openings always seemed smaller than they ought to be in order to avoid stenosis after the operation.

#### NEW YORK ACADEMY OF MEDICINE.

##### SECTION IN LARYNGOLOGY AND RHINOLOGY.

Dr. CLARENCE C. RICE in the Chair.

Meeting of October 22, 1889.

**A Year's Work in the Section.**—The CHAIRMAN opened the meeting with an address to the Section giving a brief *résumé* of the work done since his election last February. It had seemed to him that the Laryngological Section would fill a larger field of usefulness if the topics of the papers and the discussions treated of subjects which were of interest not alone to the rhinologist and laryngologist, but to those working in other special lines of medical study, and to the general practitioner also, for there were many medical subjects which were pertinent to this Section and at the same time perhaps of special interest to the neurologist or the dermatologist, to the general surgeon, and the family physician. It was therefore thought desirable to select such papers and arrange such discussions as would bring together these different classes of physicians, and

thus secure a respectable attendance at the meetings. No one cared to read a carefully prepared paper to empty seats, and the most enthusiastic rhinologist would fail to find any comfort in his latest ingenious instrument if it could be demonstrated only to the faithful few and the janitor. To the rhinologist, the consideration of medical subjects a little way removed from those directly relating to the nose and throat was of great value. In the daily routine office work it was almost impossible to get beyond the limitations of thought and experience which were closely identified with the class of patients they treated, and broadening medical influences were needed by no class of medical practitioners more than themselves. It was refreshing to hear the aetiology of a cold in the head described by the old-time practitioner. They liked to know how the general surgeon removed a growth or foreign body from the larynx. They were apt to get some new ideas when they closed their textbooks and listened to the neurologist's opinion of the pathology and aetiology of some of the neurotic disorders of the upper air-passages. The physician, too, who spent his time listening to the heart's action, percussing the chest, and making out the borders of the liver and spleen, could suggest causes of congestion and hypertrophy of nose, pharynx, and larynx which seemed indisputable. One other reason for avoiding the consideration of subjects of interest only to the exclusive specialist in laryngology was to be found in the fact that a number of New York's most prominent specialists had seldom favored the Section with their presence. The speaker said that if the members of the Section had lost much by their absence, they had missed hearing some very scientific and instructive papers and discussions. The "New York Medical Journal" and the "Medical Record" had both published the papers of the Section, and he believed would continue to do so. The speaker then briefly reviewed the work of the past season. He tendered his thanks to the gentlemen who had contributed so largely to the success of this Section by their active co-operation, and earnestly requested their continued assistance.

**A Laryngeal Growth.**—Dr. J. H. BILLINGS presented a male patient, about forty-five years of age, suffering from a laryngeal growth. This man, he said, had come to the hospital last spring, when the diagnosis of laryngeal growth had been arrived at, and an unsuccessful attempt had been made to remove it. Then the patient had disappeared and had not been seen again until very recently. The growth had increased in size until the stenosis was almost complete, the patient only having a space of the size of a crow's quill through which to breathe, and the condition had appeared such as to demand immediate attention. It was difficult to give any opinion as to the character of the growth. Some portions of it were as yet quite movable, but there was considerable oedema. The growth might be a papilloma.

Dr. G. B. HOPE said that the growth had hardly been under observation long enough to test the character of it. After an ineffectual effort had been made to remove a portion of the tumor it had been proposed to temporize with the case, or to obtain a small portion of the growth for microscopical examination. There had been some history of syphilis, but not a definite one. The patient had, however, been given iodide of potassium in fifteen-grain doses, and had already reported some mucous-membrane irritation. It was not desirable to interfere at the present juncture, unless the question of saving the man's life came up for immediate consideration. Opinions upon the nature of the case were divided, as to whether the tumor was of a gummatus form or something intrinsically more serious.

Dr. R. P. LINCOLN thought it better to wait and test the effect of the anti-syphilitic treatment before any radical operation was attempted. The general appearance of the parts, and

the absence of any involvement of the surrounding structures, suggested syphilitic rather than malignant trouble. The treatment which had been already instituted might demonstrate something as to the real nature of the case.

**A Foreign Body in the Bronchus.**—Dr. W. K. SIMPSON reported the history of a case of a tooth in a bronchus. This foreign body had remained in the tube more than six months and had then been expelled. The patient, after having fourteen upper teeth extracted at one sitting, under nitrous-oxide gas, had gone two days after this and had one more tooth extracted, again taking gas. On recovering this last time she had experienced a slight tickling in the throat, followed by cough. About a month after this, severe pain had been felt on the right side of the chest, in the axillary line. This pain had lasted a week and had been succeeded by a whistling sound on breathing. The cough had remained. When she was seen, on March 10, 1889, her tongue was excessively hyperæmic, the tissue was denuded, and the general appearance was that of follicular amygdalitis. The speaker had considered the cough due to the condition at the base of the tongue. The case had remained under his care until May 25th, with little change in the cough. Various forms of routine treatment, in the way of application and cauterization, had been adopted. On the above-given date pain in the right lung had been felt, and percussion had demonstrated a well-marked area of dullness. The patient was removed to a hospital, where she rapidly became worse, her temperature running as high as 105° F., and the pulse rising to 120. Light râles were detected over the area of dullness. The patient had become cyanotic, and her death was apparently imminent. She was much relieved by the inhalation of oxygen. Two days later, during a severe attack of coughing, she expectorated a thick mass of material tinged with blood, in which was imbedded the large root of a tooth. Her subsequent history had been one of rapid improvement. The hyperæmia at the base of the tongue still existed, and the question had suggested itself whether this was of itself sufficient to cause the paroxysmal cough.

Dr. R. C. MYLES, in reply to a question, said that he had always found the galvano-cautery efficient in treating such conditions at the base of the tongue. He had tried chromic acid, but it was far from satisfactory. Not infrequently it ran down upon the edges of the epiglottis and on to the hyoid bone.

The CHAIRMAN thought it most important to recognize this pathological condition, for it was one which, in addition to keeping up a distressing cough, might eventually produce catarrh of the larynx. In the majority of cases it would be necessary to use a mirror, and then the diagnosis was readily made. The enlarged papillæ were to be seen overlying the epiglottis, the latter being inflamed and congested.

**A Tooth-plate in the Laryngo-pharynx (?) for Sixteen Days.**—Dr. C. H. KNIGHT read a paper with this title. He said that the case was somewhat extraordinary in view of the shape and size of the foreign body and its prolonged retention.

Mary O'C., aged twenty-six, married, was confined with twins on July 19, 1889. After delivery she had a convulsion. Several more occurred on succeeding days. On the sixth day she had become sufficiently conscious to be aware of having considerable difficulty and pain in swallowing. The voice had gone and there was some dyspnoea. The cause seemed not to have been suspected. Matters went on in this way for some time with no attempt to take solid food, until the sixteenth day, when a violent attack of coughing and vomiting occurred. The patient had been conscious of a mass of some kind which had come partially into her mouth and dropped back again. Her dyspnoea and other symptoms had become much intensified. Her physician, who had been summoned, had failed to remove

the foreign body with instruments, but finally had succeeded in withdrawing it by means of his finger. The speaker had first seen the patient at the Vanderbilt Clinic on August 26, 1889—more than a month after the accident. She had then complained of pain on the right side of the larynx radiating upward and backward toward the ear, and aggravated by swallowing. A dysphagia had at times been so marked that she had refrained from trying to eat solid food, and in consequence her general condition was bad. The voice had been completely lost, and attempts at phonation were fatiguing and painful. Breathing was stridulous, and under exercise or excitement quite labored. There was an almost constant hacking cough, with profuse expectoration of frothy, muco-purulent sputa. Dr. James examined the lungs and found no pulmonary disease. Laryngoscopic examination showed the larynx to be very hyperæmic and distorted. The image was obscured by the abundant secretion which was present. The left side of the larynx was chiefly affected and was immovable. The epiglottis was of nearly twice the normal thickness; the left aryteno-epiglottic fold was enormously swollen and edematous. The left ventricular band was

swollen nearly to the median line and entirely concealed the left vocal cord. The middle third of the right vocal cord was visible and intensely congested. The swelling of the tissues was less on the right side. At no point could any indication of ulceration or laceration be seen.

Narrowing of the chin of the glottis was so extreme as to suggest the necessity of intubation or tracheotomy. The appearance of the parts indicated serious damage to the laryngeal cartilages. The speaker was quite prepared for necrosis with its unhappy consequences.

To his surprise, however, improvement began and steadily progressed. The left vocal cord became exposed as the swelling subsided. The left side gradually resumed its share in the respiratory and phonatory functions of the larynx. Still the voice had not been restored and the reason had become evident as the parts had approached their normal proportions. The posterior third of either vocal cord was missing; it looked as though it had been cut out with a sharp curette. Such a lesion would, of course, be permanent. In contraction of the laryngeal adductors the anterior portions approximated, leaving a wide gap at the posterior commissure. The ventricular bands appeared to assist the true cords in their attempts at phonation, but without succeeding in raising the voice above a whisper. The foreign body which had caused this condition was a hard rubber plate with the fragment of its single tooth still attached. This plate measured three inches in length and three eighths of an inch in width, its greatest thickness being less than a third of an inch. The distance between its two extremities was a little more than an inch. On one side it was smooth, on the other was the roughness for adaptation to

the alveolar processes. Projecting from its anterior margin were seven or eight sharp points, which fitted in between the teeth. The character of the lesion as it appeared suggested the position possibly assumed by the foreign body. Although any theory on that point would have to be purely speculative, it had seemed to the speaker that one arm of the plate had rested in the laryngo-pharynx, while the other had occupied the posterior commissure of the larynx, impinging upon and finally eroding the vocal bands. Had it been swallowed reversed, with the

ends of the plate looking upward, it would probably have been carried farther down, and its spontaneous expulsion have been hardly possible. Having been wedged in the position surmised, it had been firmly held by muscular spasm, and swelling and edema had quickly supervened. Finally it had been loosened by an ulcerative process and dislodged by a violent expulsive effort. The remarkable tolerance of the parts might be explained by the fact that the patient lay in a semi-conscious state for six days after the accident. The present condition of the patient showed much general improvement. She still complained of pain on swallowing and constant soreness, also of deep-seated pain in the right ear, for which the aurists could find no local cause. The larynx had nearly recovered its normal condition with the exception of each vocal cord. The parts still continued red, with more or less thin purulent secretion, which seemed to ooze from the posterior wall of the larynx. The latter fact, together with the offensive breath and persistent pain on deglutition, the speaker thought pointed to the existence of necrosis. The chronicity of these cases was well known, and it might be many months before positive proof of the suspicion appeared. The treatment in this case had consisted of the use of general tonics and local sedative applications, steam inhalations, and, externally, water fomentations. The question of treatment in such cases was always one of importance. In the event of urgent dyspnoea the foreign body must be removed or a new air-passage provided by opening the trachea. The speaker thought that his case was a most eloquent argument in favor of conservatism. In conclusion he offered the following query: In a case of firmly impacted foreign body of large size and irregular shape, would it not be wiser to defer forcible attempts at removal until it had become in a measure loosened by natural processes, provided there seemed to be danger of causing extensive laceration in the act of dragging it from its bed, and provided no urgent symptoms were present?

Dr. MAVERT said that the patient whose case had been reported by Dr. Knight had been delivered of twins in his service at the hospital. He had, however, seen her some time before this, and she was at that time somewhat edematous in the lower extremities; her urine was albuminous and of high specific gravity, but contained no casts. She had given birth to a child three years before without any complications. He had restricted her to appropriate diet, under which the condition of the urine had improved. When she next reported at the hospital she was in labor and was delivered of twins. No chloroform was administered. During the afternoon, a few hours after delivery, a violent headache set in, for which she was given morphine, potassium bromide, and chloral. Soon after this he was told that she had had a convulsion. When he arrived at the patient's bedside she was in the stage of stupor, but soon after went into a well-marked eclamptic condition, during which she

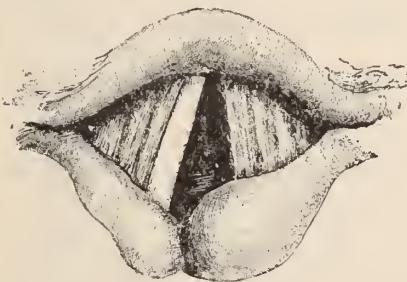

FIG. 1.

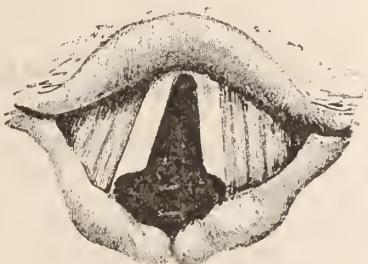

FIG. 2.

FIG. 3.

bit her tongue, and the speaker observed that she had no artificial teeth. She had at intervals several more seizures, which eventually yielded to treatment. During the first twenty-four hours after delivery the patient had first complained of soreness in the throat, and considerable mucus seemed to be accumulating, with some slight cough attending. He made an ordinary examination with a tongue depressor, but, knowing nothing of the existence of any foreign body in the mouth, suspected no complication of that kind. She was treated on general principles as having uremia and acute Bright's disease, being given nothing but liquid diet, which she was able to swallow readily. About a day or so after her delivery he was told that the patient had missed her artificial dental plate, the size of which she had described. Then her throat was examined, but without using a mirror, and nothing was seen. Four days later she sent for him to say that the plate was in her throat. Then the laryngoscope was used, the partially broken tooth and dental plate were seen, and an attempt was made to remove them with a light dressing forceps. These did not answer, and he introduced his finger, and, after several trials, removed the plate.

Dr. S. D. POWELL said that he had not had very extensive experience with foreign bodies in the air-passages. The first case had been that of a colored man, who, while laughing with his mouth full at dinner, had got a piece of meat with bone attached into his windpipe. The meat had entered between the vocal cords, the bone remaining free. The speaker was sent for, and succeeded with his fingers in pulling away the bone only, breaking it away from the meat, which was firmly fixed between the vocal cords. He then at once did laryngotomy, and with a probe pushed the meat out of the larynx, whence it was removed with a forceps. Another instance had been that of a child, five years of age, who was brought to his office on account of painful deglutition and loss of voice. Examination revealed a foreign body lodged below the vocal cords, which were very edematous, the body having been in the trachea several days. He attempted to get hold of it with forceps, but failed, and performed thyreotomy and succeeded in removing a small shell of about half an inch in diameter. Frequently these cases were not seen until all the spasmotic symptoms had passed off. It was at all times well to endeavor to quiet the patient. If much spasm existed, the throat should be swabbed out with a brush soaked in a 15-per-cent. to 20-per-cent. solution of cocaine. Then it was well to find whether reasonably strong evidence could be urged that something had really been swallowed which demanded attention. He deprecated the plan of suddenly inverting a child supposed or known to have swallowed something. The method of at once throwing the child down and then inverting it was apt to produce spasm and cause death. It was better to let the child remain perfectly quiet until the spasm had subsided. It was not well to rely on the absence of acute symptoms. The trachea would become more or less tolerant of a foreign body after a few hours. Delay in this event was much more dangerous than an operation. Tracheotomy and laryngotomy were not difficult or dangerous operations, and it was much more satisfactory to have made some effort. The question of probing should be determined by the character of the foreign body. If this was perfectly round and smooth, like a pea or bean, its use was of very questionable utility. He disputed the judgment which urged the use of probes and forceps in the trachea.

Dr. LINCOLN remarked that there could be no law laid down *ex cathedra*; each case must be a case *sui generis*, and must throw the practitioner upon his own resources. It was necessary first to know what one had to deal with and determine what should be done. As to the propriety of inverting patients, which practice had been deprecated by Dr. Powell, he thought that the

expedient had saved many lives. He should be sorry if any one were deterred from trying it. It was a simple procedure when the emergency was so great as to allow of no delay for anæsthetics of any kind. Among several cases illustrative of the vagaries to which foreign bodies in the air-passages were liable, he narrated one to show that the foreign body was not always there. He had received a summons to go at once to a gentleman's house. On arriving there, he learned that two surgeons, well known and able men, had already been sent for, they having been notified that the patient had insisted upon it that he had swallowed his false teeth. They came prepared to make an examination and passed bougies into the stomach, but failed to discover anything. The patient was very much depressed, as he had been notified of the seriousness of a contemplated operation. The speaker urged that it was utterly impossible for the teeth to have been swallowed, the size of the plate making it mechanically impracticable. While they were still in consultation a messenger arrived with a package containing the missing teeth.

The discussion then became general, many members relating interesting experiences within their knowledge of foreign bodies in the upper air-passages, and the various means adopted for their removal.

The CHAIRMAN said that cocaine had so revolutionized the work of examining the laryngo-pharynx that it could now be done with a minimum of discomfort to the patient. The parts could be quieted to such an extent that any one accustomed to the manipulation of the necessary instruments would have no difficulty. The cases should, however, without doubt, be sent to experts. He had been called in consultation to a case in the country. The doctor in attendance showed him a foreign body in the patient's throat. It was the epiglottis. The doctor, who had been working at it for some hours, had not succeeded in entirely removing it.

## Book Notices.

*A Manual of Minor Surgery and Bandaging, for the Use of House-Surgeons, Dressers, and Junior Practitioners.* By CHRISTOPHER HEATH, F. R. C. S., Surgeon to University College Hospital and Holme Professor of Clinical Surgery in University College, London, etc. Ninth Edition. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. xvi-361. [Price, \$2.]

WE should be glad if this book could be placed in the hands of every student after he has passed his examinations and is waiting for the day to come when he is to enter upon his duties on the hospital staff. All through his hospital life, indeed, he could profitably keep it within reach. It is practical, and there is no need for the author to tell us that he has been a house surgeon; the book could not have been written by one who had not been one. The mutual relations between the house staff and the powers that be could not have been treated of so delicately and reasonably, neither could such sound advice have been given, by any but one who had borne his part in the battles between these two great powers.

The work differs from most books on surgery in that it deals more with those minor points the knowledge of which is usually acquired by oral instruction or simply by imitation, but which to a considerable degree conduce to success in surgical practice. It is written in the author's well-known clear style, and is creditably got up by the publishers.

## BOOKS AND PAMPHLETS RECEIVED.

The Principles and Practice of Surgery. By John Ashhurst, Jr., M. D., Boston, Professor of Surgery and of Clinical Surgery in the University of Pennsylvania; Surgeon to the Pennsylvania Hospital, etc. Fifth Edition, enlarged and thoroughly revised. With Six Hundred and Forty-two Illustrations. Philadelphia: Lea Brothers & Co., 1889. Pp. xxviii-33 to 1148. [Price, \$6.]

Guide médical à l'exposition universelle internationale de 1889 à Paris. Par Marcel Baudouin, secrétaire de la rédaction du Progrès médical. Avec la collaboration de MM. P. Achalme, G. Capus, P. Kerval, L. Lamotte, A. Raoult, L. Regnier, A. Rousselet. 1er fascicule—Instruments de chirurgie et de précision. Avec nombreuses figures dans le texte. Paris: E. Lecrosnier et Babé, 1889. [Prix, 3fr. 50.] [Publications du "Progrès médical."]

La pertosse e le sue vicende scientifiche. Valore ed efficacia di un metodo curativo speciale. Por Dott. G. Guidi. Firenze: G. Civelli, 1889. Pp. 99.

Disturbed Equilibrium of the Muscles of the Eye as a Factor in the Causation of Nervous Diseases. By A. Friedenwald, M. D., Baltimore. [Reprinted from the "Transactions of the Medical and Chirurgical Faculty of Maryland."]

Periostitis of the Ribs after Typhoid Fever, and its Probable Dependence on Medication. By S. O. Lewis Potter, M. D., San Francisco, Cal. [Reprinted from the "Pacific Medical Journal."]

On a General System of reporting Autopsies in American Asylums for the Insane. By H. E. Allison, M. D., Auburn, N. Y.

Il calomelano nella febbre tifoide. Per il Dott. Umberto Dieci. [Estratto dalla "Rassegna di scienze mediche."]

Biennial Report of Medical Examiner in Chief, American Legion of Honor, 1887-'84, J. Foster Bush, M. D.

The Value of the Electrical Methods employed for the Resuscitation of Persons who have ceased breathing. By H. A. Hare, M. D., and Edward Martin, M. D. [Reprinted from the "University Medical Magazine."]

Experiments to determine the Value of Oxygen in the Resuscitation of Animals poisoned by CO or Ordinary Coal Gas. By H. A. Hare, M. D., and Edward Martin, M. D. [Reprinted from the "University Medical Magazine."]

The Proposed New Lunacy Law. By Frederick Peterson, M. D. [Reprinted from the "Medical Record."]

On Unusual Methods of acquiring Syphilis, with Reports of Cases. By L. Duncan Bulkley, A. M., M. D. [Reprinted from the "Medical News."]

The Education of Girls from a Medical Standpoint. By Edward W. Jenks, M. D., LL. D., Detroit. [Reprinted from the "Transactions of the Michigan State Medical Society."]

The Ship's Surgeon of To-day. By Charles Henry Leet, Fellow of the Royal College of Surgeons, England, etc.

Contributo allo studio delle nefriti. Nota del Dott. Giuseppe Bassi. [Estratto dalla "Rivista clinica archivio italiano di clinica medica."]

Ricerche sul soffio sottoclavicolare, del Dott. Carlo Borsari. [Estratto dalla "Rivista clinica archivio italiano di clinica medica."]

Un caso di atassia locomotrice curato con la sospensione e seguito da morte. Pel Dott. Carlo Borsari. [Estratto dalla "Riforma medica."]

Un caso di atossicamento carbonico con paralisi del trigemino. Pel Dott. Carlo Borsari. [Estratto dalla "Riforma medica."]

Esiste una peritonite eroinica essudativa idiopatica? Pel Dott. Giuseppe Molinari. [Estratto dalla "Riforma medica."]

A Manual of Obstetrics. By A. F. A. King, A. M., M. D., Professor of Obstetrics and Diseases of Women and Children in the Medical Department of the Columbian University, Washington, D. C., and in the University of Vermont, etc. With One Hundred and Forty-one Illustrations. Fourth Edition. Philadelphia: Lea Brothers & Co., 1889. Pp. xxiv-25 to 431. [Price, \$2.50.]

A Reference Hand-book of the Medical Sciences, embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By Various Writers. Illustrated by Chromolithographs and Fine Wood Engravings. Edited by Albert H. Buck, M. D., New York city. Volume VIII. New York: William Wood & Company, 1889. Pp. vi-801.

Ninth Annual Report of the State Board of Health of New York. Transmitted to the Legislature February 26, 1889.

The Medical News Visiting-List, 1890. Philadelphia: Lea Brothers & Co., 1889.

Papillome et tuberculose du larynx. Par le Dr. A. Gougenheim, médecin de l'hôpital Lariboisière. [Extrait des "Annales des maladies de l'oreille, du larynx, du nez et du pharynx."]

On Subluxation of the Head of the Radius in Children; with a Résumé of One Hundred Consecutive Cases. By W. W. Van Arsdale, M. D., New York. [Reprinted from the "Annals of Surgery."]

The Education of Girls from a Medical Standpoint. By Edward W. Jenks, M. D., LL. D., Detroit, Mich. [Reprinted from the "Transactions of the Michigan State Medical Society."]

Transactions of the Tenth Annual Meeting of the American Laryngological Association, held in the city of Washington, September 18, 19, and 20, 1888.

Report on a Second Series of One Hundred Successive Cataract Extractions without Iridectomy. By H. Knapp. [Reprinted from the "Archives of Ophthalmology."]

Constitution and By-laws of the Association of the Alumni of the College of Physicians and Surgeons in the City of New York. Incorporated May 12, 1873.

Transactions of the Medical and Chirurgical Faculty of the State of Maryland at its Ninety-first Annual Session, held at Baltimore, Md., April, 1889.

A Contribution to the Surgery of the Spinal Cord. By William Thorburn, B. S., B. Sc., M. D. (Lond.), Fellow of the Royal College of Surgeons of England, etc. With Diagrams, Illustrations, and Tables. Philadelphia: Blakiston, Son, & Co., 1889. Pp. vii-230. [Price, \$4.50.]

An Introduction to the Study of Organic Chemistry. By Adolph Pinner, Ph. D., Professor of Chemistry in the University of Berlin. Translated and revised from the Fifth German Edition by Peter T. Austen, Ph. D., F. C. S., Professor of Analytical and Applied Chemistry in Rutgers College and the New Jersey State Scientific School. Second Revised Edition. New York: John Wiley & Sons, 1889. Pp. xxi-403.

Chemical Lecture Notes. By Peter T. Austen, Ph. D., F. C. S., etc. New York: John Wiley & Sons, 1888. Pp. ii-98.

A Hand-book of Physical Diagnosis of Diseases of the Organs of Respiration and the Heart, and of Aortic Aneurysm. By R. C. M. Page, M. D., Professor of General Medicine and Diseases of the Chest in the New York Polyclinic, etc. New York: J. H. Vail & Co., 1889. Pp. viii-291.

## Reports on the Progress of Medicine.

### OBSTETRICS.

BY ANDREW F. CURRIER, M. D.

**Intra-uterine Fractures** ("Gaz. méd.", March 2, 1889).—All writers now admit the possibility of accidents of this kind. Traumatic fractures now excite very little discussion with regard to their aetiology. Whatever be the manner by which the traumatism is applied, it appears to be the sole cause in such cases. Such a traumatism is usually experienced in the second half of pregnancy. It is not necessarily followed by abortion; on the contrary, the pregnancy usually continues to term. The possibility of intra-uterine fractures of the cranium is one which may involve legal questions of great importance. In fractures with any form of arrest of development or fault of conformation there is usually a history of traumatism in connection with the mother. The relations between such a traumatism and different malformations of the foetus give rise to numerous hypotheses. There seems to be no such thing as syphilitic fracture. What has been described as such is probably of the nature of an epiphyseal displacement. Fractures of rachitic origin, fractures due to fragility or softness of the foetal skeleton, might be referred to the class of spontaneous fractures. The former of these constitute a distinct nosological type; as to the latter,

histological examinations are not sufficiently numerous, as yet, to make of them a special type. The congenital fractures which occur most frequently are those of the leg. They are often associated with deformities of different kinds, which are located mainly in the limb which has sustained injury. A striking peculiarity in some cases is the complete or partial absence of the fibula. As to the variety in the complications, it seems to be about the same as in adults. Complete cure during intra-uterine life is an unquestionable fact. Treatment by osteoclasis, osteotomy, or tenotomy diminishes the importance of deformities resulting from intra-uterine fracture. Surgical intervention should be instituted at a time when there are no malformations which are incompatible with the life of the child.

**Acute Meningitis during Pregnancy** (Le Page, *ibid.*, March 9, 1889).—If an acute disorder occurs to a woman who has reached the latter months of pregnancy the question often arises whether it is desirable to terminate the pregnancy artificially. Obstetricians are now almost unanimous in advising, in such cases, an expectant line of treatment—(1) because the acute disease, if severe, almost always causes spontaneous interruption of the pregnancy; (2) because the prognosis of the disease in the mother would be aggravated by operative interference; (3) because the foetus usually participates in the disease of the mother, and its existence would be compromised by such interference.

Though these are good reasons for the greater number of grave acute diseases, and especially for the eruptive fevers, they may not serve as guides for all acute diseases. Each pathological group brings its own particular indications, and this is eminently true concerning meningitis. Whether tuberculous in character or simply inflammatory, it is not rare in adult life, and may occur in pregnant women. Of seven cases which have been analyzed by Chambrelin, in six delivery did not take place spontaneously; in the seventh it occurred a few hours before the death of the mother. In all the cases in which no attempt at extraction was made, the autopsy showed that no pathological changes had taken place in the foetus. In all the cases in which the child was extracted it was born alive. From these cases it might be concluded that if a woman had reached the seventh month of pregnancy and meningitis should then supervene, premature labor should be instituted prior to the death of the mother, as one would then be able, in all probability, to extract a living child. Such a course would not affect the prognosis in the mother's case, since that is almost absolutely fatal. The objection might be made, in case of tuberculous meningitis, that it would be useless to extract a child which would probably be infected by the disease and would die a few days after birth. But the reply to this would be that it is often very difficult to decide before death whether a meningitis is of a tuberculous character, and also that the transmission of the tuberculous infection from the mother to the child may not be fatal. Furthermore, a physician has no right to anticipate the future in such a way, his first duty being to save life whenever it is possible.

**The Microbic Origin of Puerperal Fever** (Smith, "Traus. of the Royal Medical and Surgical Society").—The author has made cultivations in gelatin with blood taken from the heart of a woman who died from puerperal fever, and after an interval of two or three days many colonies of a micrococcus were evident. Rats inoculated with the microbe died after three or four days, the micrococcus being found in their blood. Inoculations were also made in the ears of rabbits, and at the end of twenty-four hours a circumscribed redness, without tendency to diffusion, was apparent, differing in that respect from the redness of erysipelas. The redness disappeared after two or three days. A new series of cultivations and inoculations with blood taken from the finger of a woman sick with puerperal fever gave similar results. The following conclusions were reached:

1. There exists in the blood of women suffering with puerperal fever a particular micro-organism.
2. This micro-organism is a streptococcus which differs much from others, as shown by cultivation and inoculation.
3. The action of this micro-organism upon rats and rabbits is very definite.
4. It differs decidedly from the *Streptococcus erysipelatus* of Fehlisen and the streptococcus of Rosenbach.

**Rupture and Suppuration of the Pelvic Joints during Labor and the Puerperal Period** (Dührssen, "Arch. f. Gyn.", xxxv, 1).—The un-

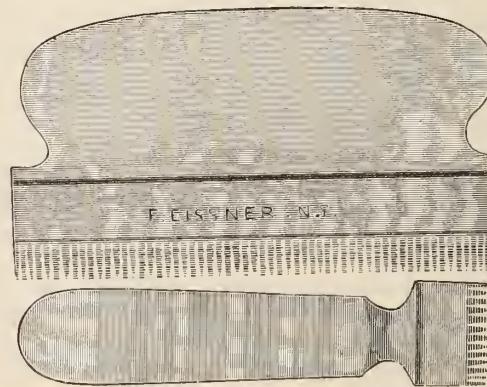

qualified statement of the text-books that the prognosis in suppuration of the symphysis is unfavorable is not strictly correct. One should not include in this class the cases in which there is general septicæmia or pyæmæia, in which the prognosis is always bad. The prognosis will depend upon the treatment which is followed, and it will be unfavorable only in cases in which no incision is made. If an incision is not made, a cure will result only when there is an open rupture of the symphysis with free discharge of the pus, or when the pus is discharged from a spontaneous opening. After the pus has been discharged there is usually healing by bony callus. The causes of suppuration of the symphysis are pyæmæia from metastatic inflammation of the joint; infection of a non-septic nature through a vaginal wound, which may not occur until the puerperal period; and tuberculosis. A rupture of the symphysis having occurred, the presence of fever for the first seven days does not necessarily imply suppuration. It may be dependent upon the absorption of extravasated blood. Should the fever continue, with constant pain and increased swelling in the joint, the evidence is that the extravasated blood has undergone suppuration. Suppuration in the symphysis when the latter has not ruptured may easily be overlooked. Hence, when puerperal fever without apparent cause occurs, the syntheses of the pelvis must not be overlooked in one's examinations. Incisions should be made early in order to anticipate the burrowing of pus. Extraction of the after-coming shoulders, even though difficult and requiring the use of some force, will not cause rupture of the syntheses unless there are pathological changes in the latter.

## New Inventions, etc.

### TWO SCARIFICATORS FOR THE SURGICAL TREATMENT OF ERYSPIELAS.

BY A. SEIBERT, M. D.,  
NEW YORK.

THE accompanying cut represents the scarificators designed by me as best adapted for making the surgical "fence" in the healthy skin surrounding the inflamed cutis in erysipelas. The smaller instrument is used for drawing the long bloody line, and the comb-like, larger one for crossing this at right angles. The cut shows the instruments of their right size.

The scarificators are made of steel and each of one piece, have no nooks or corners, and may be easily sterilized by boiling.

In reference to the three cases of erysipelas in children successfully treated by me by my modification of the Riedel-Kraske method ("New York Medical Journal," October 19, 1889), I can now report a case of severe facial erysipelas in an anæmic woman aged fifty-eight years, which had existed for five days and had spread from ear to ear and from the chin to the scalp. The "fence" made encroached about an inch above the forehead upon the capillitium, the hair being first cut off with scissors.

The temperature fell in six hours after the little operation (executed without anaesthesia) from 104·5° to 99° F., the erysipelas came up to the "fence," but never crossed it, and the patient was practically well the next day and was up and about in forty-eight hours after the treatment was instituted.\* Two weeks after, no trace of the work of the scarificators could be detected. The points of the instruments being partly blunt and partly sharpened, the incisions can necessarily only be made superficially and only deep enough to draw blood, thus preventing any possible future scar.

## Miscellany.

**Retention of Urine from Enlarged Prostate.**—This condition of advanced life is met with very often both in city and country practice, and is generally easy of diagnosis, yet every consulting surgeon has seen cases where the exact condition was not made out. There are many causes of retention, but hypertrophy of the prostate gland is by far the most common. At the recent meeting of the British Medical Association held at Leeds, Dr. McGill opened the discussion on the subject, which was reported in full in the "British Medical Journal." He laid down several propositions :

1. Prostatic enlargements which give rise to urinary symptoms are intravesical and not rectal. The severity of the symptoms bears no relation to the apparent size of the enlarged gland as felt through the rectum. Nearly every man above the age of fifty-five has this enlargement, yet only about 50 per cent. have any urinary troubles. This is owing to the direction in which the gland is enlarged. An enormous gland may project toward the perineum or rectum, and give no urinary symptoms, while severe symptoms may be produced by a normal-sized gland as felt through the rectum. The enlargement may extend toward the rectum so as nearly to fill the lower aperture of the pelvis, causing complete intestinal obstruction. He mentions several varieties of intravesical enlargement : (1) a projecting middle lobe; (2) a middle lobe with the lateral lobes forming three distinct projections; (3) the lateral lobes alone; (4) a pedunculated growth springing from the lateral lobe alone; (5) a uniform circular projection surrounding the internal orifice of the urethra. This latter variety is quite common, but has to be seen *in situ*.

2. Retention is caused by a valve-like action of the intravesical prostate, the urethral orifice being closed more or less completely by the contraction of the bladder on its contents. A patient, finding himself unable to void his urine, soon ceases the violent efforts, the pressure on the valve is lessened, the urethral orifice is released, and a small amount of urine passes away. If he attempts to expel it more quickly, the flow is again stopped and it requires several trials of this kind to get relief. The time comes when he can not get any relief, although the bladder contains urine to the amount of a pint or more. The pressure, with the consequent desire of micturition, is accounted for by the fact that a more violent contraction of the wall is required to completely than to partially empty the organ, and that its muscular coat acts to greater advantage, and consequently with greater force, in its partially contracted than in its distended condition.

3. In many cases self-catheterism is the only treatment required. Under this head we desire to speak of the careless way in which many physicians cleanse their instruments. Dipping into water and wiping with a rag is not at all sufficient to render them antiseptic. The way catheters are made makes it almost impossible to keep them clean, for in the space below the eye there is the best chance for filth to collect. The end should be solid instead of hollow. After use, the metal instruments should be put into boiling water and allowed to remain a few minutes and then passed through an alcohol flame until all organic matter within is volatilized by burning, and this should be continued until

all smoke and steam have ceased to escape. Occasionally catheters should be put into boiling water and allowed to remain an hour or two.

4. When the catheter treatment fails or is unavailable, non-radical measures are necessary. It is the writer's belief that, sooner or later, in the cases treated with the catheter the prostatic enlargement causes death. The urine becomes thick and ammoniacal, the desire to micturate becomes continuous, the passage of a catheter relieves for but a few minutes, and the suffering and discomfort are constant. The greatest care can not always prevent them, or the grossest carelessness induce them. Some patients, especially if of a nervous temperament, can not learn to use the instrument themselves. The constant attendance of a surgeon is impossible, and thus the catheter treatment fails.

5. This treatment, to be effectual, should for a time thoroughly drain the bladder and permanently remove the cause of the obstruction. Perineal drainage was introduced for the purpose of giving relief in cystitis. This relief is only temporary. Either the patient must always wear a urinal or else the urinary fistula be allowed to close with the probable recurrence of the symptoms.

6. These indications can best be fulfilled by a suprapubic rather than by a urethral or perineal operation. Dr. McGill prefers the suprapubic for the following reasons: It is more generally applicable. It can be performed with greater precision and completed with greater certainty. It insures complete and most efficient drainage. It is equally safe. He goes on to speak of the *technique* founded on an experience of thirty-seven suprapubic operations. A table of twenty-four cases is given, which includes seven cases of lithotomy. Out of this number three patients died from the operation and one from pneumonia while he was convalescent, two were under treatment when the discussion took place, and one had been lost sight of. Of the remaining ten, eight have continued well. In six of the recorded cases the prostatic retention was of long standing, and in all of them the bladder had expelled its contents since the operation. Two of the men operated upon were under the age of fifty-five. The author gives Dr. Belfield, of Chicago, the credit of first performing this operation, which he did in 1886. The discussion was participated in by ten of the leading surgeons, and it was generally conceded that this operation was justifiable in cases of prostatic retention, and would occupy a permanent place in operative surgery.

**Physicians as Financiers.**—The "Cincinnati Medical News" says: "Physicians are generally admitted to be exceedingly poor financiers. There is probably no class of men who realize so little financially from their labors. Persons are often astonished in how straitened circumstances many physicians, who were known during life to have had large practices, on dying, leave their families. They lived moderately; indulged in no luxuries; yet, after all debts have been paid, there will be left to the families of each one probably only a very unostentatious dwelling. For the last twenty-five or thirty years efforts have been made to simplify the business books of physicians, so that as little time as possible would be required for a medical man to enter his charges and keep something like a systematic account of his business. It has been found impossible for one engaged in the active practice of medicine to keep what is called a day-book, a cash-book, and a ledger, for with such a set of books, oftentimes not having time to enter any charges for two or three days, he will frequently forget many items. Then, again, frequently he will let his ledger go unposted for weeks and months, and when called upon to make out a bill he will in consequence not be able, and will be under the necessity of asking the applicant to call again. Visiting lists have been constructed to enable physicians more easily to keep account of their services; and they have certainly been of great use. We feel sure that through them we have saved many dollars which, without them, we should have lost. The very best book that we know of for a physician in which he can keep an account of his services to all his patrons is 'Bernd's Physician's Register.' For a physician to keep one of these requires no skill, no knowledge of book-keeping. A ten-year-old child can master it; and yet a more methodical, a better adapted method of keeping a physician's accounts could not be devised. If a doctor can not with one of these register all his business, so that he can know at any time who owes him and who does not, there will be no hope of being able to

\* This patient was also demonstrated to my class at the New York Polyclinic four days after the operation.

devise anything for him so that he can keep an account of his business. We consider that the members of the medical profession are under great obligation to Messrs. Henry Bernd & Co. for their 'Register.' We hope they will have a large sale, not for the sake of the Bernds merely, but for the sake of the families of physicians."

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the abstract of sanitary reports received by him during the week ending November 15th:

CITIES.	Week ending—	Estimated population.	DEATHS FROM—									
			Total deaths from all causes.	Cholera.	Yellow fever.	Small-pox.	Variolæ.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Malaria.
New York, N. Y.	Nov. 9.	1,588,363	615					8	2	15	4	5

**The Health of Connecticut.**—According to the State Board of Health's "Monthly Bulletin," the total number of deaths reported from 166 towns during the month of October was 1,027, including 7 from scarlet fever, 6 from cerebro-spinal meningitis, 71 from diphtheria and croup, 12 from whooping-cough, 37 from typhoid fever, 10 from malarial fever, and 13 from typho-malarial fever. There were also 148 deaths from consumption, 64 from pneumonia, and 34 from bronchitis.

**The Health of San Francisco.**—According to the Health Department's "Condensed Statement of Mortality" for October, the whole number of deaths was 507, including 2 from cerebro-spinal meningitis, 14 from cholera infantum, 10 from croup and diphtheria, 3 from erysipelas, 30 from typhoid fever, 2 from whooping-cough, and 3 from scarlet fever.

**The New York Academy of Medicine.**—At the next meeting of the Section in Laryngology and Rhinology, on Tuesday evening, the 26th inst., Dr. H. Hollbrook Curtis will report "A Case of Cocaine Habit, with Remarks on the Dangers of the Use of Cocaine"; Dr. George H. Fox will report "A Case of Erythematous Lupus of the Face and Oral Cavity"; and there will be a discussion (by Dr. G. H. Fox, Dr. S. Sher-

well, Dr. E. B. Bronson, Dr. L. D. Bulkley, Dr. R. W. Taylor, and Dr. M. J. Ashe) on "Lupus of the Respiratory Mucous Membrane."

The programme for the next meeting of the Section in Obstetrics and Gynaecology, on Wednesday evening, the 27th inst., includes the following titles: "General Observations on the Use of Electricity in Gynaecology," by Dr. A. D. Rockwell; "The Treatment of Certain Pelvic Tumors by Galvano-puncture and Drainage by the Vagina, and Intra-uterine Galvanization," by Dr. A. H. Goelet; "The Galvanic Treatment of Uterine Fibromata," by Dr. E. L. H. McGinnis; "Notes regarding the Treatment of Fibromata by Electricity," by Dr. A. H. Buckmaster; and "The Value of Bipolar Faradization in Gynaecology," by Dr. A. Lapthorn Smith, of Montreal. Dr. P. F. Mundé, Dr. E. H. Grandin, Dr. J. H. Gunning, and others, of New York, Dr. Franklin H. Martin, of Chicago, and Dr. G. Betton Massey, of Philadelphia, will take part in the discussion.

**Armour's Beef Extract.**—Sir James Grant, of Ottawa, Canada, is reported as having said, after having had this preparation under observation for some months, that it has given great satisfaction as a vigorous restorer of strength in cases where a liquid form of diet was necessary.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed. (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

## Lectures and Addresses.

### THE CARTWRIGHT LECTURES

ON

### VITAL AND MEDICAL STATISTICS.

DELIVERED BEFORE THE ALUMNI ASSOCIATION OF  
THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK,

November 14, 20, and 22, 1889.

BY JOHN S. BILLINGS, M. D., LL. D.,  
U. S. ARMY.

#### LECTURE I (ABSTRACT).

I PURPOSE in these lectures to speak of vital and medical statistics, and of some of their relations to each other and to scientific and practical medicine and sanitation. The discussion will include such points as character of the data required; methods of obtaining them by the censns, by registration, and in other ways; relations of physicians to this kind of work; methods of compilation and forms of publication; the best existing sources of such data; and some of the more common fallacies in drawing conclusions from the data as ordinarily published.

These and other points will be considered in their practical application to certain questions which, I hope, may be of interest to you, both as citizens and as physicians, as for example: Is the average longevity of man in civilized countries increasing? What data are required to practically judge of the relative healthfulness of different localities, or of the same locality at different times? What are the relations of certain forms of disease to race, to climate, to locality, to occupation? What is the relative tendency to increase of population in this country in the white and colored races? What is the statistical evidence with regard to improvement in practical therapeutics as arrived at from hospital data, from death-rates in obstetric practice, etc.?

Statistics and discussions of statistical methods are, as a rule, dry and uninteresting subjects, and it is with very considerable doubt and hesitation that such a topic has been selected for these lectures. I have no new discoveries to announce, and those who are practically familiar with statistical research will find some of my statements rather elementary; but the subject is not one which lies within the ordinary range of medical studies, the data are widely scattered in literature, and I hope, at least, to be able to remind you of some of the numerous points which you may have once known, but which may have been forgotten owing to the pressure of other studies and duties.

Statistics are somewhat like old medical journals, or like revolvers in newly opened mining districts. Most men rarely use them, and find it troublesome to preserve them so as to have them easy of access; but when they do want them they want them badly.

There are many fallacies and errors connected with vital and medical statistics as ordinarily collected and used, and it is highly desirable that the physician should be aware of the more important of these, since he is constantly appealed to for decisions as to their true significance and value. "It

is as easy to tell lies with figures as with words, and bigger ones"; but while we occasionally meet with deliberate falsifications of the records, made for the purpose of magnifying or diminishing the apparent mortality or prevalence of a particular disease in a given locality, or to maintain an anti-vaccination thesis, these are not so frequent as are the errors of involuntary misstatement and misinterpretation into which those not familiar with methods of collecting and tabulating statistics are so liable to fall. Those who are not familiar with the methods of obtaining and compiling statistics of this kind are apt to be either unduly credulous or unreasonably skeptical as to their real use and value—to use the first figures which come to hand, and thence derive conclusions which are not warranted, or to reject the plain teaching of carefully compiled statistics in favor of general assertions which have no firm foundation, but which are in accord with preconceived opinions. My experience with those seeking statistical data is that the majority begin by looking for those data which are in favor of some particular conclusion with which they commence, rather than by selecting data with reference to their probable completeness and accuracy, and accepting the conclusions which may be legitimately drawn from them, whatever they may be.

Those who are engaged in the collection and compilation of official mortality and vital statistics are often at first the most skeptical as to their accuracy and utility, for their attention is so frequently and forcibly drawn to errors in the individual data that they conclude that the whole mass is unreliable; and the difficulties in the way of obtaining complete and reliable figures are seen to be so great that they incline to give up the whole matter in despair. Continued study of the subject, however, shows that many valuable conclusions or suggestions can be derived from imperfect data, and that in large masses of figures the errors either tend to neutralize each other, or to produce a constant effect in one direction which can be calculated and allowed for, so that those who have had the greatest experience are most convinced of their value. It is true that, in statistics, the inferences can not be more accurate than the data on which they are founded, but we do not look for scientific exactness from them so much as for an estimate of probabilities.

The methods which we have for advancing our knowledge of the laws of human life, of the causes of abnormality, disease, and death in man, and of means of sanitation or therapeutics, may be grouped into two classes—viz., observation and experiment—which, however, are often combined.

In the experimental method we seek to make a direct test of the variation of one particular condition, or set of conditions, upon the living organism, all other conditions being kept uniform as far as possible. Some such experiments can be made on man, but the greatest number of the problems which we may hope to solve by this method, and among these the most important, can only be approached by experiments on the lower animals. Within the last twenty years experimental physiology and pathology have

made great advances, and these methods, so far as they are applicable, give more definite results, and are more immediately satisfactory, than those derived from comparison of observations in which no definite experimental variations have been made; but so far as regards causes of disease, or the action of supposed methods of prevention, or of remedies, it is unfortunately the case that we can not draw accurate conclusions as to what will happen in man from what is observed to happen in animals. In the first place, there are many forms of disease in man, and those among the most important, as regards the suffering and loss of productive power and of life which they produce, which can not, with our present knowledge, be experimentally produced in animals, and which rarely or never occur in them.

For example: Yellow fever is a disease which, from analogy, we have reason to believe may be due to the action of one or more specific micro-organisms, or, perhaps, I should say, to the products of such organisms. We find a dozen different kinds of bacteria in persons suffering from yellow fever, and, by dint of much labor, these have been isolated and cultivated outside the human body. The problem is to determine positively, and with scientific precision, which, if any, of these is the true, essential cause of the disease. The mode of doing this is by producing the disease in a perfectly healthy person or animal by the inoculation of the suspected organism. But, thus far, we have failed to find any animal in which a disease, which can be considered as specifically identical with yellow fever, can be produced by any method; and I need hardly tell you that inoculations of such a disease as this in a human subject, under conditions which would make the results of such inoculation scientifically trustworthy, are impracticable and unjustifiable.

Those forms of disease which are common to animals and man—such, for instance, as anthrax, tuberculosis, tetanus, hydrophobia, the ordinary forms of suppuration, and also typhoid fever—are being pretty thoroughly worked out by means of such experimental inoculations as I have just referred to; and we are able to say, with a great degree of precision, not only that these diseases are due to specific forms of bacteria, but to determine enough of the characteristics of these forms to be able to identify them wherever they are found.

This method of observation may, for our purposes, be again divided into two categories. The first is that which is used in individual cases, being the form applied by the physician to each case which he has to treat. It also includes the sort of investigation which may be made in a single household, a small community, or a thinly populated district, to determine the course and cause of a particular form of endemic or epidemic disease, where the conditions affecting each family or dwelling can be studied in detail somewhat as the detective of modern fiction follows his clews. By the combination and comparison of detailed studies of this kind the greater part of our present system of diagnosis, prognosis, and therapeutics have been evolved; but it has been and will be a slow process, for each man differs from every other man in structure and mode of function, and the conditions of the environment are so multi-

form, and so variable in space and time, that "experience is doubtful, and judgment difficult." We must therefore try to supplement the information thus obtained by that derived from the second kind of observation above referred to—namely, that of collecting a few data with regard to great numbers of people, especially where these are accumulated in thickly settled localities, forming what is called the statistical method as applied to different communities. By the first method we compare individual with individual, and do so with considerable minuteness of subdivision of the conditions studied; by the second method we compare the vital phenomena of communities with those of other communities, but only on broad lines and in relation to circumstances easily noted.

The essential data of vital statistics are derived from enumerations of the living population and from records of births, marriages, and deaths. The numbering of the people is effected by a census, a term derived from the Roman Censors, a part of whose duty was to make such counts. Such enumerations were made by Moses (1490 b. c.), David (1017 b. c.); in Greece, 650 b. c.; and in Rome, beginning 566 b. c. They were probably made also in Assyria, but the Assad records have not yet been found. In modern times the first country to make a count was Sweden, in 1749. The first census in the United States was taken in 1790, as a necessary means of carrying out the constitutional provision that the basis of representation for the several States should be the number of the population in each. The first census in England was taken in 1801, and showed the number of persons, with distinction of sex, the number of houses, the number of families, and a rough statement of occupations under the general classification of agriculture, trade, manufactures or handicraft, and all others.

In the first censuses the object was to determine the number liable for military service or qualified to vote, or to fix rates of taxation, and the records were very brief. In the first United States Census the only data called for on the schedules were names of heads of families, free white males over sixteen, free white males under sixteen, free white females, all other free persons, slaves.

One of the most interesting fields of study in vital statistics is the relation of race and color to birth-rate, to certain forms of disease, or to the liability of death at certain ages. This country is, as you know, the great mixing ground for different races of the human family, and, while the mixture is rapidly becoming so intricate as to make it impossible to distinguish the several strains, it is still true that there are in this country large groups of men of quite distinct races, the record of disease and death in which would form valuable material for study upon this point were it possible to collect them.

From the sociological and political point of view this is particularly the case with regard to the negro and to those having a mixture of negro blood; and in the Southern States such questions as the following are of great practical interest: Is the negro population increasing faster than the white? Is the proportion of mixed bloods, such as mulattoes, quadroons, etc., increasing in proportion to the general population? Are the fertility and expectation of life of

mixed bloods greater or less than those of pure whites or pure blacks under the same circumstances of environment? We will return to these questions hereafter; at present I merely refer to them as being the probable reason for the introduction into the law for taking the next census of a special clause providing "that the population schedule shall include an inquiry as to the number of negroes, mulattoes, quadroons, and octoroos," an attempt to obtain information which has not heretofore been sought in this way. In obtaining the records of deaths occurring during the census year beginning June 1, 1889, an effort will be made to have the deaths of colored persons distinguished into those of pure negroes and those of mixed blood. It will probably be impossible to obtain the data for either living population or deaths with the minuteness of subdivision indicated by the words "mulatto," "quadroon," and "octoroon"; but there is reason to hope that in many sections of the country we shall be able to distinguish those of mixed blood from the pure blacks and the pure whites, and to give some opinion with regard to their diseases and death-rates. The results of the last census, although imperfect, show such marked differences as regards the mortality from certain diseases, not only between the whites and the blacks, but between those of English, Irish, and German descent, as to make it certain that it will be worth while to pursue this branch of inquiry more minutely as opportunity is offered to us hereafter.

The influence of race upon mortality is specially manifest in the death-rates of cancer. The number of deaths from cancer per 100,000 population in certain portions of the United States, with distinction of white and colored, was as follows: White, 27.96; colored, 12.67.

In the northern part of the United States the proportion of deaths from cancer in proportion to one thousand deaths from known causes, with distinction of white, colored, Irish, and German parentage, was as follows: White, 19.1; colored, 7.8; Irish parentage, 24.3; German parentage, 25.8.

It will be seen from these that the liability to death from cancer is not half as great among the colored people as it is among the whites, and that there is a greater tendency to death from cancer in persons of German parentage than in all the average white population, especially between the ages of fifteen and sixty-five.

The relation of race to vital phenomena in general, and to disease- and death-rates in particular, form one of the most interesting branches of what Galton calls the "science of heredity," but it is a branch in which little progress has yet been made, and for the study of which the United States offers greater opportunities than any other country. "The question of race influence is not merely an abstract matter fitted only for well-rounded periods in the discussions of the schools, but it profoundly affects vital and national life." It is a force which acts incessantly upon and menaces us, and, so far as we can now see, it is mainly upon the outcome of the distribution and prevalence of race that depend civilization, religion, and the future of man upon this earth. "In so far as the conditions of things tend to preserve the best types, progress is favored. In so far as they tend to destroy or to debase them with inferior types, progress is

hindered. Not every mixture of race prevails, or persists, but there has been a certain amount of mixture wherever there has been progress in human affairs. Such mixture appears to have been a consequence rather than a cause, yet it may become an important secondary cause in changing or modifying the course of human events."

The census gives us a view of the population on a certain day, and, if well taken and properly compiled, it gives a general view of the stream of life as it flows on that day, with its variations of breadth and depth, from which it is possible to calculate, within certain limits, the velocity of the current, the rapidity of change, and the probable rate of increase or decrease, especially if comparisons can be made with the results of a previous census taken in the same way. It may also indicate periods of wide-spread disaster or of migration.

In general, we may say that the census indicates the state of the population at a given period. Vital statistics, however, consider both the state and the movement of the population, and therefore for these we must have something more than the census, viz., a record of the deaths and births occurring in successive periods, from which we can compute mortality and natality rates.

Mortality, or mortality rate, refers to a ratio between the number of deaths occurring and the number of living population furnishing those deaths. It is to be distinguished from a statement of the number of deaths, since to determine the mortality in a given population, we must not only know the number of deaths, but also the population furnishing that number.  $M = \frac{D}{P}$ . In the same way, natality does not mean the number of births, but it means the ratio of the number of births to the population in which they occur.  $N = \frac{B}{P}$ .

The relations between mortality and natality are very important, as I shall have occasion to explain hereafter. The value of such statistics depends, of course, on the accuracy of the individual data, and the completeness with which these data are gathered for the given locality to which they relate.

Accurate data with regard to deaths can only be obtained by a system of registration of deaths made at the time they occur. Repeated experience has shown that it is utterly impossible to collect, at the end of a year, by any mechanism of enumeration, more than seventy per cent. of the deaths which have occurred during the preceding year, and it is now well recognized that a complete registration of deaths can only be secured by legislation which forbids a burial until a permit has been granted from a central office, which permit is issued only on the certificate of a physician, setting forth the cause of death and other facts connected with it which are of importance, and which will be presently referred to. In the great majority of cases it is comparatively easy to enforce the law, even in thinly settled rural districts, and the community soon learns to consider any attempt at burial without a permit as a suspicious circumstance, indicating a desire to conceal either the death or the cause of death, and justifying a special investigation

by the authorities. When it has been decided to require a burial permit in all cases, it is not usually difficult to require the data for registration as an indispensable preliminary to the issuing of such permit.

Any system which depends upon the returns of undertakers for a record of deaths, gives incomplete and unsatisfactory results. It is only where the permit must be obtained before burial and the certificate must be filed at a central office before the permit is issued, that a complete record of all deaths will be obtained. Any complete system of death registration should include some method of verification of the death and of its cause, which must be certified to by some person having the special knowledge which alone can enable him to give such a certificate.

In the first place, we must have this verification to insure the fact of a death having taken place. In its absence, in a large city, there is little or no difficulty in having recorded the death of a person who may be either alive and well, or non-existent, and the door is thus opened to frauds of various kinds, some of which have actually been attempted and discovered, while others, no doubt, have been successful and remain still unknown. Such verification is also necessary to insure the fact of real as opposed to apparent death in any case, and thus prevent premature burial.

The utility for this latter purpose is, of course, small, for the popular idea as to the frequency of trance or other conditions simulating death, so that the true state of affairs is not detected, is, as you all know, grossly exaggerated. Nevertheless, this consideration may enter as a factor into an argument in favor of such skilled verification. The main reason, however, for the verification of a death by expert testimony as to its cause, is that it is necessary to establish the fact that a death has taken place from what may be called natural causes as opposed to criminal causes.

This verification of death and of the causes of death may be made either by physicians employed for that particular purpose and paid by the state, or by the physician under whose charge the deceased person has been immediately previous to death; in which latter case only those cases which have not been under the treatment of a physician are referred to a public medical officer, or the coroner, for verification and determination of the cause of death.

The first system is that which is employed in France, Austria, and Belgium. The second is the one made use of in England and in this country.

All registration laws include the certificates of physicians as an essential part of their machinery. Some do this directly, requiring that physicians shall keep a list of all deaths occurring in their practice, and shall forward this list at stated times to the registrar. This method has invariably proved to be a failure, as has also the similar attempt to require of clergymen that they shall furnish lists of the marriages which they have solemnized. It is utterly impossible to enforce such laws under penalties, and not fifty per cent. of either clergymen or physicians will carry out their requirements under ordinary circumstances.

Where burial permits are required, a physician may be made responsible for a certificate as to those matters only with regard to which his special professional knowledge is

necessary—such as the cause of death, duration of sickness, etc.; or he may be required also to certify as to the age, birthplace, parentage, occupation, etc. The great majority of physicians accept without hesitation the data furnished on these points by some member of the family, or whatever appears set down in the form of certificate brought to them by the undertaker for signature. But there are always physicians who question the propriety of the law and object to certifying to that of which they can have no personal knowledge, while some few may possibly decline.

The requirements of a registration law impose upon medical men who sign certificates as to causes of death a very considerable responsibility—much more considerable, in fact, than many of them probably realize. The physician is to consider whether his knowledge of the case is sufficient to enable him to determine whether or not the death was due to what are called natural causes, whether there is reason to suspect that violence, poisoning, criminal neglect, etc., may have been more or less factors in the result, and whether any certificate as to the nature of the cause is justifiable. The pressure upon the medical man to certify to more, or sometimes less, than he knows, is occasionally very strong, but the only course in doubtful cases is to indicate clearly what one knows, as distinguished from what he merely believes on the faith of statements made by others. In ordinary matters of daily routine occurrence, in which there is no apparent motive for falsification, we constantly do, and must, accept the statements of others; the physician acts as the primary judge of the evidence submitted by relations and friends as to the time of death, the age and race of the decedent, the duration of the disease, etc., and is justified in certifying to his belief in this evidence, very much as he is justified in certifying to the date of his own birth.

There is no good reason why reports of births should be required from medical men. But, as regards reports of deaths, it is to the interest of properly qualified members of the medical profession that such certificates should be demanded from them. Whenever and wherever certificates as to the cause of death are required from physicians, there must also be established some system of determining who are physicians within the intent of the law.

At first it may be necessary to accept certificates from any one and every one who chooses to call him or herself a physician; but the character of some of the documents of this kind which will come in will very soon indicate the necessity for some discrimination. Thus it is that the certification of the causes of death by physicians is the essential foundation, and it is the only essential foundation, of legislation with regard to the qualifications which the state has a right to demand from practitioners of medicine.

The registration of marriages, births, and deaths is important to the individual, because it gives him increased security in his rights to property and to life by enabling him to furnish proof of parentage and legitimacy, by increasing the chance of detection of fraudulent claimants to property of which he is the true heir, and by discouraging criminal attempts to shorten his life, owing to the fact that evidence must be furnished that death was due to natural

causes, or a special legal investigation of the circumstances will be made. Of the importance to the community as a means of protection of health and life, and to scientific men and physicians as a means of investigation of some of their problems, I need give no proof to this audience.

We can hardly be said to have a complete system of registration of births in any State or city in this country. Probably the city of Providence, R. I., has the most complete records of this kind of any of our cities. As regards the registration of deaths, Massachusetts, New Jersey, the greater part of Connecticut and New York, a large part of Alabama and Minnesota, and most of our large cities, have now a fairly satisfactory system and complete record. For the rest of the United States there is either no system of registration, or, if any exists, it is a very imperfect and incomplete one, the results of which can not be depended upon, and which can not be compared with the results obtained in the localities above referred to as having a complete system; and the only means which we have of estimating the mortality of these localities is by the reports of deaths for the preceding year collected by the census enumerators.

It is for this reason that the decennial United States Census is a matter of such great importance to scientific medicine and to practical sanitation—of much greater importance, in fact, than most physicians and health officials seem to fully appreciate. It is true that the death records thus obtained in the large areas of the country in which there is no registration are incomplete and, as regards causes of death especially, inaccurate; but they are the best we have; they are becoming better at each census, and the death records in the registration areas serve to measure their reliability, and to indicate to some extent useful corrections.

As the value of statistics of death depends very largely upon the possibility of comparing them with corresponding statistics of the living population furnishing those deaths, it is evident that the modes and times of obtaining and of publishing the results of the census are matters of great importance to medical and sanitary statisticians. This is especially true as to the frequency with which a census is taken, the units of area made use of in its published tables, and the combinations of age, sex, race, and occupation data given in connection with such units of area.

Let us first consider briefly the time of taking the census.

The conclusions of the various statistical congresses with regard to the methods of the census are summed up by Korosi in his project for a census of the world, published in 1881.

The first of these conclusions was that the census should be taken every ten years, in the month of December and in those years the number of which terminates in zero, recommending, however, that intermediary censuses should be taken at the discretion of different governments.

The taking of the census at the end of December has the advantage that a relatively greater number of population are in their own homes than at any other time, and that it corresponds to the termination of the calendar year, at which date many State and municipal reports ter-

minate, so that all the figures being for one date are readily comparable with each other. For a very large part of this country it would be quite as easy to take the census at the end of December as on the 1st of June; but there are some sections in which attempts to take the census in the midst of cold and rainy weather for a thinly scattered population would be made under very great difficulties.

While it is not probable that any agreement for an annual census of the whole country will be made in the near future either by the United States or by State Governments, it is certainly quite possible that the desirability for more frequent enumerations in the larger towns and cities will soon become so evident as to lead to systematic arrangements for carrying it out. Even now many cities take what they call a police census, at irregular intervals of from three to five years, for the purpose mainly of making rough subdivisions of the voting populations in the form of precincts, and of obtaining information for the purpose of levying taxes, more especially for school purposes. These police censuses, however, relate only to adult males, and upon them are based estimates of the number of the remaining population, which are used by the sanitary officials in computing death-rates. These estimates, however, are almost invariably too high, as is shown by the next State or national census, and in any case afford no satisfactory basis for computation as to the number of inhabitants in the different wards of the city owing to the great variations in the ratio between the voting population and the rest of the people in different classes of society and in different parts of a town.

The death-rate, or mortality, is the ratio between quantity of life and loss of life. It refers to a definite unit of time, viz., one year's life of one person, and the quantity of life is the sum of the time lived by each of the population expressed in years. Two persons living six months each, or twelve persons living one month each, have one year of life. If the population is assumed to be stationary—that is, one in which the births and deaths, and the emigration and immigration, are exactly equal to each other and similarly distributed throughout the year—then the number of the population multiplied into the time under consideration expressed in years and fractions of years gives the quantity of life.

A population usually, however, increases in geometrical progression, and in such case we must find, by means of a well-known formula, the mean population of the period, which will be less than the arithmetical mean of the populations at the beginning and end of the period and greater than the population living in the middle of the period; but the differences are small, and, in most cases, either figure may be employed.

Various methods are used by statisticians to correct the estimates of population made for a city at periods other than during a census year, as determined by a formula of arithmetical or geometrical proportion, among which may be mentioned the use of the ratios supposed to exist between the number of houses or the number of voters, or the number of school children and the total population. The number of houses is determined from tax records or

by a special count; the number of voters by registration lists or by a police census; the number of school children by a special census; and the ratio which these bear to the whole population is guessed at or is calculated from the data obtained at the last census.

The most useful and reliable of these methods is the use of the average numbers of presumed occupants of inhabited houses, the other ratios being of very little value.

This has been very well shown by Dr. Russell, Medical Officer of Health at Glasgow, in a paper on "The Decennial Census as a Basis for Statistics in Intervening Years," Glasgow, 1881. In the case of Glasgow he considers the estimate of her population based on the number of inhabited houses, and the estimate based on preceding censuses, and finds that both methods give a population above the actually existing one as shown by the next census. The error in the estimates based on the previous census was due to a change in rate of growth. The error in that based on the number of houses was due partly to incorrect data of the number of inhabited houses, and partly to an error in calculation.

It is evident that no value can be placed on estimates of population of a city based upon the number of habitations it contains if a cottage and a tenement-house are to be equally reckoned as a habitation.

Estimates of the population based on police censuses, on the number of school children, or on city directories, are of very little use, being, in almost every case, in excess of the truth. No general rules can be laid down for the estimation of the population of a city at a period between two censuses. It is a special problem in each case, for the solution of which there is needed an acquaintance with the locality, to be sure that boundaries have not changed, the information which can be obtained from special local censuses, from the number of inhabited buildings, from migration statistics, etc., all of which must be applied to the data furnished by the last general enumeration of the people, which, in any case, must be resorted to for the ratios which are to be used.

The shorter the period for which a death-rate is given, the greater is the liability to error. The ordinary forms of weekly death-rates reported for large cities are annual death-rates; that is, they represent what would be the annual death-rate if the proportion of deaths to the population for the week continued for one year. If, for example, a town having a population of 100,000 reports as its weekly death-rate for a given week 25 per 1,000, this does not mean that during the week there occurred 2,500 deaths, but it means that if the population and number of deaths each week are continued the same during the year, 2,500 deaths would have occurred in the course of the year, or that for the week in question the number of deaths was 2,500 divided by 52.17747. A weekly death-rate is useful to show where the greatest variations have been in the year's mortality, but it is no indication of the health of a town for a particular week, and it is useless as a means of comparison of the healthfulness of one town with that of another. This is largely due to the law of probable deviation or error in mortality statistics in rela-

tion to the number of instances used as data without reference to their accuracy. This law of probable error in relation to number of data is an exceedingly important one, to be kept in view in all statistical inquiries, and especially in those relating to vital and medical statistics.

What is a fair or normal death-rate? Taking an average healthy rural district in the United States, where there is little migration, the annual gross death-rate for the whole population will be from 13 to 15 per 1,000. In towns of from 10,000 to 15,000 inhabitants, having a good general water-supply and proper sewerage, the gross death-rate should not exceed 16 per 1,000. In cities of from 20,000 to 100,000 inhabitants it should not exceed 17 per 1,000, while in cities of over 100,000 inhabitants it should not exceed 19 per 1,000. The great causes of high death-rates are poverty, overcrowding, intemperance, excess in heat and cold, with moisture, foul air, bad food, impure water, uncleanness, contagion, ignorance, etc.

*Births and Birth-rates.*—The statistics of births are of much importance in vital statistics, because of the influence of the birth-rate upon the sex and age distribution of the population. Unfortunately, in this country, as I have already explained, hardly any locality possesses such an enforced system of registration of births as to permit of an annual calculation of birth-rates and their comparison with the deaths of children under one year of age, or those born within the year. We can only obtain these data for any large extent of country by referring to the census records.

The usual method of indicating the birth-rate is by giving it as the proportion per one thousand of births to the population of all ages; but a much better and more satisfactory mode of computation is to calculate the number of births to the number of women between the ages of fifteen and fifty or fifty-five living in the community referred to.

The general subject of birth-rates is interesting chiefly, in relation to social statistics, to the fecundity or rate of increase of population or of people of different races; but in relation to mortality statistics, it may also become an important factor in the calculations.

There have been from time to time some controversies between statisticians and health officers with regard to the influence of birth-rates upon death-rates, or as to the precise relations which exist between the two. As the death-rates of infants are much greater than those of the population at higher ages, it has been claimed by some that where there is a high birth-rate there also is a high death-rate; but it can not be said that this will invariably be the case, or that the one is directly the cause of the other, except in certain cases for a comparatively short series of years.

As a rule, high birth-rates occur in cities, and in the crowded parts of cities, among the laboring classes of the population, where the causes of disease and death in infants are especially prevalent. On the other hand, it is to be noted that a high death-rate among infants has some tendency to increase the birth-rate, because the interval between child-bearing is shortened by the early death of the infant; and in the effort made by poor women to avoid frequent child-bearing, a common means is to suckle the infant up to at least two years of age, in order to prolong the

interval between pregnancies—which is a practice injurious both to the mother and to the child.

If we had under consideration a community in which there were no migrations, and in which the population neither increased nor diminished, the relations between birth-rate and death-rate and the average duration of life could be expressed by a simple formula, in such a way that, given either two of these quantities, we could determine the third. If, for example, in a population of one thousand persons, five births and five deaths occur annually, and if we assume that every individual lives to the same mean age, evidently just two hundred years would elapse before the whole of the original one thousand would have died. This two hundred years would be the mean duration of life, and this would be the case also if deaths occurred at different ages, only in such a case many would die below the mean age, when some would greatly exceed it. This subject has been considered by Dr. J. S. Bristowe in a paper "On the Mutual Relations of the Birth-rate and Death-rate."\* From the table which he gives I have extracted that part which shows the mean duration of life under certain conditions of birth-rate and death-rate, where the birth-rate varies from three to five and the death-rate from fifteen to thirty-five in a thousand.

Dr. Bristowe says: "There can be no difference in the healthiness of two localities in one of which the death-rate is twice as high as that of the other, provided other conditions are such that in both cases the inhabitants attain the same mean age; or, conversely, supposing different populations to enjoy the same mean duration of life, any differences which may be presented by their respective death-rates are due to other circumstances than differences of health." He also says that the average duration of life can be determined by the birth-rate and death-rate taken together, but not from the death-rate alone. If he means by healthiness mean duration of life, this statement is equivalent to saying that, where the mean duration of life is the same it will be alike—an indisputable proposition, though not a very instructive one. But if by healthiness is meant the sum of the conditions of the locality as to altitude, drainage, cleanliness, etc., which tend to lessen or increase deaths in the people living in it, then the statement is incorrect, for it does not take into account age, sex, or race distribution, occupations, or migrations. Setting the question of migrations entirely aside, it is perfectly possible that two populations, attaining the same mean age and having the same death-rate, may live in two localities, one of which is decidedly healthier than the other; so that, if the two communities exchanged habitations, a marked difference in the death-rates and mean age at death would result.

Putting aside all these purely speculative considerations with regard to what might happen in a stationary population where there is no migration, let us see what the significance of death-rates is in our cities and rural districts as they now exist. We wish to know how much of the death-

rate is due to peculiarities in the character and occupation of the population itself, and how much to peculiarities in the locality, and for each of these classes we wish to know how much is necessary and unavoidable, and how much is due to causes which may be modified or done away with. Precise knowledge on these points we can never have, but we can obtain a sufficient degree of probability to guide our action in the premises.

If we wish to study carefully the influence exerted upon health and life by race characteristics, by residence in a given locality, by marriage, occupation, social standing, etc., we must have the means of comparing results given in different localities, or in the same locality at different times, or for different races, occupations, etc., under like circumstances.

To accomplish this we must, as far as possible, estimate the influence of other circumstances not connected with the particular point which we are investigating, but which, notwithstanding, exercise a powerful influence upon sickness and death-rates, and of these the two most important influences are those which differences in proportion of sexes and ages of the population to be compared exert.

The means recognized as best calculated to eliminate the influence of sex and age by, as it were, reducing the population to one uniform scale in these respects is by calculating the expectation of life at each age for all the several conditions of locality, occupation, etc., which we wish to investigate; in other words, by the preparation of what are known as life-tables. A life-table shows what would be the tendency or liability to death at each age in a population in which there is no migration and in which the births and deaths just equal each other if such a population were subjected to the same influences tending to produce diseases and death as have affected the actual population under consideration and from which the data are derived. It is, of course, impossible to prepare life-tables which shall be strictly accurate and exactly comparable one with another, because it is impossible to obtain strictly accurate data. A life-table is intended to answer the question, "Of a million children born, how many of each sex die at each age?" or, "What is the time which a man or woman of a given age may be expected to live?" A strictly accurate answer to this question could be given only if we knew the precise dates of birth and death of each of a million of children born under the circumstances we are investigating, and, strictly speaking, these million children should all be born on the same day. Notwithstanding, by using large masses of data which are more or less attainable and by applying certain well-known corrections, the individual errors tend to neutralize each other, and we can prepare tables which will be quite accurate enough for purposes of comparison.

A vast amount of labor has been expended upon, and study given to, this subject; for immense business interests and important points in the jurisprudence of inheritance depend upon the existence and accuracy of these tables. Hundreds of millions of dollars have been, and now are, invested in life insurance on the faith that certain life-tables truly represent the average course and duration of the

\* "St. Thomas's Hospital Reports," New Series, vol. vii, London, 1876, p. 245.

life of a particular class of the community—and the result of more than a hundred years of experience has been applied to their correction under the powerful stimulus of urgent need, from a pecuniary point of view, to have them as accurate and reliable as possible.

In order to prepare a life-table for a given locality or occupation, we must know the number of persons living at each year of age, and the number of deaths at each age which have occurred among these persons for one or more years. We assume that deaths have occurred at regular intervals during the year for each age and proceed to compute the number of persons at each age who were living in the middle of the period for which the deaths are registered.

In using census data, however, we can not directly compare the deaths at each single year of age with the number reported by the census as living at that age, because of the strong tendency of the average man or woman to report ages either of the living or of the dead, but especially the former, in numbers which are multiples of ten or five, or in so-called round numbers.

I do not propose to describe the methods of constructing a life-table. To make one sufficiently accurate to be used for the purposes of life insurance requires elaborate calculations and corrections, and the use of complicated mathematical formulae; but the construction of an approximate life-table, in which no attempt is made to secure regular gradation, is a comparatively easy matter and has been fully described by Mr. N. H. Humphreys in a paper in the "Journal of the Statistical Society" for 1883, which method was made use of in calculating the approximate tables given in the mortality statistics of the last census.

### THE TYPHOID SPINE.\*

BY V. P. GIBNEY, A. M., M. D.,

SURGEON IN CHIEF TO THE HOSPITAL FOR RUPTURED AND CRIPPLED, NEW YORK;  
PROFESSOR OF ORTHOPÆDIC SURGERY, NEW YORK POLYCLINIC.

It is with some hesitation that I present this title for your consideration to-day. I regret that I am unable to assign a name to the condition of things which the following cases so well describe. I have often heard patients who had passed through typhoid fever say that they had never felt the same; that there was always a defect somewhere. Practitioners know very well that the sequelæ are legion, and my own attention has been drawn to a group of symptoms pertaining to the spinal column as sequel to this fever. On one or two occasions, when pressed for an anatomical diagnosis, I have used the term perispondylitis, meaning an acute inflammation of the periosteum and the fibrous structures which hold the spinal column together. My reason for the use of this term was the production of acute pain on the slightest movement, whether lateral or forward, and the ab-

sence of any marked febrile disturbance or neuralgia. The secretary, I discover, has put me down for spondylitis after typhoid fever. If I could be permitted to use this term in the rheumatic sense and not in the tuberculous sense, I should not object, but whenever one uses the term spondylitis the lesion is regarded as one of osseous tuberculosis; so that I prefer, for the present at least, to speak of the affection as a typhoid spine.

The occurrence of periostitis after typhoid fever in the long bones is not at all uncommon. Dr. Keen, of Philadelphia, in one of the Toner lectures in 1876, published in 1877, gave a full account of all the bone lesions after the continued fevers. He found 69 cases following continued fevers, of which 22 affected the head, 7 the trunk, 6 the upper extremities, 42 the lower. There were 41 cases of disease of the bone, of which number 37 followed typhoid fever. In 47 cases traced as to the date of occurrence, 10 were within two weeks, 27 from three to six weeks, and 10, months after the fever. Keen's explanation was that the earlier cases probably came from clot, and the later from enfeebled nutrition. He found that the periostitis arose spontaneously or as a result of slight injury. In all my own cases a slight injury seemed to be the exciting cause. Sir James Paget, in "St. Bartholomew's Hospital Reports for 1876," vol. xii, p. 2, says: "Periostitis most frequently is seen in the tibia." He has seen it near the femur, the ulna, and the parietal bone. He has found it always circumscribed, always occurs during convalescence, and never attended with delirium or fever or any severe constitutional disturbance. Aitken says that no man can be considered fit for military service for three or four months after an attack of severe typhoid fever.

The best description I have found of periostitis after typhoid is in "Diseases of the Bones," by Thomas Jones, F. R. C. S. Eng., etc., of Manchester, published in 1887. The explanation of periostitis is now generally considered to be a cachexia which a specific fever constitutes, and a traumatism is regarded as an exciting cause.

CASE I.—In the fall of 1882 Dr. Beverley Robinson asked me to see with him a case of a lad fifteen years of age who was convalescing from typhoid fever. Toward the end of his convalescence he had begun to complain of severe pain in his back. The lumbar spine seemed to be the portion most affected, and the suffering both night and day, especially after any movement of the body, was such that narcotics were generously employed. We found no real deformity, yet there appeared to be a fulness in this region, which, upon closer examination, disappeared. There was a moderate degree of tenderness on pressure, and very great tenderness on any lateral or forward motion. There was no special pain in the distribution of the sciatic or anterior crural nerves, no infiltration in either ilio-costal space, no psoas contraction, and no rise of temperature. I had not encountered such a case before this, and was at a loss to give an explanation, or even a prognosis. I felt it my duty to protect the spinal column, and applied an apparatus as soon as possible. This seemed to afford relief, and in the course of two or three weeks he was practically well. I did not try to omit the brace, however. This he wore for about a year. I had an opportunity of observing the case from time to time, and find on my records that on June 28, 1884, I discharged him cured. The following note was made: "There is nothing now in the way of a deformity save

\* Read before the American Orthopaedic Association at its third annual meeting.

a little deepening of the right ilio-costal space. The spinal column seems free from any deformity, either lateral or antero-posterior; no tenderness on concussion, none on movement. At times, on making a misstep, he feels a little muscular soreness in the lumbar region." I examined him in October, 1884, October, 1885, and June, 1886, always with negative results, and found him quite able to play lawn tennis or exercise to any extent. In other words, the cure was perfect, and the diagnosis never made.

I was reminded forcibly of this case in the spring of 1888, when Dr. William M. Polk asked me to see a young lady, eighteen years of age, who was convalescing from a typho-malarial fever. The same acute pain that I found in this case reminded me forcibly of the case I have just reported. In this instance, however, it was the hip that was affected. I do not remember ever to have seen such acute suffering in an adult hip. The date of my first observation was on the 22d of April, 1888. The limb lay parallel with its fellow, and I could not execute any movement without exciting loud shrieks. She was not of an hysterical temperament—that is, had never been considered so; was rather lymphatic in temperament. The limb was not wasted, but the reflex spasm was very great. Weight and pulley and a traction hip-splint succeeded in affording relief in less than a month, and by the 7th of July she was in a fair way to recover. She sailed for Europe on this date, and in October of the same year, on her return, there was no lameness, no pain, no reflex spasm. There was some limit to the free range of motion as compared with the other limb. This case, although not a spinal one, is presented as illustrative of the supposed pathology—namely, a circumarticular lesion, confined to the periosteum and ligaments.

**CASE II.**—On the 26th of December, 1888, I saw, in consultation with Dr. Partridge and Dr. Draper, of New York, a young man, twenty-four years of age, well developed, and always healthy and robust up to September, 1888. He had contracted typhoid fever during that month at a sea-side resort, and the disease pursued a typical course. Early in November, while convalescing, he went to Boston, feeling a little uneasiness after his trip. He complained of pain in his back, which continued for eight or nine days, not severe enough to confine him to bed or to prevent him from playing tennis, which game, in fact, gave him some relief. He then had a week's immunity from pain. An exacerbation came on after a fall while at tennis. The pain next day was very severe, and it was with much difficulty he was transferred from Boston to his home in New York. This was in the latter part of November. On his arrival in the city Dr. Draper was called, and, after one or two thorough examinations, could not discover any evidence of Pott's disease. After each examination, however, he would suffer excruciatingly, and large doses of morphine were required to give any relief. The exacerbations became more frequent, and an examination was not necessary to produce them. The recumbent posture was the only one that gave him any relief, and, on my examination, I found no fullness in either iliac fossa, nothing abnormal in the rectum, nothing in either ilio-costal space, no deformity of spine, no hard or soft tumor over the sacrum or over the ilium, no referred pain on pressure over the sciatic nerves. The hip-joint functions were perfect; no tenderness or pain at the sacro iliac junction (the test was made by direct pressure and by crowding the alae of the pelvis together). There was no spinal tenderness on pressure; but on deep press-

ure over the iliac region, especially on the left side, there was decided pain. Lateral and antero-posterior motion of the spine (passive) caused exquisite pain. He moved from the dorsal to the prone decubitus with the greatest care, fearing an exacerbation of pain. The temperature was 103° F., and had ranged from 101° to 103°; pulse, 120.

The result of our consultation was that he had no Pott's disease, no sacro-iliac disease, no neuritis. The question of a deep abscess was discussed, but abscess was not diagnosticated. A diagnosis of a perispondylitis, meaning either a periostitis or a subacute inflammation involving the fascia about the spinal column, was made. I believe now that he had a periostitis.

The treatment employed was with morphine to control pain, the dorsal decubitus, and the Paquelin cautery. From this time until the beginning of February he gradually improved. His exacerbations became less frequent and less severe. Toward the latter part of January he was able to sit up and even stand, but he was obliged to exercise the greatest care in moving about. I attempted early in January to fit a brace, but he was so comfortable in bed that I gave up the idea of mechanical support and decided to rely on expectant treatment purely. I made a note on March 20th that he was getting about and was nearly well. Since that a report has come to me that he has entirely recovered, has resumed business again, and does not show either deformity or awkwardness in gait.

The course pursued by this case was not at all unlike that of a periostitis, and when we consider the anatomy of the lumbar spine, the areas in this locality that are necessarily rendered sensitive by any inflammatory process, it is not at all an improbable diagnosis.

**CASE III.**—On the 13th of April, 1889, Dr. Alfred L. Loomis asked me to see with him a gentleman from London, eighteen years of age, who had but recently come from the northern part of New York State in a very helpless condition. The history was that in November, 1888, he came down with typhoid fever, was confined to his bed for several weeks with no complications, and on December 27th had sufficiently recovered to make a trip to New York. This was from Schenectady. He was then apparently well, remained in the city ten days, and returned in good condition. On January 10th, while skating, he fell and struck his left hip rather sharply. He did not apparently mind the blow, and a week or ten days later came to New York again, remaining here one week, during which time, while in the theatre one evening, experienced for the first time a pretty sharp pain in the region of his lumbar spine, and was quite stiff on getting up from the chair. He saw a physician the next day, who pronounced it lumbago, and a static electrical shock gave relief. He returned to Schenectady a day or two later, and was treated for lumbago with plasters, etc. The stiffness grew more pronounced, and his pains increased in severity. He found it difficult to assume an erect position without great pain. By the 10th of February he went to bed again, and there he remained until seen by a surgeon in Albany two or three weeks later. He regarded the case as one of psoas abscess. This is the report the patient brought to the city with him from his local physician. Neither Dr. Loomis nor myself could find any evidence of psoas abscess, but we found the patient difficult to examine by reason of the pain caused in moving in bed or sitting up. There was no rise of temperature; pulse, about 78; respirations normal. The spinous processes in the lumbar region appeared to be a little prominent, and were tender on pressure. There was no reflex spasm at hip or knee joint, and the movements, if made carefully, could be executed quite easily. He had lost flesh, but his appetite now was good,

and he suffered only from his disability. We decided upon a diagnosis of perispondylitis or, more properly, periostitis by exclusion.

The case was left in my hands, and I employed the Paquelin cautery for a week or ten days, three times a week. At the end of this time I applied a Knight spinal brace, and by the 9th of May he sailed for England, having walked about and traveled on street cars for a week prior to sailing.

In talking with Dr. Loomis at the time of the consultation, he gave me the impression that he had seen very few cases like this as a sequel to typhoid fever. As pertinent to this question I should like to present photographs of a patient, a mere lad, who came to me at the hospital about a year ago, from a town in New Jersey, with a history of these contractions following the wake of typhoid fever. His case was briefly this:

A boy, aged thirteen, admitted to the hospital 25th of June, 1888, with this history: Between four and five months ago patient had typhoid fever. Prior to that time was perfectly healthy. While confined to his bed kept both limbs flexed on abdomen, and during convalescence was unable to straighten them. On examination, he was found to be poorly nourished, quite unable to walk, unable to sit except in the position shown in the photograph—that is, thighs sharply flexed on pelvis, legs on thighs, heels touching buttocks. In dorsal decubitus any attempt at motion of the right thigh caused reflex spasm. The greatest possible extension was  $70^{\circ}$  for the right side,  $135^{\circ}$  for the left side. The greatest possible extension for the leg was, right side  $60^{\circ}$ , left side  $100^{\circ}$ . All motions at the right hip were

were limited about one half. All disease seemed to be arrested, and the patient was regarded as cured. He left wearing the splint, and is to report a few months later.

Such, in brief, is an account of the cases here presented, and a pretty careful search of textbooks has failed to reveal any cases of like nature. The reference in some journal articles to periostitis involving the trunk is so vague that I do not care to place them on record. Possibly many cases of obscure spinal injury after typhoid fever have been observed, yet in my own city, at least, I am sure they are uncommon. I wish it distinctly understood that I have not made a thorough search of literature, and make no claim to originality. My desire is simply to place these cases on record, and to call the attention not only of orthopaedic surgeons but of physicians in general to a very painful affection of the spinal column following typhoid fever, and to show by my own cases that a grave prognosis need not be given.

FIG. 1.—Best possible posture on admission into the hospital.

limited. There were several cicatrices of old bed sores over the sacrum and ilia. On July 10th he was etherized and both thighs and legs were forcibly extended, all resisting tissues being divided by the fascia knife. The limbs were very nearly straightened at the first sitting, and put up in plaster of Paris. The subsequent treatment consisted in still further overcoming the deformity by gradual means. Finally a hip splint was applied to the right limb, and at the date of his discharge, August 1st, the functions at the left hip were perfect; those at the right

## ON ELECTRO-DIAGNOSIS.\*

BY A. D. ROCKWELL, M. D.,  
PROFESSOR OF ELECTRO-THERAPEUTICS AT THE NEW YORK POST-GRADUATE  
MEDICAL SCHOOL AND HOSPITAL.

INJURY to a motor nerve is followed by certain anatomical changes associated with altered function, as well as altered electrical reactions. There is always a very definite correspondence between the two, and in the ability to determine from the electrical conditions the histological state of nerve and muscle consists in the main the art of electro-diagnosis.

When a motor nerve is divided, the muscles which it supplies are immediately paralyzed, and, no longer being in connection with their nutritive center, the spinal cord, both nerve and muscle undergo pathological changes.

Accompanying these changes are marked deviations from the normal electrical reaction of both nerve and muscle. *Immediately* after the section of a nerve there is often a temporary increase of electrical response to both currents when applied to the nerve or the motor point of the muscle.

Subsequently, however, there is a steady decrease in the readiness with which electrical reactions take place, until

finally the excitability to both currents is completely abolished. These, it should be observed, are termed *quantitative* changes. If the applications are made directly to the muscle and not to the nerve, we find quite a different set of phenomena.

The faradaic current applied thus acts very much as when it is applied to the nerve; not so the galvanie. When the latter is applied directly to the muscle there is observed an immediate diminution in the readiness of response, but in a comparatively short time an increase of the electric excitability is developed. This is a sure indication that we have yet healthy muscular fiber, but fiber deprived of its nerve influence.

Soon, however, the muscular fiber itself begins to degenerate, and the galvanic current, instead of being followed by an increased readiness of response, acts upon the muscle less and less effectually, and finally, if regeneration in the nerve structure does not take place, the galvanic irritability to muscle becomes extinct. Accompanying this decreasing readiness of response are other changes in the character of the contractions termed *qualitative*, or, as they have been termed by Erb, the reactions of degeneration. If regeneration of the nerve and muscle should occur, galvanic reaction is also re-established, but fails to reach its normal standard for a long time.

I have seen a number of cases where the response of muscle to galvanism remained below the normal standard long after the complete return of voluntary movements and perfect response of nerve to faradism. A case of facial paralysis that I have recently had illustrates many of the foregoing points:

The patient first came under my observation some six months ago, about a week subsequent to the attack, when I found marked diminution of response to both currents. The paralysis, I may say, came on quite suddenly, following a debauch. On the tenth day or thereabouts there began to be a progressive increase of response to the galvanic current, but no abnormal reactions indicating degeneration of muscular fiber. These phenomena, however, began to appear at a later period, associated with a gradual decrease of galvanic response, and now neither current, when applied to the nerve, produces the slightest effect, while galvanism directly to the muscle causes only feeble and delayed reactions, with currents as strong as can be borne by the patient.

This case illustrates in a very interesting manner the progressive anatomical changes that take place in an injured nerve and the relation these bear to electrical phenomena. The diminished reactions to both currents first observed when applied to the nerve indicated that the nerve tissue itself was structurally altered, but did not necessarily indicate muscular degeneration.

There occurred, on the contrary, increase of response to galvanism applied directly to the muscle, indicating that the muscular fibers were still healthy. This increase of reaction is said to be due to the deprivation of the inhibitory action of the paralyzed nerve as well as the altered nutrition of the muscle itself. The reactions of degeneration which finally appeared and still exist, together with the quantitative changes or decrease of response to both cur-

rents, indicate degeneration of the muscular fiber itself, which may go on to a complete extinction of the electrical reactions, which indicates complete destruction of the muscle.

As in the study of auscultation it is necessary to understand the normal action of the heart, so in the study of electro-diagnosis it is necessary to understand the order in which contractions occur in the healthy nerve and muscle when subjected to the "make and break" of the galvanic current.

Bearing in mind that in health the closing contraction is always more vigorous than the opening, whichever pole is used, and that the cathode or negative pole acts more vigorously than the anode or positive pole, it is readily appreciated that there can be but four orders of contractions elicited in health, in the following order:

1. The cathodal closure contraction, indicated by the formula CCC.
2. The anodal closure contraction, ACC.
3. The anodal opening contraction, AOC.
4. The cathodal opening contraction, COC.

When, therefore, we speak of qualitative changes occurring in the electrical response, we mean simply that this order is changed, the ACC being greater than the CCC, or the COC exceeding the AOC. These changes are also referred to as the "reactions of degeneration," and invariably indicate structural disease of muscular as well as of nerve tissue, while quantitative changes indicate degeneration of nerve tissue only. This is an important point, which it is well here to emphasize, for I find there exists a very general misapprehension in regard to it. Qualitative changes in the electrical reactions are generally if not always associated with marked quantitative changes, while quantitative are often entirely independent of qualitative alterations.

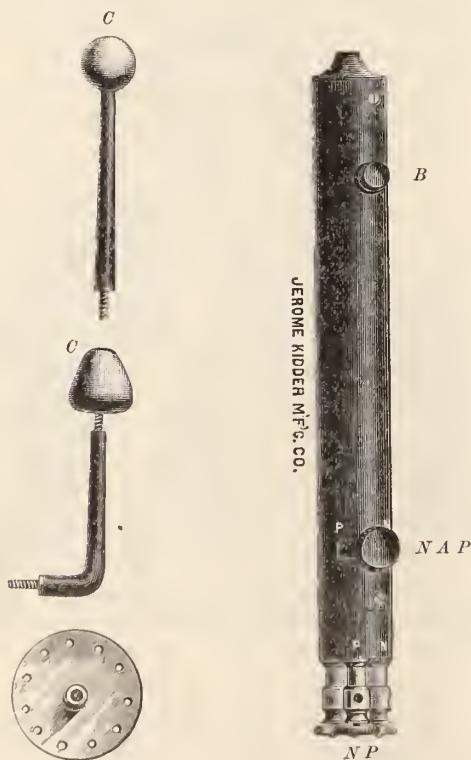

The one (quantitative) indicates more especially disease of nerve structure; the other (qualitative) suggests degeneration of muscular tissue. Such diseases as progressive muscular atrophy, pseudo-hypertrophic muscular paralysis, amyotrophic lateral sclerosis, and bulbar paralysis excellently illustrate degeneration of muscle with healthy nerve. In progressive muscular atrophy, for example, the electrical reactions demonstrate a healthy nerve, but a degenerated muscle. Either current applied to the nerve calls forth normal contractions. The faradaic current, applied directly to the muscle, calls forth contractions according to the amount of healthy fiber remaining. The fact that it produces contractions at all demonstrates the integrity of the nerve fiber, while the qualitative changes that are elicited on the application of the galvanic current to the muscle indicate the extent of the muscular degeneration. Similar phenomena are observed in the other diseases that have been mentioned in connection with progressive muscular atrophy.

The diseases, on the other hand, that show healthy muscle, but diseased nerve tissue, are confined altogether to those of central origin. These are paralysis from cerebral disease, and, with few exceptions, all those forms of spinal paralysis in which the gray matter of the spinal cord is not involved. Therefore locomotor ataxia, the various forms of multiple sclerosis without trophic changes, and spastic paralysis are seldom if ever associated with qualitative changes.

Quantitative changes are not infrequently observed in these spinal diseases, as well as in disease from cerebral lesion, but their causation is found in a general excitability due to an irritative lesion, to an absence of inhibitory action, or atrophy of muscle through disease, and not to actual degeneration.

In some nerve-trunk diseases, and also in acute affections of the gray matter of the cord, neither current applied to the nerve calls forth reactions. Faradism to muscle gives no response, but galvanism to muscle is followed by normal or increased response. This indicates that both the nerve trunk and its nerve filaments are diseased, but that the muscle itself is healthy. These phenomena are, of course, observed only in the very earliest stages of the diseases mentioned, and, in the nature of things, must, as a rule, escape observation.

Poliomyelitis anterior, on the contrary, whether occurring in the adult, or in childhood under the name of infantile paralysis, and lead palsy, uniformly yield those quantitative and qualitative changes that indicate degeneration of both nerve and muscle. There are, again, still other forms of paralyses from spinal disease where the character of the reactions varies widely, according to the seat of the lesion. In myelitis, for example, the electrical reactions may be absolutely normal, indicating that the disease is probably confined to the antero-lateral or posterior columns, while in other and the majority of cases there are quantitative and qualitative changes that clearly point to disease of the gray matter of the cord.

to the muscle directly calls forth reactions even more vigorous than normal. It is perfectly plain that this phenomenon means a diseased nerve trunk, but a healthy muscle, with healthy intramuscular nerve branches. As these reactions have been observed only in the very earliest stages of a traumatic injury to a nerve and in rheumatic neuritis, they would necessarily, in most cases, escape notice.

The electrode here presented (in two parts) is one that I have used with much satisfaction in eliciting the various abnormal reactions that are associated with the many forms of paralysis. It will be observed that there are three binding posts at the lower extremity. The one marked *P* is to be connected with the positive pole of the apparatus; the other, marked *N*, with the negative. The third post is to be connected with an electrode applied to some indifferent part of the patient's body. The small knob marked *A*, when moved toward *P*, renders the electrode *C* positive; when moved toward *N*, the tip becomes negative. *B* is an interrupting button, which when pressed closes the circuit, and by sliding it slightly forward the circuit can be kept closed, when so desired, without effort of the operator. This form of electrode is exceedingly convenient in electro-diagnosis, from the fact that, by a simple movement of the finger of the hand that holds the electrode, the knob *A* is moved, the direction of the current instantly changed, and anodal or cathodal contraction elicited in quick succession.

## STERILIZED MILK.

By WILLIAM B. WOOD, M. D.

THE numerous recent experiments with sterilized milk have revolutionized the system of infant dietary. Successive improvements in apparatus and methods indicate an intense and widespread interest in Soxhlet's discovery, and reveal how great was the felt need of some reliable food for children that should approach nearer to nature's nourishment than any of the complicated concoctions known as infants' foods. In the light of these experiments the old maxims—that mother's milk was the best and only safe nourishment for infants, and cow's milk the worst and only really dangerous substitute—must undergo material modification to conform to present facts; for while *good* mother's milk is always the best food for a baby, it is no longer the only safe nourishment, and if it is inferior in quality or deficient in quantity—as is the milk of the majority of city-bred mothers—it is not even the best food.

Cow's milk, on the other hand, although it has justly earned the reputation of collecting and at untimely moments letting loose more evils than issued from Pandora's box, is yet, when it is pressed from the udder, as thoroughly aseptic, and hence quite as innoxious, as breast milk. It absorbs impurities only upon exposure, but absorbs them so promptly and rapidly that ten minutes in foul air or unclean receptacles may render milk poisonous; and, even under the most favorable circumstances, it can not be kept entirely free from germs, more or less noxious.

By the simple process of sterilization, however, milk

An interesting deviation from the ordinary reactions found in diseased nerve and muscle, but one not very frequently met with, I imagine, is where both currents applied to the nerve, or the motor point of the muscle, fail to produce any contraction whatever, while either current applied

may be robbed of all dangerous elements, and then become the very best substitute for mother's milk.

Sterilized milk insures the infants against the calamities that follow in the train of impure food; it eliminates milk poison, the enteric diseases caused by fermentative germs—colic, diarrhoea, and dysentery—and, from the milk at least, the child can not longer absorb germs of whooping-cough, scarlet fever, measles, diphtheria, or tuberculosis. But there are other defects of bottle-feeding that simple sterilization does not touch; a child may be free from acute disease, and yet die of starvation, or fall a prey to the various chronic diseases resulting from malnutrition. An infant may be fed to repletion, and yet be but poorly nourished. Scores of even breast-fed babies are half starved, without ever really suffering from hunger; and the majority of bottle and patent food infants show signs of malnutrition up to the time they are given a mixed diet—if, indeed, they live so long.

Therefore, while the sterilization of milk robs bottle feeding of its most imminent danger, it is, in infants' feeding, by no means the only requisite to sound health and a vigorous development. Sterilized milk possesses the important negative virtue of being absolutely innoxious, but it too often lacks the necessary positive quality of adequate richness. It is well known to the profession that ordinary cow's milk does not furnish a sufficient proportion of fat properly to nourish an infant; but this knowledge is not, unfortunately, shared by the majority of mothers.

Nurse and mother almost universally consider a baby well fed if its hunger is periodically appeased and its body moderately plump. The ominous signs of malnutrition indicated by late dentition; poor bone formation, tending to rickets; broken sleep at night; general fretfulness by day; a susceptibility to colds, and a tendency to "catch" diseases as the consequence of lowered vitality—these escape the analysis that runs to ultimate causes until the baby is acutely ill, and thus come under the eye of the family physician.

Good breast milk is the ideal by which we should judge our substitutes, and it contains a larger percentage of fat than the milk of any cow, save the pure Jersey, which yields twenty per cent. or more of cream. Milk from tested Jersey cows, diluted for very young children with the due proportion of boiled water, to which has been added a small quantity of sugar and salt, is so nearly like breast milk that the digestive organs themselves can not tell the difference.

It is a great gain if the milk to be used by children, invalids, or travelers can be sterilized in the country as soon as it comes from the cow, and then be transported to town in the sterilizing bottles. As each bottle should contain only enough for one meal, the milk remains sealed until just before it is used, and so is exposed to no possible source of contamination. Where milk can not be sterilized when it is fresh, it may be prepared each morning in the nursery as soon as the day's supply is received.

If the milk is not of a grade to yield at least twenty per cent. of cream, cream should be added to it in the proportion of one ounce to three of milk. This method of enrich-

ing thin milk, which is recommended by the leading authorities in infant dietary, provides, it is true, the necessary fats, but at the expense of freshness, since the milk must stand several hours after delivery to accumulate the needed cream.

A convenient apparatus for the domestic sterilization of milk has, upon my suggestion, been manufactured by Fraser & Co., after designs in which I have aimed to lessen the possible number of flaws in the method. Carelessness and stupidity on the part of those who sterilize milk in the household often render the whole process useless. The milk, which should keep fresh at least thirty days, thus turns sour within forty-eight hours. An apparatus, therefore, which simplifies the work and diminishes the chance for mistakes is its own *raison d'être*.

Fig. 1 shows the new sterilizing bottle. It was designed so that it could easily be cleaned, having no corners or curves that would retain particles of sour milk to contami-

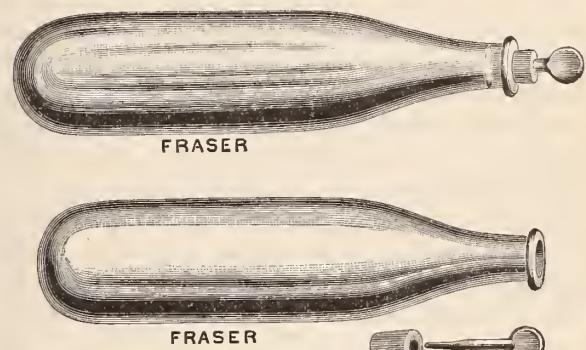

FIG. 1.

nate the next supply. The corks (rubber and glass) have been adapted from others' designs, as they have already proved all that could be desired.

Fig. 2 shows the bottles filled, corked, and placed in the rack, which is to be lowered into the tin pan where they are sterilized. This rack will also conveniently serve to

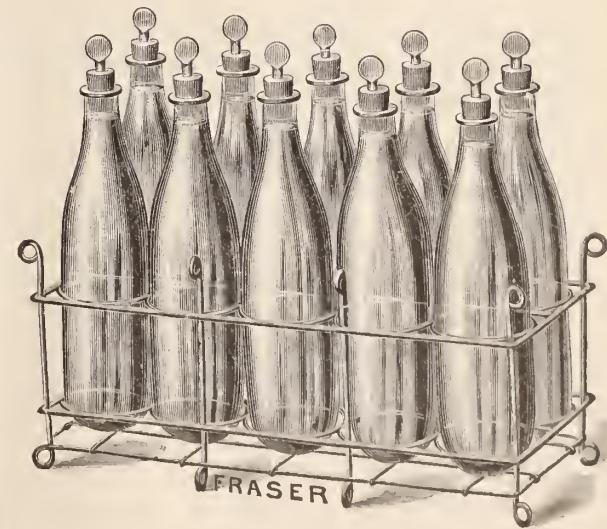

FIG. 2.

hold the bottles of milk in the ice-chest at home, or in the lunch-basket when traveling. It is light in weight, and

economizes room to the last possible degree. The small single rack (Fig. 3) is used to hold a bottle that is warmed for an infant. The bottle and rack are put into a small tin cup of warm water and placed over an aleohol lamp. The apparatus is completed by a square covered tin pan that will just fit outside the rack and bottles. For traveling, a wicker basket of a size to hold one or more dozen bottles is designed to be used.

The process of sterilizing milk is now so well known that only the briefest review of the method to be used with this apparatus will be necessary.

The bottles are filled with milk to within an inch of the top, the rubber perforated corks are inserted, the bottles placed in the wire rack, and this lowered into the tin dish. Cold water is then poured in around the bottles to within two inches of their mouths. The tin cover having been put on, the temperature of the water is gradually raised until it boils ten minutes. The glass stoppers are then inserted, and the boiling continued for twenty minutes longer. The rack containing the bottles of milk, now sterilized, is lifted out and put away where the bottles may cool gradually. If the changes of temperature are sudden, the glass becomes brittle, and numbers of the bottles are broken. If milk so prepared will not keep from one to three months, there is almost certainly some lack of cleanliness in the apparatus used.

It would seem that as yet sufficient emphasis is not laid upon the necessity of sterilizing all milk used for children and invalids. One well-known writer says: "When milk can not be obtained fresh it is well to sterilize it before using"; another that "in warm weather it is a wise precaution," and a third that, "in case of bowel or stomach trouble, sterilized milk is safer." But it is in this, as in other lines of medical research, the ounce of prevention that is the thing to be desired. Professional men who, a generation since, would have absorbed themselves in the study of disease and its remedies, now more earnestly seek to understand the necessary conditions of health and its preservation.

When all milk which is given to a child is scientifically sterilized it does not suffer from bowel trouble, nor from "sour" stomach, and it forms no indigestible curds, since cow's milk, after it is sterilized, curds in small soft flakes as mother's milk does. An infant with ordinary good heredity, who is thus fed with creamy sterilized milk, will go through with teething and suffer no disturbance or inconvenience greater than the teasing irritation of tender gums.

During the past summer several children who were losing flesh on poor breast milk were, by my advice, given instead rich Jersey milk thoroughly sterilized. In every case there was immediate and continued gain both in weight and strength. In one case the baby gained, from the second to the sixth month, a pound every ten days as regularly as clock-work, and had not a single hour's illness of any kind. At the end of that time the nurse, tired of the "fuss," failed

to sterilize the milk. The disturbance of the child's digestive system which resulted caused a loss of three pounds' weight in one week—it being that length of time before the intestinal canal could be cleared of the microbes introduced in one day's supply of unsterilized milk.

Since our scientific men have now so convincingly demonstrated that milk can not, even in the country, remain many minutes free from germs, it certainly never should be given to a baby thus contaminated.

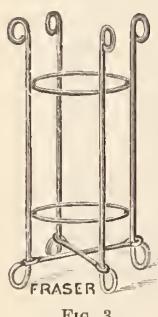

FIG. 3.

## POISONING FROM GASOLINE.

BY J. G. BILLER, M. D.,  
CORRECTIONVILLE, IOWA.

WHEN we consider the common use of the products of petroleum, it is surprising that medical literature should be so silent about them. In fact, from the silence of our literature upon the subject and from long familiarity with them, we were of the opinion that they were not at all dangerous; but a couple of cases in which children had been drinking kerosene came under our notice and the alarming symptoms, such as depression, etc., were probably as much of a surprise to us as to the friends and neighbors.

A thorough search through the literature at hand revealed but little upon the poisonous effects of kerosene, and nothing at all about gasoline except a meager account in the National Dispensatory. In August, 1888, we suddenly received more information than was pleasant upon the subject of gasoline poisoning, as the following case will show:

CASE I.—A baby, eighteen months old, was left alone in a room for a few moments, when it climbed up to a shelf where sat a pint measure one quarter full of gasoline. The child drank part and spilled the rest down the front of its dress, then set the cup down and went into the next room, where it was found by the mother lying unconscious on the floor. The mother had not been absent five minutes.

In ten minutes we saw the child and found it still unconscious, breathing or gasping about eight times a minute, pulse impalpable at the wrist, the pulsation of the heart scarcely distinguishable, the eyes rolled back, and the face livid. The skin of the neck and chest was a bright red from the spilling of the oil, the jaws were firmly closed, the arms extended and rigid, and the legs limber. The abdomen was terribly distended and tympanitic, and the surface of the body was cold and clammy.

The child was put into a warm bath and an attempt made to give an emetic, but anything in the throat caused strangulation. After being in the warm bath a few minutes the child revived, and its breathing became more natural; the rigidity of the muscles relaxed, and it spoke and seemed to recognize its parents. Its pulse was still impalpable, and, after remaining in this condition about two minutes, it suddenly dropped over, gasped a few times, and was dead.

The rapidity with which death came was astonishing, as the child did not live more than thirty minutes after drinking the oil. While in the warm bath its bowels moved very copiously. There was little time to think of treatment while the child was alive, but stimulants were what appeared to be required, and that hypodermically, but my syringe was away to be repaired, and there was no time to

send for another. The result might have been better with different treatment, but the lack of a hypodermic syringe and a stomach pump, or any other means of washing out the stomach, threw us entirely back upon external measures. Then, as before stated, we were entirely unprepared for such a case, never having seen or heard of one at that time. In the cases of kerosene drinking already mentioned the symptoms were somewhat similar, but not nearly so serious, and the stimulants could be given by the stomach.

CASE II.—November 1, 1889, child, nineteen months old. The mother had filled a small oil-can with gasoline and set it into a closet, closing the door, and turned away to attend to something else, when she heard the door open. Turning around, she saw the child raise the can to his mouth, and screamed at him, causing him to drop the can, but not before some of the gasoline had been swallowed.

We saw the child in less than three minutes. He lay almost comatose in his mother's arms. His breathing was slow and pulse imperceptible; the heart-beating was just perceptible and was so weak that at times it seemed to stop. His face was livid and cold, eyes rolled back, with pupils slightly dilated. The rest of the body was cold, with livid extremities. The mouth was filled with a sticky saliva that the child would occasionally force to the lips but not spit out, and the mouth and fauces were very red. Twenty drops fluid extract of ipecac were given by the mouth, and two drops fluid extract of digitalis and fifteen of brandy hypodermically. Nitrite of amyl was sent for at once. Allen's surgical pump was adjusted, the tube introduced into the stomach, and warm water pumped into it. The tube became stopped by undigested food when we attempted to draw the water back, so we continued to fill the stomach until the distended organ began to overflow, assisted by the continual retching caused by the irritation of the tube in the throat. Large amounts of water and food came up, all smelling strong of gasoline. This was kept up until the stomach had been thoroughly flooded. The amyl having now arrived, two drops were placed on a handkerchief and held to the child's nose. Soon the pulse began to flutter and grew quite strong. Every three or four minutes the child would drop into a half-stupid state and become pale and blue; then the amyl had to be repeated. In an hour and a half after taking the poison he had recovered enough to talk and notice things, and soon began to play with a watch, when he was pronounced out of danger.

In this case the depression came on with alarming rapidity, but, from my experience with the first case, I was at once prepared to act. The administering of an emetic is almost a waste of time, for the stomach generally fails to respond to an emetic in kerosene poisoning, and I do not think it would respond soon enough to be of any use in gasoline poisoning.

The nitrite of amyl undoubtedly was of great benefit, but still the child showed some signs of recovering before it was used.

**Chlorate of Potassium.**—Dr. Coghill, in a paper read at the Ninth International Medical Congress, confirmed the results of Wöhler that chlorate of potassium is excreted in the urine unchanged and in the full amount ingested, and hence does not give off oxygen to the tissues. Nevertheless, besides its local uses, he finds it of value in preventing abortion, in all cases of pulmonary insufficiency, as phthisis, chronic pneumonia, and bronchitis, in anæmia, chlorosis, and general malnutrition. In addition it has an antiseptic action in diseases of the genito-urinary tract where there is suppuration or purulent or phosphatic urine."—*British Medical Journal*.

## STRANGULATED UMBILICAL HERNIA, WITH LOCALIZED GANGRENE.

### RECOVERY.

BY WILLIAM HALLOCK PARK, A. B., M. D.,  
LATE HOUSE GYNÆCOLOGIST, ROOSEVELT HOSPITAL.

MARY G., aged thirty-nine, was admitted to the Roosevelt Hospital January 8, 1889, for a laceration of the cervix and perineum. She also gave the following history: In March, 1886, when four months pregnant, she noticed a small tumor at the umbilicus. This was allowed to remain unreduced. In October, 1888, the swelling became painful for the first time. The pain and tenderness increased and the patient soon was seized with severe vomiting. A physician was called, the hernia reduced, and a truss applied. Since that time the patient has worn the truss and has had no further trouble.

On admission, the patient is well nourished. The hernia is reduced and is not forced out by moderate coughing.

On the 9th of January the perineum and cervix were operated upon by Dr. George M. Tuttle.

On January 16th, after a hearty midday meal of corned beef and cabbage, the patient felt distress in the region of the umbilicus, and on examination found a tender swelling present, but did not call attention to it till four hours later, when she was seized with vomiting. On examining her at 7 P. M., I found a tense, tympanitic, and very tender swelling of the size of a child's fist. Attempts to reduce it were absolutely without effect. How long the hernia had been present before being noticed by the patient is uncertain, as no recent examination had been made. Opium was given and cold applied. At 10 P. M. the vomiting had become frequent. The local conditions remained the same.

Dr. Charles McBurney, who happened to be at the hospital, kindly looked at the case and advised immediate operation. Two hours were unavoidably lost in consulting with Dr. Tuttle and in getting the patient's consent. Owing to the sickness of Dr. Tuttle, I was forced to operate in his place. Dr. Brockway, the house surgeon, kindly assisted me.

The patient at this time was considerably prostrated; the vomiting had become almost constant, and the matter ejected was green and foul-smelling. The operation was begun at 12.30 A. M. with ether narcosis. A three-inch vertical incision was made over the tumor and carefully carried down to the sac, which, when free, proved to be pear-shaped, with its neck constricted by and adherent to a very tight ring. As a fold of the tense sac was pinched up between two forceps and divided, gas and cloudy serum escaped. Within were found rather more than four inches of darkly congested small intestines. At the part farthest removed from the constriction and nearly opposite to the insertion of the mesentery were two gangrenous spots, each half an inch in diameter and about a quarter of an inch apart. In one of these was a perforation from which cloudy, slightly smelling fluid escaped. The loop of intestine was carefully irrigated with warm 1-to-1,000 bichloride-of mercury solution, pinched up between the fingers, and the two gangrenous portions were removed by a single elliptical incision whose long diameter ran diagonal to the length of the bowel. The constriction at the neck of the sac was so tight that the contents of the intestines were absolutely prevented from passing through into the wound. The interior of the loop was thoroughly cleansed with hot water.

The edges of the opening were now carefully approximated by the fingers and united by three continuous sutures of No. 1 catgut. The first united, without tension, the divided surfaces of the mucous membrane. The second united the muscular layers. The third brought narrow surfaces of inverted marginal peri-

tonæum in close apposition—a Lambert suture, modified only in that it was passed continuously. The ring constricting the hernia was now divided on a director. The collapsed intestine expanded and the circulation quickly improved. There being no leakage at the site of the sutured wound, the intestinal loop was returned into the abdomen.

The remains of the sac external to the ring were then excised. Two silver-wire sutures were then passed through the entire thickness of the abdominal wall, including the peritonæum. The peritoneal edges were further united by three heavy catgut sutures. The silver wires were then fastened and the edges of skin carefully united by interrupted sutures of silk-worm gut. The wound was finally cleansed, dusted with iodoform, and covered with bichloride gauze. Time under ether, two hours. The patient passed the first twenty-four hours without any bad symptoms. At 5 P. M. the abdomen was soft, pulse 98, respiration 22, temperature 99° F.

On the afternoon of the second day the patient was given an ounce of beef-tea by the mouth; this was quickly vomited. The vomiting of greenish-colored fluid was repeated some seven or eight times during the next two days. The abdomen became very slightly distended, but the pulse, temperature, and respiration remained the same.

On the fourth day the patient was given a copious injection of warm boric-acid solution. This was followed by four fairly large faecal movements. The patient also retained small quantities of peptonized milk given by the mouth.

On the tenth day the sutures were removed from the wound, which had healed by primary union. Since the last note she has steadily improved. Bowels move once every day.

*February 7th.*—Patient is to-day sent to her home, apparently cured.

*March 1st.*—Patient's physician reports that she has just passed through a sickness giving the symptoms of acute intestinal obstruction. The vomiting and prostration were marked. The symptoms increased for some twelve hours, and then gradually abated.

*June 1st.*—Since March the patient has been well. To-day, on examination, I find no return of the hernia.

## GRATIFICATION OF THE MIND AS A REMEDY FOR STERILITY.

By M. J. BURSTEIN, M. D.

Mrs. B., aged twenty-four, consulted me on October 20, 1888: "Doctor, I am married since three years and have no children. I have been doctoring myself for the past two years, and now I want you to tell me whether I am able to bear any, or I have to give it up for a good job. I am very anxious to have a baby. I have been going around from doctor to doctor with no result." Her history is as follows: She is a native of Russia; has been healthy since her childhood; began to menstruate at the age of fourteen, and was not troubled up to her marriage. At times she had some pains in her back before the flow started, but these pains were insignificant; menstruation lasted about five days, and the loss of blood has been moderate. Since her marriage, however, she feels a heaviness in the abdomen, sometimes pains in the back, pains and weakness in her limbs, dizziness, indigestion, suffers from chronic constipation, indisposed to be in company, no desire for sexual intercourse. She feels something wrong with her womb ("walking of the womb," as she called it). Has lost flesh and strength and become anaemic. She does very little work about the house, and

is constantly worrying about her incapability of bearing children. She stated that she would submit to any operation if it would remedy the defects of her body in regard to her being sterile. She had heard different stories from women about various methods of treatment, and, as it seemed to me, the pessary treatment ("ring inside," as she called it) was, in her opinion, the best one of all.

Placing the woman on my operating-table, I found that the uterus was of a normal size and color, no elongation of the cervix (a very slight anteversion, however); I could pass a sound through the cervical canal very easily; no pain on touch in the ovarian region, but a slight tenderness over the whole abdomen.

Giving her a tonic pill and directing her to take some vaginal injections, I assured her that she would become pregnant sooner or later. In about a week she called again, and insisted on being operated upon with this "ring." I promised her that I would do so as soon as she should get more strength to stand the operation (no other treatment was, according to her imagination, of any avail). She came once more and told me that she feared to wait any longer, and that she wanted to stop the "walking of the womb" at once. This was on the 11th of November, 1888. I showed her a "ring" by which I would stop "walking" immediately. I inserted a Hodge pessary, *which I immediately removed* (causing her a little pain), and when she got up I asked her how she felt. "Splendidly; why, I feel that it does not 'walk' any more; I feel much easier." I gave her instructions to give up treatment, but keep on taking good food and sufficient exercise; she was not to fear to walk, as the "ring" would hold everything in position. She left me on that day, and I had almost forgotten about her. On the 25th of July, 1889, the same little woman came in with a smile. "Well, doctor, I believe it is about time to remove the 'ring.' I am already in the family way since five months; I am tired wearing it; eight months is enough!" I examined the woman "to remove the ring," and found that she was right. She is now at full term and is as healthy as "she was always." Did not the satisfaction of her mind cure her?

182 HENRY STREET, NEW YORK, November, 1889.

## THE SEPARATION OF THE POISON OF THE "LOCO-WEEED."

By MARY GAGE DAY, M. D.,  
WICHITA, KAN.

In making the separation by the following method, only the plants gathered in the fall were used.

The roots, stems, and leaves were boiled ten hours, strained, and the decoction concentrated to a syrup, poured, while hot, into a hot flask, corked, and set away. At the end of ten days the syrup had separated into two layers—the upper a blackish liquid, the lower a brownish sediment. The liquid was poured into a flask and covered with six times its volume of very dilute alcohol, 30 per cent. (the sediment also was washed with the dilute alcohol, to insure complete removal of the liquid), corked, and let stand three days; agitated occasionally; then filtered, and the filtrate slowly evaporated in the air, when crystals formed. It was found important not to hurry the evaporation, for when this took place too rapidly the crystals did not form.

These crystals are microscopic in size, blue-white in color, and of a variety of forms. The most characteristic are slender and pointed, arranged in rosettes or grouped in

various ways. They are soluble in distilled water and very dilute alcohol, very sparingly soluble in strong alcohol, not soluble in chloroform or ether.

The evaporated mass containing the crystals, when dissolved in distilled water, is slightly acid in reaction. A small amount of this fed to a kitten produced the train of characteristic toxic symptoms—sleepiness, loss of appetite, retching, and diarrhoea—that is produced by quite large amounts of the decoction.

I therefore conclude that the substance which separates in the crystalline form by the above-described method is the poison of the "loco-weed," but defer naming it until an ultimate analysis is made, which will be done during the year at the Hygienic Laboratory of the University of Michigan.

After a more extended study I hope to be able to enter more fully into the discussion of the chemistry and the physiological action of this poison.

#### A FATAL CASE OF CARBOLIC-ACID POISONING.

BY S. T. RICCI MAN, A. B., M. D.,  
PRINCETON, KANSAS.

ON July 26, 1889, at the noon hour, a child seven months old received a superficial burn on the left arm and thigh from a cup of hot coffee. A mixture, consisting of equal parts of carbolic acid and sweet oil, was applied by the mother, being a recipe taken from a domestic medical book in her possession. About half an ounce of 95-per-cent. carbolic acid was thus used. In two hours the child passed into a condition of stupor, which, continuing, alarmed the family, and I was summoned.

Arriving at 7 p. m., I found the child lying quietly, with the exception of an occasional movement, made by flexing the legs upon the thighs and these upon the abdomen, and then forcibly extending them. The eyes were fixed, the pupils contracted to the size of a pin's head, the pulse 120, weak, breathing irregular, occasionally sighing, swallowing performed with great difficulty, mucus expectorated rather than vomited, the odor of carbolic acid being plainly perceptible in the breath.

Not having atropine with me, I administered four minimis of the fluid extract of belladonna by the mouth, a portion of it being rejected. At the end of an hour the pupils had begun to dilate, a slight blush was barely perceptible, and swallowing less difficult. A small quantity of whisky was then given with two minimis of belladonna.

At the end of another hour the pupils were normal, the erythematous blush quite perceptible, swallowing somewhat improved, pulse and respiration the same. Learning that no urine had been passed since noon, and not desiring to substitute belladonna for carbolic-acid poisoning, I discontinued the former and ordered small doses of nitrate of potassium and whisky to be given at intervals during the night.

At eight o'clock next morning the pulse was 160, weaker, temperature 103° F., face blanched, pupils larger than normal, eyes fixed, the child lying quietly. The mother showed me a napkin with a dense smoky stain, three of which had been removed during the night, adding that the stains would not wash out. The child continued to grow weaker, the pulse rising higher, until convulsions set in at five o'clock, and death occurred an hour later—thirty hours from the application of the acid.

No post-mortem was allowed.

## THE NEW YORK MEDICAL JOURNAL, *A Weekly Review of Medicine.*

Published by  
D. APPLETON & CO.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, NOVEMBER 30, 1889.

#### THE CONGRESS OF PSYCHOLOGICAL PHYSIOLOGY AND HYPNOTISM.

INTERESTING things, according to the "Progrès médical," were discussed last summer by the learned body above mentioned. Among them, hypnotism received serious consideration. Whether the hypnotic sleep and normal sleep were identical in kind, and whether susceptibility to the hypnotic influence existed in greater degree among those deficient in nerve force or among those who possessed nerve force to the natural extent were some of the questions raised. M. Richet inclined to the opinion that persons without any neuropathic defect were hypnotizable, in spite of the prevailing idea that only the nervously weak could be overcome. Bernheim thought that with patience everybody could be put to sleep, and such was the theory of all the Nancy school. At the same time, he said, there must be a certain impressibility, which he hesitated to call a neuropathic impressibility, because it existed, he believed, in inverse ratio to nervous defect. Hypnotic sensibility existed at all ages. Oschorowicz confirmed the idea that nerve deficiency lessened hypnotic susceptibility, especially in neurasthenics. The question of nationality as a factor in susceptibility was raised. The conclusions arrived at were to the effect that the French were no more susceptible than those of other races; and that, generally speaking, all persons of every rank were hypnotizable, except certain peculiar individuals whom nobody could impress under any circumstances, and the victims of hysteria gravior. Richet raised a question concerning the personal influence of the experimenter, remarking that the old magnetizers had considered it highly important. Myers, of London, spoke from definite experiment to the effect that the will of the operator sometimes produced impressions upon the subject and sometimes did not. Richet suggested the following division of conditions characterized by change in the personality of the individual: 1. Spontaneous phenomena, either normal or pathological, such as sleep, somnambulism, etc. 2. Induced nervous states—such as those brought about by suggestion. 3. Actions at a distance, mental suggestion, and telepathy, phenomena not yet irrefutable and belonging to a science still so embryonic as to be outside the pale of discussion. Bernheim spoke of the two theories in regard to hypnotism—*suggestion*, which he himself maintains, and *fluidism*, of which idea Oschorowicz is the apostle and party representative. The theory of fluidism is to the effect that action is produced upon the organism without cerebral intervention. This may be possible, yet up to the present time it has not been proved. Passes, fixing the gaze upon brilliant objects, etc., are said not to belong to suggestion. Surely sug-

gestion plays a part. Fixing the eyes upon a brilliant point, an upward convergence, and raising the eyelids produce fatigue conducive to slumber, and bring about indirect suggestion.

The rôle and action of physical agents may thus be explained on the ground of indirect suggestion. Liebeault's experiments on infants would seem to refute this idea. He cared for sick babies suffering from various digestive disorders, whom he cured by simple laying on of hands. In such little children is suggestion possible? Why not? The journey, the visit, make an impression to which the infant responds. Babies are *suggestible* when a month old, possibly when a day old. Ballet felt himself astray among such distinctions. Up to the present time he had supposed that there could be no suggestion without definite prevision on the part of the experimenter. After some little skirmishing, Richet remarked that words certainly played some part in the discussion. Under the influence of external objects there was always mental reaction. Now, if this was called suggestion, then everything was suggestion. But suggestion in its hypnotic sense meant only an indication of the experimenter's thought or of the thought of the subject. Important as this may be, it is by no means everything. Dali-newsky, of Karkoff, said that hypnotism in general presented an assemblage of psycho-physiological phenomena common to man and animals. To find out the laws of its action, to reach any complete analysis, a careful study of the hypnotic state in animals was essential, their psychic organization being far simpler than man's. He himself had induced the hypnotic state in the crawfish, the crab, the shrimp, the lobster, the cuttle-fish, the electric eel, the brill, the leech, the frog, the tadpole, the triton, the lizard, the crocodile, the serpent, the tortoise, and certain birds. The general picture of the hypnotic state among animals was this: The animal was placed in some abnormal posture. A slight but prolonged effort on the part of the experimenter overcame its resistance, and voluntary movements were paralyzed; the animal was now quiescent. Marked anesthesia of the skin and mucous surfaces was then developed. Inward excitement, such as that induced by artificial obstruction of the respiratory tract, no longer provoked voluntary movements. Convulsive movements now began, giving to the phenomena present the characteristics of a violent psychical emotion. Repetitions of the hypnotic state diminished the animal's resistance. It became more and more susceptible to the hypnotic influence. Verbal suggestion in man and sense-suggestion, executed in animals by the hands of the hypnotizer, were homologous. Here we were dealing with psychical acts that were unconscious and instinctive.

#### OCULAR DEFECTS AND THE NEUROSES.

THE Commission on the Treatment of Epilepsy and Chorea by the Correction of Ocular Defects presented its report to the Neurological Society on November 5th, as we have already announced. The terms of the original agreement made between the Commission and Dr. Stevens, the changes in the original plan, the difficulties encountered by the Commission, together

with a summary of cases, were set forth in due form. Dr. Stevens replied with some spirit, and endeavored to explain certain ambiguities with the same freedom of speech that had characterized criticisms of himself and his methods. The evening was unique in the annals of neurological science, and those who were absent missed much that printed accounts are powerless to convey. An obstreperous chorus chimed in now and then, like the bassi profundi and the tenori robusti of the opera who had forgotten their parts and gave forth notes at the wrong moment. Some fair-minded members, who believed in aiming straight at the target and hitting the bull's-eye every time, suggested that the speaker should not be interrupted, as the reader of the report had been listened to in silence. A good deal of the discussion was controversial and personal, recalling in a measure the "Society upon the Stanislaus" as described by "Truthful James." When all was told—and it took some hours to tell it—the fact remained that six patients out of fourteen had been improved by ocular tenotomy, though none of them had been cured. Now, what does this prove, and does it prove anything? It would seem to prove that Dr. Stevens's method is a therapeutic measure valuable as an adjunct, and that, in certain cases where toxic medication is unwise, it constitutes one more means of alleviating suffering. This fact remains, according to the report of the Commission, and in spite of the frank fencing-match in which adjectives were the weapons used. "Wisdom suggests leaving words for facts, since facts form a more rational basis for theories." Hypnotism is, in a certain sense, a new remedy. It does relieve, though it may not cure. Though its future is difficult to prophesy, shall it be abandoned and ignored? Ocular tenotomy has relieved in certain given cases, but cured in none of them. Is it an utterly despicable method of procedure, without a leg to stand on? Let the fair-minded physician investigate the matter for himself, remembering that science and preconceived opinions are incompatible. Tenets are fixed, while science is progressive. According to Erichsen, in his address at King's College, the real object of medical education is to train the mind to remain open to the reception of truth throughout life, and to meet the varying emergencies of a professional career. The mind ever open to truth is the fair mind, and the verdict of the fair mind is the only one worth having.

#### MINOR PARAGRAPHS.

##### THE MEDICAL ASPECTS OF THE WANDERING JEW.

EUGENE SUE was a medical man, well trained in the science of his time. According to the "Lancet," he was a surgeon to the royal household, and served also in the army and navy. He was the fourth in direct descent that had been educated in the medical art. His father and grandfather were both graduates of Edinburgh. His father translated into French the principal treatises of the Scottish school. He made some original investigations concerning galvanism and the guillotine, and he served as chief of the medical staff of the Imperial Guard during the campaign into Russia and subsequently became physician to Louis XVIII. On his death he endowed the Academy of Fine Arts with a museum of natural history and comparative anato-

my brought together by four generations of physicians in his family. The great-grandfather of Eugene was one of the prominent physicians of the early part of the eighteenth century. The author of the "Wandering Jew" brings his fine medical training into requisition in those passages that depict the cholera visitation of 1832 and its manifold effects upon the citizens of Paris. Sue inherited a fortune when about twenty-five years of age, and immediately left the naval service to put into exercise his predilection for imaginative composition.

#### GARROD'S SULPHUR LOZENGE.

In our issue of July 13th reference was made to Sir A. B. Garrod's paper, in the "Lancet," on the usefulness of small doses of sulphur. At that time, so far as we could learn, no "compound sulphur lozenge," such as Dr. Garrod had used, had been in the market in this country. Since that time two drug-houses have announced the preparation of a Garrod's lozenge. One of these closely follows the English physician's formula, which orders five grains of sulphur and one grain of cream of tartar in each compressed lozenge. This is the product of a Baltimore house of high repute. Another large firm, doing business in Philadelphia, has made a similar preparation, but the formula is varied so as to add to the two ingredients named three others, as follows: extract of ipecac, one one hundredth of a grain; extract of capsicum, one five-hundredth of a grain; and arsenious acid, one one-thousandth of a grain, in each lozenge.

#### SYPHILIS AND THE SPEAKING-TUBE.

The Paris correspondent of the "American Practitioner" gives an account of a case of syphilis of the mouth with a history of unusual origin. It is from the clinic of Dr. Vidal at the Saint-Louis Hospital. The patient, a girl of twenty years, had for three months had superficial lesions of the lips, which were thought to be eczematous. On her admission to the hospital, however, the diagnosis of chancre became incontrovertible. The subsequent inquiry regarding the method of inoculation showed some unexpected, because unusual, results. The patient was a factory girl, and there was working in the same part of the building a young man who had sores about his lips, and he as well as the girl and several others had frequent occasion to speak through the same speaking-tube. It was by placing his lips, which were sore with secondary symptoms of the disease, on the mouth-piece of the tube and leaving on it virus to be taken up that he infected the others, who also pressed their mouths against it. As the writer of the letter says, "If this is true, this mode of contagion deserves to be brought into notice."

#### THE NEW YORK SURGEON OF TO-DAY.

The "American Practitioner" has a letter from a Kentucky physician who has been visiting among the surgical leaders of New York. This visitor appears to have formerly had several misconceptions, which have been set aright by ocular demonstration. He expected to see brilliancy in operative methods, but the acme of brilliancy is simply "satisfactory results"; there is no hurry. The value of time is acknowledged, but accuracy is valued even more. He found a carefulness and patience amounting almost to tediousness in operations. There is a rigid observance of antiseptic cleanliness and asepsis, without exception, among those surgeons—seven or eight are named—whose clinics were followed by the visitor, with much attention to surgical details to the end that haemorrhage, shock, and exposure to cold may be reduced to the minimum. Anæsthesia

by ether is preferred, but in the case of children chloroform is used occasionally; in plastic face operations, ether by the rectum has its advocates. To sum up: he found an abundance of rare and classical operations performed with all the courage and authority of the master; the operator occupies the position of one who is beyond criticism, who acknowledges no restraint, except that of his judgment and conscience, and who is strengthened by his position to aim at everything possible to human skill and endurance.

#### THE CONFORMATION OF THE CHEST AND THE TENDENCY TO CONSUMPTION.

The "Deutsche Medizinal-Zeitung" contains an article on this subject by Dr. Maszkowski. The writer states that it is maintained by many observers that disproportion in the form of the chest is an important factor in the tendency to tuberculosis. The results of a series of investigations have not led him to coincide with the conclusions of others in this respect. He selected 275 healthy individuals and the same number of persons suffering from various stages of pulmonary tuberculosis. These persons were subjected to close and careful comparative anatomical measurements, and from these the following conclusions were deduced: 1. That there existed no characteristic form of the thorax in those predisposed to pulmonary tuberculosis. 2. That changes in the form and diminution in the capacity of the chest, when such took place, appeared as concomitants and developed as the disease progressed. It was a matter for remark that the general form of the chest in some of the tuberculous patients was even more favorable, if irregularity was alleged as a predisposing cause of disease, than was found in some of the perfectly healthy persons.

#### THE TREATMENT OF PHLEGMASIA DOLENS.

The "Union médicale" attributes to Delore and Poulet the following sketch of the proper treatment of phlegmasia alba dolens:

Absolute rest in the dorsal decubitus, the affected member placed in an attitude of forced extension, and a mixture of oil and chloroform applied; then cotton batting is placed around the limb, which is to be kept warm at an even temperature. Movement and repeated examinations are to be avoided. To combat pain, narcotics by the mouth, subcutaneous injections of morphine, and laxatives are in order. When pain begins to subside, alkaline and diuretic drinks may be given to hasten resolution of the œdema. If there is much œdema, the fluid may be allowed to ooze out through small incisions or through a drainage-tube. The patient should be kept in bed for thirty days after the cessation of pain and until the œdema has almost completely disappeared.

#### OPHTHALMIA PHOTO-ELECTRICA.

According to the "Deutsche Medizinal-Zeitung," Dr. Lubinski has observed a peculiar form of inflammation of the eyes, usually in persons employed about electric lights, to which he has given the name ophthalmia photo-electrica. It appears to be due to looking at the very bright light from a short distance, without proper protection to the eyes, such as dark glasses. Soon after thus looking at the light a succession of bright spots appears before the eyes, each remaining but a short time and then being replaced by another. During the following night the patient suffers severe ocular pain, with lacrymation and photophobia. The lids are swollen, the movements of the eye are painful, and there is circumcorneal injection, with hyperæmia

of the entire eye. This condition continues from an hour and a half to three hours. Then the patient falls asleep and awakes in the morning apparently well, except for a tired feeling in the eyes. The retinæ are still hyperæmic, and sometimes venous pulsation can be seen. Lubinski recommends cold applications, very frequent instillations of cocaine, and chloral or quinine with morphine.

#### CARBOLIC ACID IN THE TREATMENT OF NEURALGIA.

DR. JULIUS GARST, of the Indian Reservation, Tacoma, Washington Territory, writes that recently a case of severe neuralgia, that had continued about three months, came under his care. The patient had taken the usual tonics, also quinine in large doses, and acetanilide, without relief. The pain was severe in the areas supplied by the infra-orbital, the supra-orbital, the temporo-malar, and the great occipital nerves, also in a spot a little to the left of the seventh cervical vertebra. There was no tenderness along the spine. Complete relief followed the injection of several drops of a fifty-per-cent. solution of carbolic acid at the points from which the pain radiated. Two weeks had passed, at the date of Dr. Garst's letter, without any return of the pain, and during that time trinitrin had been taken.

#### THE BABIES' HOSPITAL.

DR. L. EMMETT HOLT has been appointed attending physician to the hospital in the place of Dr. Sarah J. McNutt and Dr. Julia McNutt, resigned. The hospital is now permanently located in a building of its own on the corner of Fifty-fifth Street and Lexington Avenue, where it has a capacity of thirty-five beds. Any sick children under two years of age are admitted, excepting those with infectious diseases. In connection with this hospital a training school for nurse girls will be opened in December, under the patronage of Mrs. R. W. Chapin. The hospital has been in active operation in its new quarters since the middle of October. It will be formally opened to the profession and the public on December 6th.

#### ITEMS, ETC.

**The New York Society for the Relief of the Widows and Orphans of Medical Men.**—At the recent annual meeting, Dr. Henry Tuck, of the New York Life Insurance Company, was elected president. The treasurer's report showed a net increase of receipts to the amount of \$4,445.84 during the year, making the total assets \$166,163.63.

**Change of Address.**—Dr. L. H. Dunning, from South Bend, Ind., to No. 19 West Ohio Street, Indianapolis.

#### Society Meetings for the Coming Week:

**MONDAY, December 2d:** New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morrisania Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica Medical Library Association; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., City Medical Association; Chicago Medical Society.

**TUESDAY, December 3d:** New York Obstetrical Society (private); New York Neurological Society; Elmira, N. Y., Academy of Medicine; Buffalo Medical and Surgical Association; Ogdensburg Medical Association; Medical Societies of the Counties of Herkimer (semi-annual—Herkimer) and Saratoga (Ballston Spa), N. Y.; Hudson, N. J., County Medical

Society (Jersey City); Androscoggins, Me., County Medical Association (Lewiston); Baltimore Academy of Medicine.

**WEDNESDAY, December 4th:** Society of the Alumni of Bellevue Hospital; Harlem Medical Association of the City of New York; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond (Stapleton), N. Y.; Penobscot, Me., County Medical Society (Bangor); Bridgeport, Conn., Medical Association.

**THURSDAY, December 5th:** New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua; Medical Society of the County of Orleans (annual—Albion), N. Y.; Boston Medico-psychological Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington).

**FRIDAY, December 6th:** Practitioners' Society of New York (private); Baltimore Clinical Society.

**SATURDAY, December 7th:** Clinical Society of the New York Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

### Letters to the Editor.

#### A NATIONAL MEDICAL SOCIETY ON AN ELEVATED AND PERMANENT BASIS.

BOSTON, November 4, 1889.

To the Editor of the *New York Medical Journal*:

SIR: Recently, in conversation, a professional gentleman of experience (teacher in one of our schools) said that there were already too many medical societies in this country, and that the American Medical Association, if wisely conducted, would be quite enough; the various specialties could be arranged as sections or branches of this one general comprehensive body. Very soon afterward I had occasion to examine the renewed appeal for members lately made by an aspiring medical society; the weight of my friend's words became heavier—and yet more heavy as I further thought upon the number of existing social organizations in medicine. The name of any such company of individuals goes for little if not sustained by the character, personal and scholarly, not less than professional, of those in membership and in control; a high-sounding title appears absurd, or pitiful rather, when names of merited eminence are conspicuously absent.

Verily, considering the numerous societies and the evident tendency to the formation of yet more, the well-wishing observer must query what will the outcome be—chaos? dispute? The very fact of there being so many independent, even rival, bodies, argues (to the disinterested and impartial) that the profession has still to find and *put in action* the elements and means of stability and popularity which attract men of worth—elements and means by which, at the same time, a widespread usefulness may be attained.

Inasmuch as the present seems to be a society-generating epoch, I am emboldened to hope the hour opportune to establish in the United States a national organization on such a basis that good results and permanence will follow. In pursuance of this idea, I venture to bring again before the profession (and the general public) a *plan* (outlined in the "Boston Medical and Surgical Journal" of July 25, 1872) the main points of which are given below. For details the reader is referred to the original paper.

In future, then, let this (one and only) association have a truly representative governing body, elevation to which should be the

reward of scholarly accomplishments, professional ability, usefulness, and eminence. Two delegates from each State would, probably, be a sufficiently large number for all practical purposes. These should constitute the National Council of this American Medical Society. It should meet at least once a year, and continue in session long enough to attend to all legitimate business, scientific and professional, giving advice, editing rules (on ethics), publishing transactions of value, etc.—everything concerning the interests of the profession throughout the Union—being thus a complete senate, as it were. The term of service should be six years, each State electing one delegate or senator every three years. To free them as much as possible from local and temporary influences, they could be chosen by a State council, which, for this and other duties, might be composed in the following manner:

Let each of the several State societies select from among its most experienced and best qualified men a number equal to that State's representatives in Congress; that is, one perhaps from each Congressional district, one third (as near as may be) each year. These should hold office for three years, and be the State councilors of the national society or association. They could meet yearly or oftener, and do the work fitly falling upon a State or local committee. Each of these State boards should, once in three years, choose a national councilor from among their own number, or at large, as found best qualified and worthy. These local bodies could do preliminary work, revision of which should be left to the experience, sober judgment, and deliberate action of the National Council, whose members, moreover, might be allowed a seat, without a vote, at sessions of the State Council, in order to inform themselves of matters under consideration. Members of the State Council could be permitted the privilege of a seat, without a vote, at meetings of the National Council.

Matters of business and control should be left entirely with the National Council. The State councils (and societies) could then devote all their energies to professional and other allied scientific work. Existing State societies might be branches of the larger organization, and their members be the ordinary members of the National Association. Specialty societies and the present subdivisions within State limits could remain very much as they are now—all being united in one national confraternity. General meetings could be arranged by the National Council for orations in medicine and surgery, reports, discussions, etc., as deemed advisable, on which all ordinary members should be entitled to attend. Of course, various questions for solution arise when details are thought of, but the obstacles to bringing all our medical societies into harmonious co-operation or complete organic union do not seem insuperable—may it not be hoped?

As may be observed, this plan forms a governing body as a beginning; but, is not that the way in which any successful enterprise is started and carried on? The brain must direct, or the less intelligent (or less moral) members (*corporis*) will shipwreck the company.

Judged by their actions, the great majority of the more prominent portion of the profession in this country do not seem to recognize, in any existing organization commensurate with our territorial domain, a national medical society on an elevated and permanent basis. The arrangement above referred to, thought superior to any other yet offered, appears to be easily feasible (without revolution), to be well adapted to readily place any association which may adopt it enduringly upon a dignified professional and scientific basis, and to render fellowship and position therein attractive to men of merit. Praiseworthy effort of mediocre intellect could be rewarded by membership or office in the State societies and councils, while the Na-

tional Council would offer fit prizes for the honorable ambition of genius and eminent talent. "Under such a plan the American Medical Association would soon become a 'power' in the land; and connection with it, even as a member merely, be an object of just pride with every high-minded and well-educated practitioner throughout the country."

Moreover, as international reunions are the custom of the day, it may not be superfluous to think upon the opinion which medical men outside society bounds, or the profession abroad, would have if there were an association that should really represent those who devote themselves to the science and art of medicine in America.

JURE ET BENE.

## Proceedings of Societies.

### NEW YORK ACADEMY OF MEDICINE.

*Meeting of November 7, 1889.*

The President, Dr. ALFRED L. LOOMIS, in the Chair.

#### A Plea for the Practical Utilization of Hydrotherapy.—

Dr. S. BARUCH, in a paper with this title, opened with a review of the history of the treatment of disease by hydrotherapeutic measures from the time of Hippocrates until the present age. He also quoted the opinions of the leading clinical teachers of Germany, France, and Italy as evidence of the high appreciation with which scientific treatment by means of water was regarded by recognized therapeutists of the present day. The use of water, he asserted, had maintained its hold upon some of the most able physicians in every century of medical history, despite the prejudices of the laity and of the medical profession at large. These prejudices had failed to abolish it from the therapeutic armamentarium, as had been the fate of many other equally vaunted remedies. Indeed, it was to-day more firmly entrenched than ever, not only on clinical grounds, but because its use was based upon well-ascertained and exact physiological facts. From carefully elaborated experimentation on man and animals, certain data as to the physiological action of water were deduced. The caliber of the blood-vessels could be diminished to any extent by cold water, until the coats of the vessels would lose their tone altogether. The application of cold water resembled that of irritants in producing reflex action from the central organ. Irritants excited considerable influence on the heart and vessels, and as, in proportion to the irritability of the individual, powerful cutaneous stimuli would lessen or weaken cardiac action, relatively weak stimulation would strengthen that action and narrow the lumen of the vessels. Changes produced by continued stimulation of the skin lasted sometimes after its removal, and relaxation of the pulse often followed powerful stimulation. The excitant effects of weak cutaneous stimulation continued after its conclusion, but were also followed by a less pronounced relaxation. Powerful cutaneous stimulation was always followed, after a period of warming, by a cooling down of the body heat which might last over an hour. Sometimes this occurred during stimulation, but, as a rule, took place after its cessation.

From observations made on the circulation of the rabbit trephined for the purpose, definite results of the effect of water stimuli were arrived at. A cold stream of water applied to the belly or back of the animal was at once responded to by the blood-vessels of the pia mater, contracting them if brief, dilating them if prolonged. A warm compress applied to the belly or back contracted the vessels. Cold baths produced dilatation

of the vessels in proportion to the extent of the body immersed. It was only after prolonged immersion in cold baths that a contraction of the vessels, as a result of the reduced blood temperature, took place. Immersion of the body in warm water brought about decided contraction of the vessels of the pia mater, and they remained contracted for some time afterward. By demonstrations on man it was found that the application of cold to certain definite parts of the surface exercised a positive influence upon definite vascular areas. It was a well-known fact that the human body was not affected by cold and heat like an inanimate body; that it reacted against the thermic stimuli. It must be remembered that the vital processes by which the system endeavored to protect itself against thermic disturbing influences were also definitely ascertained. By means of the calorimeter it had been positively demonstrated that the radiation of heat depended upon the cutaneous circulation. It was found that during the most active condition of the skin function three and a half times more heat might be retained in the body than the average loss of heat, or that it might be increased three and a half times. As the great bulk of the heat was produced in the voluntary muscles, which formed about one half of the entire body, it followed that the increased activity of the muscles aroused by the external application of cold was capable of producing an increase of heat. In the muscular reaction produced by the warm moisture of the pack, a condition most favorable to the nutrition of the muscles was brought about. The excretion of carbon dioxide was increased by the application of cold. It was also shown that there was a corresponding increase in the consumption of oxygen. The writer said that, from the conclusions of reliable experimenters, we were warranted in affirming as a physical law that, under the influence of cold, oxygen combustion was energized and augmented, on condition always that refrigeration did not exceed certain limits and cause depression of the rectal temperature below 30° C. (86° F.). It was found that the wet pack increased the elimination of the fluids and solids of the urine.

The writer did not maintain that in hydrotherapy we possessed a universal remedy, but that it was an indispensable auxiliary to other methods of treatment. His definition of hydrotherapy was the utilization of water at any temperature, internally or externally, for the treatment of disease. He did not say for the cure of disease. He hoped by this definition to emancipate it from hydropathy, or "cold-water cure." In dyspepsia and gastro-intestinal diseases water had been used with great success. By removing the products of fermentation and cleansing the mucous membrane, it restored tone and vigor to the gastric lining and enabled the natural forces to come into play. Another class of cases which offered a broad field for the employment of hydrotherapy was that to which belonged neurasthenia and other nervous diseases—rheumatism, gout, anæmia and chlorosis, obesity, and scrofula. In these cases the benefit derived from the application of water seemed to be produced by an increase in assimilative processes and in nutritive and tissue changes. He divided neurasthenia into two types—the crethetic and the true asthenic. The former was characterized by an instability of nerve forces, the latter by their enfeeblement. The former required soothing ablutions, or prolonged wet pack, followed by the half bath of 65° to 70° F. once or twice daily. The asthenic form, on the contrary, required the stimulus from the active reaction produced by the impingement of a mass of cold water for a brief period. Under the author's observations many cases of hysteria had yielded to the tonic influence of various hydrotherapeutic procedures. In chronic constipation the results were excellent. Statistics whose source was unimpeachable demonstrated that the mortality of typhoid fever had been reduced from twenty-five per cent. to two per cent. by the sys-

tematic bathing under Ernest Brand's method. The author gave the histories of a number of cases which had been considered hopeless, but in which the patients were now in comparatively good health from the application of water as a remedial agent. He said that the results in the Montefiore Home for Chronic Invalids were exceedingly good considering the desperate and hopeless class of cases, and that the last report recorded six cured and thirty-five improved sufficiently to return to their homes and daily work.

Dr. G. A. PEABODY thought it was deplorable that it was possible to enumerate only two or three physicians in this great city who were known to avail themselves of hydrotherapeutics in the treatment of typhoid fever. The old prejudice still existed that it was a dangerous procedure suddenly to lower the temperature of the medium by which a patient was surrounded. The results at present achieved from the routine treatment of typhoid fever were by no means satisfactory. The statistics of mortality from the disease in this country was such as would be considered unjustifiable in any European capital. The death-rate here was from twenty to thirty per cent., and during the civil war had been from forty to fifty per cent. Dr. Brand had collected the data for a list of cases numbering about six thousand in which hydrotherapeutic treatment had been employed by physicians having faith in it. The mortality in these cases showed only 3·9 per cent. In the French and Austrian armies the method was not employed systematically from the beginning of the disease, and the typhoid-fever mortality-rate was 36·9 per cent. in the French and 27·4 per cent. in the Austrian army. In the German army, where there existed more or less system in respect of this method of treating typhoid fever, the death-rate was 9·6 per cent., and in the second army corps, in which the treatment was systematized, the mortality-rate was only a little over three per cent. He thought the profession in America had as yet not risen superior to its own prejudices against the use of the bath in typhoid-fever cases, while the expense and difficulties attending the conscientious administration of the system might also have stood somewhat in the way of its more general adoption. As to the various methods for the employment of the treatment, he thought there was little question but that the cold bath at from 65° to 68° F. was the most preferable form. The baths should be begun as early as possible in the cases and should be continued at intervals indicated by the patient's temperature, which should not at any time be allowed to rise above 102° F. Drugs he considered were at present employed in a most illogical manner. There was no sense in administering antipyretics in such a way as to keep a patient's temperature alternating between 98° and 106°. This course was anything but scientific, and if by the cold bath a uniform temperature of 102° could be assured, at least the comfort of the patient would be thereby promoted and complications prevented. Many patients came to the hospitals at a late stage of the disease with their hearts already enfeebled, their lungs not working well, and showing general symptoms of congestion, and of course it was not advisable to plunge such patients into cold water. His own practice was to employ in these cases the wet pack, and it always answered well. The sheet should be wet with water at about 55° to 60°, then wrung out, and during its application ice might be rubbed over it. The graduated bath he did not approve of; it was more troublesome to manage and more trying to the patient. Cold affusions were not advisable, in his opinion, as they gave too great a shock. The cold sponge-bath gave unsatisfactory results. It was a most unwise and reprehensible practice to apply cold in cases in which the internal temperature was high and the surface of the body cool.

Dr. A. A. SMITH said that he was a warm advocate of the

use of the bath, and it was his practice to employ it in typhoid cases in his service at Bellevue Hospital. He was grateful to the author of the paper for the suggestions thrown out as to the utility of hydrotherapeutic treatment for cases of the neurasthenic type. Hysteria, it had also been stated, was amenable to this line of treatment. When the speaker was an interne at Bellevue Hospital, acute hysteria, with convulsions or coma, was treated by filling a large syringe with cold water, armed with which, the doctor would stand at the foot of the bed and endeavor to direct a stream of water so as to hit the patient between the eyes. While this method was often effective he did not consider it hydrotherapy of the best kind, and he did not allow it to be practiced now. He had arrived at the conclusion that, underlying all these cases of hysteria, there existed some nerve disease which a conscientious physician could not afford to ignore. While not wishing to depreciate the value of the hydrotherapeutic treatment as a valuable adjunct in cases of neurasthenia, hysteria, and allied conditions, he thought that its use had been at present too limited to warrant the assumption that the method would certainly result in a cure.

Dr. M. PUTNAM JACOBI read the history of a case of typhoid fever which had come under her immediate notice at the New York Infirmary, and in which treatment by the bath had been systematically carried out. The patient was admitted on the eighth day of the illness. Baths were given from the day of admission until the thirty-second. The bath was administered whenever the temperature rose to  $103^{\circ}$  or over, and was for some time required about every three hours. The case was one of severe infection, for there were early and for a time violent delirium, very feeble and gaseous pulse, great prostration of strength, sordes and brown tongue as early as the eighth day, pulmonary congestion, small bed-sores, and immense destruction of blood-corpuscles, as shown by the large amount of coloring matter found in the urine by the sulphuric-acid test; finally, the high and persistent fever. The duration of the fever did not seem to be markedly lessened by the treatment, but its danger was removed by lessening its intensity and introducing incessant but not too profound remissions. On the second day of treatment the evening temperature was over  $106^{\circ}$  F., but never afterward. Though the fever lasted forty days, all serious symptoms disappeared within the first week, and no new ones appeared. The first bath was given at a temperature of  $70^{\circ}$  F., but was followed by temporary collapse and violent delirium. After this the temperature of the baths was  $80^{\circ}$ , then  $75^{\circ}$ , and of only five or ten minutes' duration, reaching finally fifteen minutes' duration. This method differed from that of Brand in its intensity, and possibly for that reason the reduction of temperature effected by each bath was not so marked as was stated by others—thus,  $2.5^{\circ}$  during the first week,  $3.1^{\circ}$  during the second, and about  $4^{\circ}$  the third week. As far as it went, this case tended to justify Dr. Baruch's assertion that the cold-bath method was to be considered as contrafebrile rather than antipyretic. It was a question whether repeated exposure of the nervous system to an extensive amount of temperature change could be practiced with impunity. It also seemed to the speaker that clinical evidence in favor of cold baths was far less for other fevers, especially the eruptive, than for typhoid. Possibly the fact that the skin and subcutaneous tissues, with their heat-regulating mechanisms, were involved in the eruptive fevers, might have something to do with this difference. Probably, also, the germs of different infectious diseases behaved quite differently toward different temperatures.

Dr. G. B. FOWLER said he was surprised to learn that the bath was not more universally in use. He had employed it ever since commencing practice. It was his custom to use it in scarlet fever, pneumonia, and the bronchitis of children. He expected

from it in such cases more than the mere reduction of temperature. He looked for it to act in a curative way, for by the radiation which it produced it would bring about changes in nutrition physiologically less violent than by the use of other remedies. The author of the paper had omitted the consideration of the therapeutic value of water as a beverage. In cases of fever the speaker held it as important that water should be given the patient to drink as that it should be applied externally. He always advised that these fever patients should be given access to plenty of water.

Dr. BARUCH, in the course of a brief reply, said that as to the curability of hysteria by the use of hydrotherapeutical methods—the feasibility of which Dr. Smith had expressed himself somewhat skeptical upon—he considered that, when he stated that patients of this type, who had been examined and pronounced incurable before admittance to the Montefiore Home, could be sent out benefited, he was adducing a pretty convincing proof that there was something in hydrotherapy, when added to other means which had already been tried.

#### NEW YORK ACADEMY OF MEDICINE.

##### SECTION IN SURGERY.

*Meeting of November 11, 1889.*

Dr. ROBERT ABBE in the Chair.

**Suture of the Quadriceps Femoris Tendon.**—Dr. W. T. BULL referred to a case which had been made the subject of a paper read before the Surgical Society last year, in which, after suturing the quadriceps tendon, the speaker could report recovery of the motions of the joint and a generally very satisfactory result. He regretted that the patient was not present, but thought it interesting to be able to complete the record begun by introducing another case of the same general character. He then presented a young man, aged seventeen, who, on the 29th of last April, was admitted to the New York Hospital with a cut across the knee received from a circular saw. The injury was three quarters of an inch above the patella, laying open the joint and denuding the internal condyle of the femur of its cartilage and severing the quadriceps femoris. A three-inch incision was made upward from the center of the wound, and the ends of the tendon were approximated and sutured with catgut. A drainage-tube was inserted and removed on the fourth day. The patient was up and around, with his limb in plaster of Paris, on the tenth day. He was discharged at the expiration of the fourth week, and the plaster dressing was removed three weeks later. Motion had gradually been restored to the joint, and at the present time the power of extension was normal, and there existed no interference with flexion. While in such accidents as the one just described there could be no doubt as to the propriety of suturing the tendons, in subcutaneous ruptures of the tendons some hesitation might be felt. His search for statistical and other information on the point had not enlightened him much; but the result obtained in his first case would lead him to attempt suture and not leave the repair to nature unaided. Though this question might not be of the same interest as had pertained to that of dealing with simple fracture of the patella, still the status of surgical procedures in the latter ease was pretty well fixed, while the best method of dealing with subcutaneous rupture of the quadriceps femoris was still open to settlement.

**Suture of the Ligamentum Patellæ.**—Dr. R. G. WIENER showed a patient whose tendon he had sutured at a point below the patella. The operation had been done in this case some five years ago by Dr. Sands at the Roosevelt Hospital, and with good results as to union and motion. In December last the

patient had fallen down stairs and had ruptured the tendon once more, when he came under the speaker's care at Charity Hospital in June last. The patella was found to be four inches above the joint, and the power of extension was entirely absent. On the 29th of June an incision nine inches in length was made, laying bare all the tissues down to the joint. No remains of the patellar tendon could be discovered. It was impossible to make the patella approach its proper relation to the joint, and the operator then divided the quadriceps-femoris tendon above the patella, and, after restoring the latter to its proper position, drilled both it and the tibia, and secured the patella to the latter with stout wire. The continuity of the tendon above was then restored by suture. After a lapse of two weeks, primary union was found to have resulted throughout.

The CHAIRMAN thought the case seemed to answer Dr. Bull's question as to the advisability of dealing with these subcutaneous ruptures by operation. Motion appeared to be fairly restored.

**Double Femoral Hernia in a Boy.**—Dr. MILLIKEN presented a case of double femoral hernia in a boy, explaining that the lesion was a rare one, being seldom observed in persons under twenty years of age.

**Colo-colostomy for Cancer.**—Dr. WILLY MEYER presented a female patient, thirty-four years of age, upon whom he had performed a colo-colostomy for irremovable cancerous growths causing stricture at the hepatic curvature of the large intestine. The operation had taken place at the German Hospital on July 22, 1888, and the case had been reported in detail in the "Medical Record" and "New York Medical Journal" of November 27, 1888. The speaker said that he would not recapitulate the details of the case further than to state that the artificial anastomosis between the transverse and ascending colon had been made without the use of Senn's bone plates—the only material recommended up to that time for use in this class of operation—but had been completed by a double row of continuous catgut suture. The patient had made a rapid recovery and had constantly improved since the operation, immediately previous to which she had weighed only one hundred and twelve pounds, while four months later she had weighed one hundred and fifty-five pounds. Her present weight was one hundred and fifty-one pounds. Twelve weeks after the date of the operation the patient had felt sufficiently strong and well to attend to cooking and general housework. At the end of February of the present year she had resumed her former position as stewardess in the service of the North German Lloyd Steamship Company. Since then she had made three trips from Breinen to Baltimore, visited England six times, and was now here after her third trip to New York, thus proving her ability to undertake quite heavy work. The patient had stated that her appetite was excellent and that she could with impunity partake of any kind of food except green vegetables and salads. She also had a normally formed passage from the bowels daily, and this without the use of cathartics or enemata. Only occasionally pain was present on the right side of the abdomen. Though no microscopic examination of the growth had been made, the speaker considered the diagnosis of cancer as beyond question. There was at the present time a distinct, uneven growth in the right hypochondriac region which was painful on pressure, also still the long, hard cord running parallel to Poupart's ligament, an infiltrated carcinomatous ligamentum coli. Furthermore, there was now an unevenly indurated inguinal gland on the right side which the patient stated had been of only half its present size eight months ago. The speaker apologized for presenting the same patient to a meeting of surgeons for the second time. He thought his possible justification lay in the fact that it was the first ease, so far as he could ascertain from investigation into

the literature of the subject, in which an artificial anastomosis between two different regions of the colon had been successfully established. He also deemed the continuous general improvement in the health of a patient afflicted with cancer of the gut not admitting of removal a matter of sufficient interest to lay before the Section.

Dr. BULL asked why, in consideration of the condition of the patient at present, it would not be proper to entertain the idea of removing the growth. He asked this question without being familiar with the previous history of the case.

Dr. MEYER replied that he would certainly have removed the growth at the time of the first operation, but it was seen that the whole of the ascending colon was studded with the carcinomatous infiltration and he would have had to cut it entirely away, as well as part of the transverse colon. He had not thought it wise to subject the patient to any more formidable operation, and so had only stitched the portions of the colon together.

**Carcinoma of the Neck.**—Dr. F. S. DENNIS presented a patient from whose neck he had three weeks before removed a vascular sarcoma of fifteen years' standing. This latter fact he said was the point of interest, as, of course, sarcomatous growths in any other region were very malignant. Some slight hardness was to be made out about the parotid gland, but he did not think that in so short a time it indicated any return of the growth. The tumor was situated beneath the parotid and reached to the base of the skull, and was of about the size of a child's head.

**Suppurative Articular Rheumatism.**—The speaker then showed a case which he said was quite rare. The patient had been brought into the hospital suffering from acute articular rheumatism, upon which condition suppuration of the knee joint had supervened. The pus formation had been ushered in by repeated intercurrent chills and a temperature of 103° F. The speaker had opened the joint in several places, giving perfect drainage at three points and affording opportunity for thorough irrigation. The case was interesting, because it was seldom that, after a joint had been opened for acute inflammation, so good a result followed. A quart of pus had been taken from the joint.

**Paralysis of the Arm after Subluxation of the Humerus.**—Dr. DENNIS then presented the case of a boy who had last summer fallen from a horse. The patient had been supposed to have sustained a dislocation of the head of the humerus, which had been reduced. At the present time there existed complete paralysis of the arm and subluxation of the shoulder joint. The question at issue seemed to be as to whether the paralysis was due to laceration of the brachial plexus or to a fracture which, in process of union, had involved the nerves in the new formation. Sensation was unimpaired at the back of the arm, but was lost on the fore part. The speaker proposed to cut down and open the joint and dissect down to the plexus, and unite any divided ends he might find torn.

Dr. F. KAMMERER inquired if any histological diagnosis had been made in the case of sarcoma of the neck, because he had had several such cases in which he had done extensive operations. He had always considered them more malignant than bone sarcomata.

Dr. S. D. POWELL thought that the boy's case was one of atrophy of the deltoid with relaxation of the capsular ligament to which was due the slipping down of the head of the humerus. He did not think the head of the bone really left the glenoid cavity.

Dr. A. G. GERSTER had seen paralysis of the nerves composing the brachial plexus followed by dislocation of the shoulder joint in fractures of the humerus which took place in the

vicinity of the joint. He recollects four cases, in all of which the paralysis had resulted from traumatism. In all these cases function had been restored in time. In the case of a boy who had sustained a fracture of the neck of the scapula, function had returned, although the paralysis had persisted for a year and a quarter. The fracture, however, was still present and could yet be demonstrated. He therefore deemed it better to wait and subject these patients to treatment calculated to restore function. Suturing of the nerves could be done a long time after the initial injury with every prospect of success. In the matter of the knee-joint case presented by Dr. Dennis, with a history of acute articular rheumatism, it had occurred to the speaker that it might have been one of infectious osteomyelitis. The fact of an abscess being found in the leg seemed to indicate this. It was extremely rare to find pus in joints affected by acute articular rheumatism.

DR. DENNIS explained that the case had been referred to his service at Bellevue Hospital from the medical side, where he believed the diagnosis had been made in the service of Dr. Janeway.

Dr. R. F. WEIR said that Dr. Dennis seemed to have got a very good result—better, in fact, than was customary at the hands of himself and many of his colleagues. Mr. Treves had suggested and practiced thorough and continuous irrigation of the joint in these cases, water being allowed to flow through the joint for a number of days—in one instance for twenty-seven days. This washed out the pus as it formed.

Dr. DENNIS stated that he had at present a case of chronic arthritis in which the tubes through the open joint were flushed out from day to day. In the case he had presented he had not supposed for a moment that the man would get well, but the operation seemed the only chance indicated.

The CHAIRMAN thought the case of dislocation one of special interest. Such paralyses were generally considered as due to laceration of what had been termed by Erb the fifth root group, and as occurring near the transverse processes, and corresponded to paralyses in infants resulting from pressure of this root, due to forceps injury or cramped position *in utero*. If the boy's weight had been directed to the shoulder when the accident happened, it seemed that the various nerve roots would have been torn higher up, and that there the lesion would have to be looked for.

**Cancer of the Rectum; Removal of the Coccyx and Part of the Sacrum for Extirpation of the Growth.**—Dr. GERSTER presented a Hebrew laborer upon whom he had made an excision of the rectum for cancerous growth. The man had suffered for some six months before admission to the hospital from difficulty at stool. When admitted he was somewhat emaciated and cachectic. Examination had revealed a rather irregular nodular tumor, occupying the lower portion of the rectum and situated as high as the finger could reach. The growth sent out a finger-like extension to the margin of the anus, involving at that point the sphincter. Careful exploration under anaesthesia showed no involvement of the glands, but small portions of the tumor removed for microscopical examination showed it to be a glandular cancer. The point in the case was that, in operating, he had adopted the plan of removing, in addition to the coccyx, as was the custom, a large portion of the sacrum. It was well known to operators that the removal of growths occupying this part of the pelvis was a procedure fraught with considerable difficulty by reason of the lack of space. This was particularly so in men, in whom the pelvis was narrower than in women. The vessels retracted as soon as they were cut, and there was great danger from uncontrollable hemorrhage. Then, whenever the operation extended high up, the peritoneum was necessarily included, and, as long as the surgeon was unable to recognize

when he wounded it, infection was likely to result. But, if everything was clear and the necessary precautions could be taken, this danger was reduced to a minimum, as the wounded peritoneum could be closed, and the operation and subsequent treatment be conducted extraperitoneally. He considered the suggestion of the removal of such a sufficiently large portion of the sacrum as would enable the surgeon to know exactly what he was doing a very important improvement in this operation. He believed the method feasible, not only in cancerous growths of the rectum, but also in those of the uterus, and for such inflammatory processes between the rectum and bladder as perforated the latter viscera and could not be reached in any other way. It would also be noticed that he had succeeded in giving his patient a practicable sphincter, which enabled him to retain soft faeces.

**Fractures of the Base of the Skull.**—Dr. DENNIS then read a paper on this subject. He considered that the treatment of fractures of the base of the skull ought to be governed by the same careful technique as was followed in the more modern operations. Though the injury was generally regarded as uniformly fatal, and all the text-books agreed as to the mortality point, still he believed such fractures to be amenable to surgical treatment, and considered that the great majority of patients so injured died from causes which could be wholly prevented by the surgeon. There were, he continued, three varieties of fractures of the base of the skull—those in the anterior fossa, in the middle and posterior fossae, and in the posterior fossa. Three symptoms were characteristic of these fractures, and these were haemorrhage, the escape of cerebro-spinal fluid, and coma. Though these symptoms were not severally of sufficient import to determine a diagnosis, yet, when found together, they constituted the essentials for an absolute diagnosis of basal fracture. In cases where the membrana tympani was not ruptured and the characteristic bleeding from the ear or nose was absent, the blood might find its way to the stomach, and then the first intimation of the haemorrhage going on from the brain would be the haematemesis. Then, even when bleeding did occur from the ear, it was not a reliable diagnostic point, as it might be simply the direct result of a lacerated membrana tympani, or occur from the soft tissues in the canal. The cerebro-spinal fluid usually found its way from the brain through the transverse fissure in the petrous portion of the temporal bone and a tear in the arachnoid membrane. The discovery of shreds of brain-substance in any fluid discharged from the ear rendered the diagnosis absolute. Coma was present, in a greater or less degree, according to the severity or situation of the lesion, and careful observation and consideration of the physiological disturbances would determine approximately the extent to which the lesion was affecting each nerve.

Fractures at the base of the skull should be considered in the same category as those of the vertex or of long bones, and, this admitted, they should be treated on the general principles of aseptic surgery, and with the same attention to detail and technique as was given to other fractures. The patient should be removed to a room specially prepared, and isolated from such septic influences as would be present in the operating-room of a hospital. The scalp should be shaved and thoroughly washed with soap and water, and irrigated with a 1-to-500 bichloride solution. The external auditory canals and nasal passages should also be thoroughly cleansed and irrigated, and these canals protected from the entrance of septic germs by plugging with iodoform gauze and absorbent cotton. In ordinary fractures of the base there would be rupture of the membrana tympani and discharges from the auditory canal; but if the membrane was not ruptured it would be found distended by the accumulation behind, and it might in such event be wise to puncture it and

allow the escape of the blood and cerebro-spinal fluid. For the purpose of further insuring such patients against the possibility of infection, the speaker recommended the wearing of a specially constructed cap of bichloride gauze or carbolized absorbent cotton. This cap should cover the entire head and protect everything. These cases too often ended fatally from causes which could be prevented by the surgeon—such as basilar meningitis, cerebral abscess, pyæmia, suppuration in the petrous portion of the temporal bone, leptomeningitis, and other complications. He further suggested that all cases of injury about the head, associated with haemorrhage, should be treated with antiseptic precautions. The speaker then presented a young man who had recovered from fracture at the base of the skull. This patient had struck his head upon a rail in falling from the top of a car. The symptoms were haemorrhage from the ears, nose, and mouth, coma, and stertorous breathing. The day following the injury the patient had to be tied in bed. There was also discharge of cerebro-spinal fluid from both ears, which had continued for two weeks, and the life of the patient had also been threatened by a severe glossitis. The patient had received such treatment as was generally indicated in the speaker's paper, the discharge being kept perfectly aseptic, and in one month from the injury had left the hospital, and at the present time was in good health and able to work as well as ever.

Dr. WEIR said that in fractures of the anterior portion of the base of the skull it was generally recognized that the prognosis was the most encouraging, in those occurring in the middle portion less so, while those of the middle and posterior or posterior fossæ alone were the most serious. So far as his memory served him he could not, however, recollect that the fatality in these injuries had resulted specially from septic complication. That the patients had died from haemorrhage, or the presence of the resultant clot, had been demonstrated at the post-mortem examinations in many instances. When these cases did not terminate thus primarily from haemorrhage, and the patients lasted for twenty-four or forty-eight hours, there was reason to hope they would be able to contend against the inflammatory processes and to feel reliance that they would come through without permanent damage. In the New York Hospital it was the custom to wash out and plug the ears with iodoform packing. He did not think they had resorted to the use of the cap. He had endeavored at one time to render the nasal cavity aseptic, but, on reflecting that the air was coming from behind and that he could not wash out the nose, and that any fluids passed into the nostrils would not reach up any distance, he had abandoned the procedure.

Dr. GERSTER said he was fully in accord with Dr. Dennis as to the importance of cleanliness in these cases of fracture. The author of the paper had, however, spoken of bone fractures in general by way of comparison, but the speaker thought that it should be remembered that many of these fractures did not communicate with the open air, and such simple fractures possessed the best of antisepsis in their surroundings. In basal fractures of the skull, where no channel of communication existed with the air, such rigid precautions were not indicated. There were basal injuries which were not bone fractures but which yet led to bone suppuration or osteomyelitis. Still he was of opinion that many cases of meningitis could be traced to neglect of such precautions as might ward off suppuration.

Dr. J. A. WYETH said he thought the question of drainage in this class of fractures worthy of more special consideration. It went without saying that every modern surgeon recognized and accepted the desirability of rendering aseptic any wound tissue, whether at the base of the skull or the base of the heel. In a very severe case, reported by a recent writer, in which the fracture at the base was complicated by compound fracture of

the frontal bone, the very courageous surgeon, knowing he could not hope to clean out the immense wound, had bored through the horizontal plate of the ethmoid bone and drained by means of a tube passed up the nose and through the perforated ethmoid plate. By thus establishing a perfect drainage the surgeon had saved the patient's life. Such methods might be applicable for drainage of the posterior fossæ.

Some further discussion ensued, followed by a brief reply from Dr. Dennis.

Dr. KAMMERER then reported a case of operation on a sarcoma of the dura mater and ligature of the longitudinal sinus.

## Book Notices.

*Diphtheria: its Nature and Treatment.* By C. E. BILLINGTON, M. D. And Intubation in Croup and other Acute and Chronic Forms of Stenosis of the Larynx. By JOSEPH O'Dwyer, M. D. New York: William Wood & Co., 1889. Pp. iv-326. [Price, \$2.50.]

The chief object of the first part of this excellent work is to enlarge and develop the author's views on diphtheria as briefly expressed in his previous writings on the subject, and to review the more recent methods of its therapeutics. He gives a brief but important summary of the history of this disease, both before and after the time of Bretonneau, whose investigations placed diphtheria in the definite place it occupies to-day in nosology.

The chapter on aetiology is a comprehensive résumé of our present knowledge on the subject and is full of instruction. It is not so much a discussion of the opinions of other authors as it is a series of abstracts of their researches. What will interest the reader is the able exposition of the present status of bacteriological investigation regarding the cause of this disease. The positive data touching the two varieties of germs found in diphtheria, resulting from the works of Oertel, Klebs, Löfller, Roux, and Yersin, are clearly enunciated and constitute the most recent progress in this direction.

After devoting twenty-two pages to the pathology of the affection, the author reviews its symptoms as evoked by the numerous localizations of the diseased area—in the respiratory tract from the nasal passages to the alveoli of the lungs, in the digestive tract from the lips to the anus, in the genito-urinary organs, and on the skin. This part of the work is the least satisfactory, but it is completed and amplified by a very excellent chapter on diagnosis, rendered still more practical and instructive by fine lithographic plates from drawings by Dr. Henry Macdonald, which give a fair representation of the diphtheritic patches as seen on the palate and the tonsils of the living patient. But what constitutes the best feature of this work is the complete and painstaking manner in which the most important portion of all is written—that concerning the treatment. The author deserves great credit for his systematic and separate description both of the different modes of employing remedies in this disease and of the multitudinous substances which have been and are still administered. He treats of caustics, astringents, agents for the destruction of false membrane, solvents of false membrane, and, above all, antiseptics, of which the description and the directions for employing them cover forty of the one hundred and fifteen pages devoted to treatment. The author gives his own method of treatment, including that of nasal and of laryngeal diphtheria, and adds a sufficient description of tracheotomy, with cuts of the instruments used.

The last forty pages are written by Dr. O'Dwyer, who here summarizes his previous writings on intubation, an operation which he has perfected and which is already well known by the profession. He describes the instruments and the operation in full and shows its advantages. We know of no book more practical and satisfactory to the practitioner who has to treat diphtheria than this one.

## GENERAL LITERARY NOTES.

AMONG recent foreign publications we note the following:

F. ALCAN, Paris.—L. Landouzy, "De la mortalité parisienne du premier âge (enfants de un jour à deux ans)." — Lardier, "Hygiène publique. De l'isolement et de la désinfection dans la rougeole." — Macario, "Manuel d'hydrothérapie." (2fr. 50.) — Charles Ferré, "Du traitement des aliénés dans les familles." (2fr. 50.)

J. B. BAILLIÈRE, Paris.—L. Raphael, "Diphthérie et choléra." (4fr.) — Nothnagel and Rossbach, "Nouveaux éléments de matière médicale et thérapeutique." Translated from the German by J. Alquier. 1 vol. (16fr.) — A. Collineau, "L'hygiène à l'école." (3fr. 50.)

BUREAUX DU PROGRÈS MÉDICAL, Paris.—Bourneville and Rousselet, "Manuel de l'assistance publique à Paris." (0.30c.) — E. Huet, "De la chorée échrorique." (5fr.) — L. Minor, "Contribution à l'étude de l'étiologie du tabes." (2fr.) — Parinaud, "Compte rendu du service ophthalmologique pour l'année 1888." (1fr.) — B. Narich, "Proposition d'un nouvel embryotome rachidien avec treize expériences à l'appui." (1fr. 50.) — P. Philippe, "Traitement des anévrismes par l'introduction de corps étrangers dans la poche anévrismale." (1fr.)

A. Coccoz, Paris.—A. Weber, "Traitement par l'électricité et le massage." (5fr.)

O. DOIX, Paris.—A. Dufour, "Contribution à l'étude des auto-intoxications, des manifestations morbides du surmenage physique." (3fr.) — M. Natier, "Fièvre des foins. Pathogénie et traitement." (3fr.) — J. Chopin, "Élimination de l'acide salicylique suivant les divers états des reins." (2fr.) — F. Raymond, "L'étude des maladies du système nerveux en Russie." (3fr.) — Joal, "Étude étiologique sur l'œsophagisme." — P. Morot, "De la congestion du foie, esquisse de semiologie clinique." — L. Testut, "Traité d'anatomie humaine." (16fr.)

GAULHIER, Nice.—Berlin, "Le lavage de la vessie par la voie sus-pubienne, comme complément de la fonction evacuatrice."

GONNOUILHON, Bordeaux.—G. Morice, "Considérations générales sur la résorciné. Son action sur les surfaces ulcérées et le lupus en particulier."

LECRONIER & BABÉ, Paris.—J. A. Fost, "Nouveaux faits confirmant l'efficacité de l'électrolyse linéaire dans le traitement des rétrécissements de l'urètre." — A. Bordier, "Bibliothèque anthropologique." Vol. X. (8fr.) — Thomas, "Dictionnaire abrégé des sciences médicales." (7fr.) — G. Martin, "Étiologie de la myopie." (1fr.) — "L'Année médicale." Eleventh year. (4fr.) Vols. I to X. (16fr.) — L. de Wecker and J. Masselon, "Manuel d'ophthalmologie." (29 fr.)

HENRY OLLIER, Paris.—A. Cabanès, "De l'emploi de l'hydrastis canadensis en médecine."

SAGNOL PÈRE, Paris.—J. Sagnol, "L'Égalité des sexes."

CHARLES SCHUCHARDT, Geneva.—P. Glatz, "Des dyspepsies avec suppression de la sécrétion du suc gastrique et plus particulièrement de la dyspepsie neurasthénique."

BERGMANN, Wiesbaden.—O. Leichtenstern, "Zur Pathologie des Illeus."

BREITKOPF & HÄRTEL, Leipzig.—A. P. J. Dose, "Zur Kenntniss der Gesundheitsverhältnisse des Marschlandes." — Heinrich Fritsch, "Sechzig Fälle von Laparotomyomotomie." "Volkmann's Sammlung," No. 339. (0.75M.) — Leopold Landau, "Diagnose und Therapie des Gebärmutterkrebses." "Volkmann's Sammlung," 338. (0.75M.)

HERMANN COSTENOBLE, Jena.—H. Hirschberg, "Der Zucker als Nahrungs- und Heilmittel."

ENKE, Stuttgart.—Rafaël Coën, "Das Stotterübel." — P. Müller, "Handbuch der Geburtshilfe." Vol. III.

FISCHER, Berlin.—Euge Hahn, "Behandlung des Genu valgum und varum." (0.60M.) — Arthur Hartmann, "Die Krankheiten des Ohres." 4th ed.

GUSTAV FOCK, Leipzig.—Karl Gumpertz, "Zur Kenntniss des Lippenkarzinoms." (1M.)

IEUSER, Neuwied.—W. Brügelmann, "Ueber den Hypnotismus." (0.75M.) — Eugen Grätzer, "Medizinische Uebungsbücher." I. "Krankheitstypen der inneren Medizin." (2.40M.)

HIRSCHWALD, Berlin.—Oskar Israel, "Praktikum der pathologischen Histologie."

MORITZ PERLES, Vienna.—T. Kitz, "Bakteriologische und pathologisch-histologische Uebungen für Thierärzte." (7M.)

SCHUMACHER, Berlin.—C. Posner, "Ueber Propeptonurie. Zugleich ein Beitrag zur Chemie des Samens." — E. Senger, "Ueber die Einwirkungen unserer Wundmittel auf den menschlichen Organismus und über ihre Leistungsfähigkeit."

J. SPRINGER, Berlin.—S. Rosenberg, "Ueber die Wirkung des Pernbalsams auf die idiopathischen Leukoplakien und sonstigen Epitheltrübungen der Mundschleimhaut."

G. THIENNE, Leipzig.—W. D. Miller, "Die Mikroorganismen der Mundhöhle." (18fr.)

URBAN & SCHWARZENBERG, Vienna.—San-Rat Gijurkovechky, "Pathologie und Therapie der männlichen Impotenz." — Julius Hochenegger, "Jahresbericht der chirurgischen Klinik des Hofraths Prof. Albert." — R. von Jakob, "Klinische Diagnostik." 2d edit. — H. Eichhorst, "Handbuch der speziellen Pathologie und Therapie für praktische Aerzte und Studirende." Vol. I. "Krankheiten des Cirkulations- und Respirations-Apparates." 4th edit. (2M.)

F. C. W. VOGEL, Leipzig.—F. A. Hoffmann, "Vorlesungen über allgemeine Therapie." 2d edit. (10M.)

K. J. WEYSS, Berne.—Theodor Kocher, "Vorkommen und Vertheilung des Kropfes in Kanton Bern." (1.60M.)

BIZZONI, Pavia.—B. Vittorio, "Sulla sensibilità della periferia della retina per la luce e per gli colori in occhi normali ed in alcuni casi patologici."

FRATELLI CENTENARI, Rome.—P. Canalis and E. di Mattei, "Contribuzione alla studia della influenza della putrefazione sui germi del colera e del tifo."

G. CIVELLI, Milan.—Pietro Canalis, "Sulla disinfestazione dei carri."

FERRARI, Venice.—V. Tecchio, "La vena d'oro nel quadriennio 1884-88."

LE MONNIER, Florence.—G. Palichi, "Il bacillo dello scheurlen e un saprofita della pella."

A. Tocco & Co., Naples.—A. Zuccarelli, "Inversione congenita dell'istinto sessuale in due donne."

E. CUESTA, Madrid.—Vinals y Tornero, "Programa de obstetricia práctica."

FOMENTO, Mexico.—S. M. Pereira, "Cartilla de hygiene para diminuir la mortalidad en los niños."

G. JUSTE, Madrid.—P. Gomez de la Mata, "Terapéutica moderna de la tisis pulmonar; estudio y descripción de los tratamientos recomendados en los últimos años."

## BOOKS AND PAMPHLETS RECEIVED.

The Honors of the Empire State in the War of the Rebellion. By Thomas S. Townsend, Compiler of the "Library of National Records." New York: A. Lovell & Co., 1889. Pp. vi-11 to 416. [Price, \$2.50.]

Foods for the Fat: a Treatise on Corpulence and a Dietary for its Cure. By Nathaniel Edward Davies, Member of the Royal College of Surgeons, England. American Edition. Edited by Charles W. Greene, A. M., M. D. Philadelphia: J. B. Lippincott Company, 1889. Pp. vii-9 to 138. [Price, 75 cents.]

Annual Report of the Health Department of the City and County of San Francisco. For the Fiscal Year ending June 30, 1889.

Report of the Committee on Dental Practice. By M. L. Rhein, M. D., D. D. S., New York. [Reprinted from the "Dental Review."]

Chloride of Methyl. By M. L. Rhein, M. D., D. D. S., New York. [Reprinted from the "Dental Review."]

Enteralgia and Chronic Peritonitis. By A. Jacobi, of New York. [Reprinted from the "Transactions of the Medical Society of Virginia."]

Manual of Drill of the Ambulance Detachment. For the Provisional Use of the Hospital Corps and Company Bearers of the United States Army. By William D. Dietz, Captain and Assistant Surgeon, U. S. Army.

On the Treatment of the So-called Perityphlitic Abscess. By Robert F. Weir, M. D., Surgeon to the New York Hospital, etc. [Reprinted from the "Transactions of the New York State Medical Society."]

Some of the Limitations of Medicine. By Stephen S. Burt, M. D., Professor of Clinical Medicine and Physical Diagnosis, New York Post-graduate Medical School and Hospital. [Reprinted from the "Popular Science Monthly."]

Lehrbuch der allgemeinen und speciellen pathologischen Anatomie für Aerzte und Studirende. Von Dr. Ernst Ziegler, Professor der pathologischen Anatomie und der allgemeinen Pathologie an der Universität Freiburg in Baden. Zwei Bände. Sechste verbesserte und theilweise neu bearbeitete Auflage. Erster Band. Allgemeine pathologische Anatomie und Pathogenese. Mit 343 theils schwarzen, theils farbigen Abbildungen und einer Tafel in Chromolithographie. Jena: Gustav Fischer, 1889. Pp. xiv-567.

Egypt as a Winter Resort. By F. M. Sandwith, F. R. G. S., formerly Vice-Director of the Sanitary Department of Egypt. London: Kegan Paul, Trench, & Co., 1889. Pp. vi-153. [Price, 3s. 6d.]

Description of a Case of Embolism of the Left Central Retinal Artery. By Charles A. Oliver, M. D., of Philadelphia. [Reprinted from the "Transactions of the American Ophthalmological Society."]

A Treatise on Diseases of the Nose and Throat, in Two Volumes. By Francke Huntington Bosworth, A. M., M. D., Professor of Diseases of the Throat in Bellevue Hospital Medical College, New York, etc. Volume One. Diseases of the Nose and Naso-pharynx. With 4 Colored Plates and 182 Woodcuts. New York: William Wood & Company, 1889. Pp. xviii-3 to 670.

## Miscellany.

**Sore Nipples.**—Dr. J. Elliott Langstaff, of Brooklyn, writes to us as follows: "If the following sentence, 'a sore nipple causes great pain when the child nurses,' which occurs in a very valuable 'System of Obstetrics,' were reversed, it would approach my experience with this important disease. I have found that great pain when the child nurses is generally followed by inflammation, excoriation, fissure, and sometimes mastitis. This pain, which is the first symptom of sore nipple, is caused by the sudden tension on the lactiferous ducts produced by the child each time it begins to nurse. Until the nipple is elongated sufficiently to fill the child's mouth and allow it to swallow without losing its hold, there is a constant jerking, with friction between the tongue and nipple. Acting on this theory, I have directed the mother or nurse to manipulate the nipple and areola between the thumb and two fingers, using vaseline and drawing gently outward for about a minute. The child is then put to the breast and nurses quietly, saving the mother that agonizing pain which is generally experienced in the case of a short nipple. I have yet to hear of a case where pain has not been relieved by this method, and I have seen deep fissures heal in a few days after this relief from pain. If mothers were treated for retracted nipple immediately after each confinement, there would be very few cases of sore nipple, and as long as the women of the present day will not recognize the evil effects of the corset, there will exist this condition of short nipple."

The North Texas Medical Association will meet in Gainesville on Tuesday, Wednesday, and Thursday, December 10th, 11th, and 12th, under the presidency of Dr. J. T. Wilson, of Sherman. The programme includes the following titles:

"Exophthalmic Goitre," by Dr. T. M. Taylor, of Sherman; "Valvular Lesions of the Heart," by Dr. M. C. McBride, of Lebanon; "Acute Articular Rheumatism," by Dr. J. D. Bedford, of Ilione Grove; "Puerperal Fever," by Dr. O. H. Caldwell, of Dodds; "The Diagnosis and Treatment of Pelvic Cellulitis," by Dr. J. E. Gilcrest, of Gainesville; "The Most Desirable Position for a Woman in Labor," by Dr. Alonzo Sims, of McKinney; "Traumatic Cataraet," by Dr. R. H. Chilton, of Dallas; "The Indications in the Surgery of the Larynx and Trachea," by Dr. E. W. Rush, of Paris; "Surgical Cases, including two Cases of Laparotomy," by Dr. J. M. Inge, of Denton; "A New Artificial Drum Membrane," by Dr. H. N. Spencer, of St. Louis; "Herpes Progenitalis," by Dr. G. Frank Lydston, of Chicago, Ill.; "Extirpation of the Ileocecal Junction," by Dr. J. F. Hooks, of Paris; and "Cerebrospinal Meningitis," by Dr. S. D. Moore, of Van Alstyne.

## ANSWERS TO CORRESPONDENTS.

No. 299.—By evaporation on a water-bath.

No. 300.—1. We have not been able to ascertain. 2. Registration of the diploma at the County Clerk's office.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

## Lectures and Addresses.

### THE CARTWRIGHT LECTURES

ON

### VITAL AND MEDICAL STATISTICS.

DELIVERED BEFORE THE ALUMNI ASSOCIATION OF  
THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK,

November 14, 20, and 22, 1889.

BY JOHN S. BILLINGS, M. D., LL. D., D. C. L.,  
U. S. ARMY.

#### LECTURE II (ABSTRACT).

THE term "expectation of life" is used by different writers in different senses, and hence has often given rise to confusion and misunderstanding. It should be used only in the sense of the mean after-lifetime—that is, the average number of years which persons at any given age in a given place may expect to live. In a stationary population, where there is no migration, and where the births are exactly equal in number to the deaths, the expectation of life at any age would be found by dividing the sum of the number of years which the whole population lived after that age by the number actually living at that age.

The term "expectation of life" is often confused with the "probable duration of life," which is the age at which a certain number of new-born children will be reduced one half, so that for any one of these children it is an equal chance as to whether it will die before or after that age. The difference between the probable duration of life and the expectation of life may be understood from the following example: Suppose that of 100 children born, 30 live one year, 20 live five years, 30 live forty years, and 20 live sixty years. Then the probable duration of life is five years, because at the end of five years just one half of these children will be dead, so that at the beginning it is an even chance for any one child as to whether it will die before or after the age of five years; but the expectation of life of any one of these children is 25.3 years, because these 100 children will in all live 25,300 years of life. In like manner, if ten of these children were to die at the end of every five years, the probable duration of life would be 25 years, and the expectation of life would be 27.5.

Another phrase sometimes used in vital statistics is "specific intensity of life." This is the quotient of the dividend of the number of persons living at any age by the number dying at that age—that is  $\frac{Px}{Dx}$ , being the reverse of the ordinary mortality ratio.

The chief source of error in an approximate life table, constructed directly from the census figures and a registration of deaths without correction or adjustment, is due to the fact that there is a very considerable error in the number given of the living population in the first six or seven years of life. Usually the census figures show that the number of children two years old is greater than the number one year old, and that the number four years old is greater than the number two years old, owing to a tendency

to erroneously report a child as being older than it is. If we undertake to adjust or correct these figures so as to truly represent the number living at each year, we usually have to make some assumptions as to the law governing the mortality, or as to what is sometimes called the law of life. This expression, the law of life, refers to the hypothesis that variations in mortality at successive ages take place in a regular succession which may be geometrically represented by a curve, and that, therefore, if we know the mortality at certain ages in a given community, we can, if we know this curve and if the number of observations were sufficient, deduce the mortality at other ages. Numerous formulae have been proposed for this purpose, from that of De Moivre, in 1727, which is  $Y = 86 - x$  ( $x$  being the age and  $Y$  the corresponding number of the living), to the latest and most generally accepted formula of Gompertz, as modified by Mr. Makeham. This last is based on the assumption that a person's power of resisting death decreases as his years increase, so that at the end of infinitely small periods of time he loses infinitely small portions of his remaining power to resist destruction, death being considered as the consequence of two generally coexisting causes—the one a progressive, necessary deterioration; the other, chance.

Calculations and corrections based on such formulae as these give interesting results and are useful to life insurance work, but they are unnecessary for the purposes of the sanitary statistician. Even the fundamental hypothesis upon which Gompertz's law is based—that the proportion of deaths at a given age is constant—is always untrue for any given age, as the prevalence of infections and contagious diseases of various kinds, and of various lethality, varies with different years, and for this reason it is desirable to have the records of deaths for a considerable period of time, at least three years, and better ten to twenty years, in order to correct these variations.

The most useful life tables for sanitary purposes are those which relate to certain circumscribed localities, such as a single city, or even a single ward of a city; but for scientific and medical purposes the most useful are those which relate to particular classes of people, particular occupations, etc. There is a special difficulty in preparing an accurate life table for a city, due to the effect of migration into and out of the city from and to the surrounding country, which disturbs very much the rates of death at different ages. The mortality in a great city is almost always reported as less than that which the actually existing causes of death and disease tend to produce, because domestic servants, shop girls, and others who have come from the country, go back to their rural homes when their health begins to fail after a year or two of city life, and there die. This is especially the case in regard to deaths from consumption and diseases of that class. The groups of ages which are thus specially affected are those between fifteen and twenty-five years, and therefore the mortality at this group of ages in the large cities as calculated from the number of deaths is too small to properly represent the causes of death acting on the population at those ages. On the other hand, the mortality at the same ages in the rural

districts near the city will be correspondingly unduly increased.

The data necessary for the construction of life tables are comparatively rarely available for the purposes of the sanitarian. Hence, while admitting that these furnish the only true measure of public health, registrars of vital statistics and sanitarians have sought for other standards for such measurement, the data for which could be more readily obtained and more easily applied. Especially has the search been made for some means of measuring sanitary conditions and progress from the data furnished by deaths alone without reference to population. One of the most common of these is the use of the period of infancy from nothing to five years, by comparing the number of deaths at this period with the total number of deaths. It is very certain that the period of infancy gives the most sensitive test of sanitary conditions, but the comparison must be made, not with the total number of deaths at all ages, but with the number of the living population furnishing such deaths.

In Europe it is more common to confine the calculation to children under one year of age, and these are much more valuable there than they would be in this country, because they have there a much more complete registration of births, and therefore the relation between the number of infants born and dying within the first year of life can be ascertained with an exactness which is quite out of the question in this country.

The test of sanitary condition which is most generally employed in this country is the proportion of the number of deaths which occur in children under five years of age to the whole number of deaths reported. This does fairly well in computing the rates of the same city, in which it may be presumed that the general ratio of age distribution is nearly uniform at different times, but it is a very fallacious method of comparing rates of different cities or localities. For example, during the last census year the ratio of deaths under five years per 1,000 of total deaths was, in Alabama, 475·9 for males; in California, 250; but in Alabama the proportion of male children under five years to the total population is 17·5 per cent., while in California it is only 9·1, or but little over half the Alabama ratio, and hence the true rate is actually higher in California than it is in Alabama, although the figures would indicate the reverse.

Another test which has been proposed is that of the mean age at death, which is the quotient of the sum of the ages of different individuals at death divided by the total number of deaths. This is only useful in comparing the conditions of two populations when the age and sex constitutions of these populations are the same. It is out of the question to apply the test to different occupations—as, for example, to compare the mean age at death of major-generals with that of second lieutenants. The chief use of this test is in its application to different causes of death, but even for this purpose the death-rate in relation to population is much better.

A considerable part of the errors to which one is liable in comparing the mean age of different occupations at death may be avoided by excluding from the computation all deaths of children under five years of age.

Although the expectation of life, or mean after-lifetime, is the standard of comparison almost universally accepted by statisticians, it is, in some respects, not a very satisfactory one, since it is often misunderstood by the public, which is apt to use the word "mean" in the sense of usual or ordinary, that which occurs most frequently. But the ordinary lifetime, or, as Bertillon calls it, the *vie normal*, is a very different matter.

The great majority of the mortality statistics prior to the present century are necessarily incorrect and unreliable, because they are based, for the most part, on the data of deaths alone. The deaths can only be taken as a measure of probable duration of life for any community when the births and deaths are equal and there is no migration, a state of matters which must very rarely happen and be of very brief existence.

Among the many expedients which used to be employed for estimating population was that of multiplying the number of living in which one death was supposed to occur by the number of deaths. That is to say, by guessing at a factor which could only be ascertained by comparing the annual deaths with the number living. Take, for example, the estimates of the population in London made by Graunt, in 1662, on the basis of one death occurring out of every thirty-two living, which made the population to be 403,000. In 1683, Petty, taking the mortality to be one to thirty persons living, made the population to be 669,930.

It may, perhaps, be asked why it is, if the nature of the data which are required to make mortality statistics reliable and satisfactory is so well known, that more of them are not provided by the municipal and state officers charged with the registration of vital statistics. For example, New York city has a very perfect system of registration of deaths, which is in competent hands and is well executed. Why, then, has New York city published no separate mortality report since 1883; and why, in the reports which it has published, does it not give the data with minuteness of grouping, so that we might know the number of deaths at each age, of each sex, and of each race and occupation, in each ward, from each cause of death, instead of giving, as it gave in its last report, the number of deaths from each, of a few causes of death for each, of a few groups of ages, and separately for each sex, and for natives of the United States, natives of foreign countries and colored; to which is added a statement of the deaths from zymotic diseases in each ward?

In order to understand the answer to this, it is necessary to have a clear conception of the difference in cost of tabulation and publication, according to the mode of grouping of the data.

When we have to tabulate data in such a way that the individual items are to be distributed through a thousand columns or more, and each of these to be summed up for different localities, a vast amount of clerical labor is required. For distributing in a thousand spaces the various items assigned in each death certificate, if it be done by the old-fashioned system of tallying on a large sheet, an expert clerk will not be able to tally off more than a thousand records of death per day; so that for, say, thirty thousand

deaths, which is less than the average number of annual deaths in New York city for the last ten years, it would require the labor of a clerk thirty days to produce a single page table—about one per cent. of what is needed.

By the use of cards, chips, or slips, tallying machines, addin machines, and sorting boxes of various kinds, this labor may be much reduced. One of the latest methods of doing this is by the use of cards of a uniform size in which holes punched in certain parts of the card correspond to the various divisions of locality, time of death, sex, age, occupation, cause of death, marital condition, etc. These cards may then be passed through a machine which registers on a series of dials such combinations of the data as the dials may be adjusted for, by means of electrical connections established between a metal plate below and a series of metal rods above, wherever there is a hole in the card.

Death-rates, even when derived from complete and accurate data and compiled in the most satisfactory manner in the form of life tables, necessarily give only a very imperfect view of the prevalence of disease in a community, or of the relative amount of disability among the people, requiring extra labor by the productive class due to the recurrence of sickness. Many forms of disease which render life more or less of a burden, and some of which totally disable the individual from earning his subsistence, seldom or never appear in the registers as a cause of death, while even of those diseases which are reported as causes of a considerable proportion of deaths we can rarely at present indicate any definite or certain relation between the number of cases of the disease and the number of deaths reported. For example, it is well known to all practicing physicians that the mortality varies greatly in different epidemics of such diseases as scarlet fever, measles, small-pox, whooping-cough, yellow fever, etc., the variations appearing to depend principally upon the particular conditions of the environment as to temperature, moisture, winds, density of the population, etc., at the time of the outbreak, and also upon particular conditions of the specific virus or micro-organisms causing diseases of this kind.

Take, for example, the spread of yellow fever in Texas and along the Gulf coast during the year 1867. Here the specific cause of this disease appears to have entered the United States by two distinct routes, one coming from Vera Cruz, Mexico, and the other coming from the usual source, Havana. At that time the United States had a comparatively large number of troops along the southern border of the country, and hence we have a series of returns showing not merely the number of deaths, but also the number of cases of sickness from this disease occurring in a given population.

Now, in those places where the disease was of Mexican origin, the cases were more fatal than those of Cuban origin, "two out of every five cases of the former dying, while the mortality of the latter was only two out of seven. The ratio of deaths was 400 per 1,000 cases for the first of these groups, 284 per 1,000 for the second."\*

For the great majority of diseases it is not possible to obtain statistics as to their prevalence among a general population. The only sources to which we can look for information of this kind are the records of the army and navy, of the police force in certain cities, of the employees of railroads, and of the members of certain societies having insurance against sickness. The records of the army and navy are especially valuable in this point of view, but they relate only to males of certain groups of ages and of a carefully selected class of population.

In the last United States Census an attempt was made to obtain on the schedules of the living population the number of those who, on the first day of June, 1880, were so sick or disabled as to be unable to pursue their ordinary occupations. This was the first attempt of the kind which has been made in this country, but similar attempts were made in two censuses in Ireland, in a census of the Australian Colonies, and in a census of Hungary.

Several attempts have been made to induce physicians to keep a record of all the cases which they treat, but with very little result. In 1857 the Metropolitan Association of Health Officers in London carried out a systematic registration of all cases of sickness which received attention at the public expense—as in hospitals, dispensaries, almshouses, etc. About one half of the hospitals and dispensaries in the district contributed information, but the enterprise broke down before the end of the second year; and, while results gave some interesting indications for the time as to the prevalence and progress of certain forms of epidemic disease, the records have very little statistical value, as they have no definite relation to the numbers of the population furnishing the cases of sickness.

It is very improbable that anything like complete returnus of sickness will ever be obtained for any large body of the civil population. Such registration will always be confined to infectious and spreading diseases; in other words, those which are known or supposed to be preventable. In order to make a registration of this kind of any great practical value, it must be continuous and compulsory. The plan of endeavoring to get the medical men of a locality to voluntarily contribute this information, even when accompanied by the offer of the payment of a fee, has produced partial and incomplete results, which become more and more incomplete as time goes on and the first enthusiasm in favor of the new plan dies away.

On the part of some members of the medical profession, both in Great Britain and in this country, strong objections are urged to compulsory notification of disease, and especially to that form which requires the doctor to furnish such notification direct to the sanitary authorities. It is urged that such notification is a violation of professional secrecy, that it leads to concealment of cases of such disease and the refraining from calling in a medical attendant, and that it tends to throw the treatment of such cases into the hands of a lower class of practitioners, who are willing to run the risks of violation of the law, or even to make false returns for the sake of securing an increased practice. There is, however, little difficulty in keeping the information furnished strictly confidential, provided the health officer is a man of

\* War Department, Surgeon-General's Office, Washington, 1886, Circular No. 1, page 18.

tact and discretion, and provided also that the press does not insist upon being too inquisitive with regard to matters of this kind.

Any system of compulsory notification, however, which has to be continuously successful involves two things:

First, that the health officer shall not be in any way engaged in or connected with private practice, so as to do away with all reluctance on the part of general practitioners reporting their private cases.

The second is that, to obtain any benefit from notification, special hospital accommodations for such forms of diseases as are reported must be provided by the community, and there must be a power of compulsory removal of patients to such hospitals in certain cases.

Undoubtedly, valuable statistical data might be obtained by the simple notification alone; but the desire to obtain statistical information will never be accepted as a sufficient ground for legislation requiring compulsory notification.

We hear very much in recent years of the proportion of deaths from zymotic diseases as a test of the salubrity or sanitary condition of a place; but, as there is no general agreement as to what is and what is not a zymotic disease, and as the term rests on a theory of causation of disease which is now definitely abandoned, it should no longer be made use of. It is much better to select the mortality from certain forms of disease, and specify these in order that we may know exactly what we are talking about, and be sure that the matters compared between two localities are the same. English health officers often use the term "seven principal zymotic diseases," by which they mean small-pox, measles, scarlet fever, diphtheria, whooping-cough, typhus fever, and enteric fever. If this is the selection, it is not a good one, for it omits the diarrhoeal diseases. Forty years ago, near the commencement of the speculations of Dr. Farr and Mr. Simon as to the causation of disease, nearly all of the contagious diseases were grouped together as zymotic diseases, and were supposed to be more or less connected with filth. At present we know that the cleanliness of the surroundings has little or nothing to do with the prevalence of small-pox, measles, scarlet fever, or whooping-cough; so that these, which are typical zymotic diseases, are of very little interest in connection with the question as to local causes of disease in a place connected with uncleanliness and to be remedied by sanitary effort.

Their relative prevalence and the mortality due to them is of interest in a totally different connection, and their separation involves an entirely different field of sanitary work. Such diseases as phthisis, diphtheria, and the various forms of diarrhoeal disease, including cholera infantum or the summer diarrhoea of children, of England, are of especial interest as regards the field of local sanitary work in relation to sewerage, drainage, and cleanliness.

The influence of habitation upon death-rates, and on the prevalence of certain forms of disease, is indicated by statistics given by Dr. Korosi for the city of Budapest, where the deaths are reported with the following classification, viz.:

1. Persons in a habitation where at most two persons dwell in the same room.

2. Persons dwelling where from two to five persons dwell in one room.

3. Where there are from five to ten in a room.

4. Where there are more than ten in a room.

Comparisons thus made indicate that contagious diseases, with the exception of scarlatina and typhus, are more frequent and more fatal in the crowded houses, and that the same is true of congenital debility and diarrhoea, while tuberculosis and pneumonia do not seem to be specially influenced by this cause (?!). As the figures of deaths in these categories are not comparable with those of the living population, the results have not much value.\*

What has been the influence of modern civilization upon the average duration of human life, upon rate of population, upon the average health and vitality of the races which it has affected? The present population of the world is between 1,500,000,000 and 1,600,000,000, of which there are in Europe over 350,000,000, and of European stock in other countries 100,000,000; in all, say, 450,000,000 as against 150,000,000 in 1788. (See Giffen, "Jubilee Volume of Statistics," 1885, p. 99.)

Evidently the birth and death rates now prevailing in Europe and the United States can not have long continued, for, if we suppose a population to double itself only once in a century, 1,000,000 of people living twelve hundred years ago would have developed into a population of over 4,000,000,000 by this time.

What, then, is the difference between the expectation of life in New York at the present day and that in European cities one, three, five, ten, or twenty centuries ago? This question has been asked in various shapes many times, and many attempts have been made to answer it, the general conclusion being that there has been a very great increase in the average longevity of man in civilized countries, not only within the last thousand years, but within the last century. Notwithstanding, it must be confessed that the statistical records bearing on this point are very incomplete, vague, and unsatisfactory, and that it is only for the last forty or fifty years that we can speak with anything like scientific precision as to the amount of progress made.

So far as what is termed potential longevity—that is to say, the maximum duration of life possible in an individual of the race—is concerned, there is no evidence that this has changed for at least two thousand years, being for man generally taken as a hundred years. You will remember the scriptural declaration that the years of a man "are three score years and ten, and if by reason of strength they be four score years, yet is their strength labor and sorrow"; notwithstanding, there are sufficient records to prove that even in those days the potential longevity of man was as great as it is at present.

But when we come to the average longevity and expectation of life at birth, there is sufficient evidence to indicate that it has increased; but whether this is due to the preservation of more infant lives for a few years, although they may still die before the productive period is reached, or to

\* Korosi, "Influence des habitations sur les causes des décès," etc., Paris, 1877.

an increase of the number of those who live into and share the working period of life, is still uncertain, for this question can only be settled by comparative life tables, and I have already explained that we have no reliable life tables that are much over fifty years old.

The most important contributions to our knowledge of the increase in the duration of life in recent years is contained in a paper on the decline in the English death-rate, by Noel Humphreys, published in the "Journal of the Statistical Society" in 1883; and in a report by Dr. William Ogle in a supplement to the "Forty-fifth Annual Report of the Registrar-General of England," published in 1885.

The conclusions, as based upon English life tables, comparing periods from 1838 to 1854, and from 1871 to 1880, are as follows:

The mean after-lifetime of a male at birth was for the first period 35·91 years, for the second 41·35, showing an average gain of nearly a year and a half. The mean after-lifetime continues longer in the second period than in the first for each year of life until the nineteenth. At the close of the nineteenth year the expectation of life was exactly the same in each period—viz., 40·17 years. From that time onward the after-lifetime is shorter in the recent period than in the older one; that is to say, the individual male in England lives on an average a shorter time after he is nineteen years old than he did forty years ago; but the number of males out of equal numbers at the start who survive to live these shorter lives is very much greater than it was formerly, so that the aggregate life of the whole is considerably increased. The gain is greater in females than in males. Thus, in the first period the expectation of life in females was 41·85, while in the second period it was 44·62, being a gain of 2·77 years on an average for each female. The after-lifetime continues longer in the new period down to the completion of the forty-fifth year, when the expectation of life becomes the same—viz., 24·06.

The earliest attempt to give vital statistics for the United States is probably a paper by Edward Wigglesworth, published in the "Memoirs of the American Academy of Arts and Sciences," 1793, vol. ii, page 131, entitled "A Table showing the Probability of the Duration, the Decrement, and the Expectation of Life, in the States of Massachusetts and New Hampshire, formed from Sixty-two Bills of Mortality on the Files of the American Academy of Arts and Sciences in the year 1789." The whole number of deaths reported on these bills was four thousand eight hundred and ninety-three. He had no data of population, but the reports indicated that the births in the locality sending the bills were twice as many as the deaths. As his calculations are based solely on the deaths alone at certain ages, the conclusions are evidently entirely unreliable; but, such as they are, they are as follows:

The expectation of life at birth was 28·15 years; at five years, 40·87; at ten, 39·23; at fifteen, 36·16; at twenty, 34·21.

By another calculation he finds that the expectation at birth was 35·47, and at five years of age 48·46.

Another paper is by J. E. Worcester, printed in the "Memoirs of the American Academy of Arts and Sciences,"

Philadelphia, 1833, vol. i, new series, page 1, and entitled: "Remarks on Longevity and the Expectation of Life in the United States, relating more particularly to the State of New Hampshire." Taking the bills of mortality of thirty-two townships in New Hampshire for an average length of time of twenty-one years, he found that the death-rate was 1 in 83, or 12·04 in 1,000. He wisely remarks that the ratio is so small as to excite suspicion concerning the accuracy of the bills.

You are all, no doubt, familiar with what is known as the Malthusian theory, which is, essentially, that population is limited by the means of subsistence available, that population increases in a geometrical proportion, while the means of subsistence do not increase in a faster ratio than arithmetical progression; that, therefore, the growth of population is checked by want of means of subsistence, and, therefore, that the increase of mankind may be considered as the chief source of misery, which misery, together with moral restraint to a limited extent, and vice, check the superior growth of population, keeping it at a level with the means of subsistence.

If this doctrine be applied to the lower animals or to an extremely savage and ignorant set of men, it is very nearly correct; for in this case the term "means of subsistence" applies almost exclusively to the natural produce of the earth. As soon, however, as man applies his intelligence to the increase of the means of subsistence by improvements in agriculture, by manufactures, etc., it is no longer true that the means of subsistence increase in an arithmetical proportion. They may increase, and for the last fifty years have, throughout civilized regions of the world, actually increased in a ratio more rapid than geometrical proportion and more rapid than the increase of population; and it is therefore substantially true that "the character of every race of men is the real limit to its numbers in the world, if allowance be made for accidents of position and time."\*

The uneducated and unskilled laboring classes, who are without capital, when gathered together in large masses, tend constantly to illustrate the theory of Malthus by increasing faster than they can provide means of subsistence for themselves and their families.

But this tendency is opposed by the advance in knowledge, increase in energy, and improvement in inventions in the educated classes, who, although it may be said that they are acting only from selfish interests, are, nevertheless, led by those interests to expand the fields of agriculture, manufactures, and commerce, and thus to both increase the means of subsistence and to lessen the price thereof.

Under favorable conditions a population is capable of doubling its number every twenty-five years. In the United States, between the years 1790 and 1860, the population doubled itself about once in twenty-three years and a half. But a portion of this increase was due to immigration.

Whether in the future a systematic attempt to maintain an equilibrium between subsistence and population will become a practical problem of national policy is at present a purely theoretical speculation, for it is very easy to show, as

\* Farr, "Vital Statistics," London, 1885, p. 16.

has been done by Mr. Atkinson (see papers by Atkinson in "Scribner"), that the means of subsistence at present at our command can easily be quadrupled, as the increase of the population occurs to both require and produce such increase.

One of the most interesting and important questions in vital statistics in this country is that relating to the relative increase in the white and colored population in the Southern States, and the influence which has been and will be exerted upon this by the abolition of slavery. On the one hand it is claimed that the large increase in the colored population between 1870 and 1880 indicates that in fifty, or at most a hundred, years more it will greatly predominate.\* On the other hand, it is affirmed that the greater increase of the colored population is apparent rather than real.

We have little information of value relative to the vital statistics of the colored population in the South previous to the abolition of slavery. The only two Southern States having registration laws which were to any extent enforced were Kentucky and South Carolina. The Kentucky reports relating to the registry and returns of births, marriages, and deaths are eight in number, commencing January 1, 1852, and extending to December 31, 1859, the last report being printed in the early part of 1861. The South Carolina annual reports of registration of births, deaths, and marriages begin with the year 1853 and end with the year 1859. In neither State was the registration of either births or deaths in any year sufficiently complete to permit of accurate comparisons with the number of living population, either for the whites or blacks.

The conclusions drawn by the registrars may be summed up in the statement that the birth-rate of the slaves was much greater than that of the whites in South Carolina, while the difference was not marked in Kentucky; that in both States the death-rate of the negro was decidedly greater than that of the whites, especially in infancy, and that the average age at death was decidedly higher in the whites.

The average mortality in a population of a little over 43,000,000 whites was recorded as 14.74 per 1,000, while in a population of 6,752,000 colored the recorded mortality was 17.28 per 1,000. Is it known that each of these recorded death-rates is much lower than the actual one, owing to failure to record the whole number of deaths occurring during the census year; but it is also known that the proportion of failures to record was decidedly greater among the colored than among the whites, and hence the difference between the death-rates of the two races is even greater than that indicated by these figures.

How far is this excessive mortality in the colored population due to racee characteristics? It is due to peculiar susceptibility on the part of the negro to certain distinctive forms of disease, or to his having less vital force and capacity to resist disease and death? Undoubtedly the great mass of the colored population is poor and ignorant, lives in the dampest and dirtiest parts of cities, and in the midst

of unhealthy surroundings, and is in other respects unusually exposed to well-reeognized causes of disease.

The statistics of 1880 show that the colored race is peculiarly liable to fatal results from certain forms of disease, especially consumption, pneumonia, diarrhoeal diseases, affections of pregnancy, scrofula, and venereal diseases; and that, on the other hand, it is much less liable than the white race to fatal results from cancer, diphtheria, diseases of the nervous system, scarlet fever, and suicide.

Notwithstanding the interest and importance of the question, we have at present no sufficient data to determine whether the negro, under the same circumstances as to poverty, etc., is or is not more prolific or short-lived than the whites, and absolutely no data of any value for determining the relative fertility and mortality of the mixed bloods, including mulattoes, quadroons, octofoons, etc. An effort will be made in the coming census to supply this deficiency as far as possible. In the enumeration of the population those of mixed blood will be recorded separate from the pure whites and the pure blacks, and an effort will be made to obtain corresponding records of deaths in order to determine the death-rates of these mixed bloods. An effort will also be made to determine the birth and death rates of certain classes of poor and ignorant whites, such as the tenement-house population in our Northern cities, as distinguished from those of the mass of the white population, which will give us a better means of comparison of the mortality of the two races under comparatively similar circumstances than we now have.

In studying the causes of disease and death in communities a very important point to be considered is the relative poverty, ease, or luxury in which different parts of the population live, or the sickness and death-rates of so-called social classes.

That extreme poverty, producing inability to obtain the amount of food, clothing, and shelter requisite to preserve health, is a direct cause of high death-rates, especially in northern climates, is known to all; but the extent to which this factor of want influences the death-rates in different countries or communities is by no means easy to determine, and thus far we have, for the most part, only data bearing indirectly on this subject. For the provident and presumably well-to-do classes we have the statistics of life-insurance companies; but these are for selected lives, which fact tends to give a low death-rate during the early years of the policy-holders, while, on the other hand, the tendency to cease paying annual dues and to give up the insurance is greater in those who are well and strong than in those who have reason to suspect that they are diseased, so that the death-rates in the greater ages are higher in the insured than in those not insured. We can also draw some inferences from the vital statistics of occupations, from tenement-house statistics, etc.; but it is very difficult to distinguish between effects of density of population, occupation, race, intemperance, uncleanly habits, and actual want of the necessities of life.

The tendency now is to accumulate the best and the worst of the racee in cit es. They draw to them the most enterprising, vigorous, and prudent, whose tendency is to late marriages and few children, and thus tend, after a time,

\* See paper by E. W. Gilliam, "Popular Science Monthly," xxii, 433.

to lower the standard of the race. Where the tendency is to replace a feeble and lower race by a better one there is progress; where the tendency is the reverse there is decay. "The hope that by increased knowledge, charity, and co-operation, the feeble, sickly, and incompetent can be so cared for that they shall become strong and vigorous, is that held by most men of the present day, but there is nothing in the laws of heredity which gives any foundation for this hope."

"What is to be the outcome of this modern civilization? Its enemies are not without but within—not savage nations on its borders, but dwellers in its own cities. The general tone of modern European literature is pessimistic as to the future, filled with doubts and fears as to what the coming supreme democracy will do. In this country it is more hopeful, and looks forward to progress in improvement in the physical conditions of the race, though admitting the dangers and difficulties which this very physical improvement tends to produce." But whatever be the views of individual thinkers and writers, on one point all can agree, and that is as to the desirability of having at our command definite, positive information as to the character, amount, and set of currents of this stream of human life in different countries and localities. An important part of such knowledge is that which relates to the composition of and changes in the population in different countries, which is the special field of vital statistics.

### THE BOTE.

DESCRIPTION OF A PECULIAR SEXUAL PERVERSION  
FOUND AMONG NORTH AMERICAN INDIANS.

By A. B. HOLDER, M. D.,  
MEMPHIS, TENN.

DESIRING absolutely to avoid discussion of the existence or non-existence of the anomaly classically known as hermaphroditism, in which, in one individual, are found more or less developed the sexual organs of both male and female, I have chosen the word in the heading of this article to designate a class which exists as a class, so far as my knowledge goes, nowhere but among certain tribes of the American Indians.

The word *bō-tē'* I have chosen as being the most familiar to me and not likely to convey a wrong impression, since I shall be the first, perhaps, to translate into English and define it. It is the word used by the Absaroke Indians of Montana, and literally means "not man, not woman." A corresponding Tulalip word, used by Indians of Washington Territory, is "burdash," meaning "half man, half woman." As the Absaroke is an unwritten language, in the orthography of the word I have adopted the alphabet suggested by the Smithsonian Institution to secure uniform spelling of Indian words. These words are appropriate as descriptive of manners and practice, but are not, by the In-

dians themselves, intended to convey the idea of anomalous sexual conformation.

The practice of the bote among civilized races is not unknown to specialists, but no name suited to ears polite, even though professional, has been given it. The practice is to produce the sexual orgasm by taking the male organ of the active party in the lips of the bote, the bote probably experiencing the orgasm at the same time. Of the latter supposition I have not been able to satisfy myself, but I can in no other way account for the infatuation of the act.

Of all the many varieties of sexual perversions, this, it seems to me, is the most debased that could be conceived of.

In the Crow or Absaroke tribe, of which I have had medical charge for two years, there are at present five bote (in this dialect there is no plural form, the number being indicated by the qualifying words), and about this number has flourished for years past.

While in reports of physicians and others concerning various Indian tribes I find no mention of this class, and while in personal replies from physicians in charge of more than twenty agencies I have been able to get little positive evidence concerning them, yet I feel assured that the bote is to be found in nearly all tribes of Indians, of the Northwest at least.

From physicians I have obtained the following information:

Dr. Joseph B. Graham, of Lower Brûlé Agency, Dakota, reports one "so-called hermaphrodite who affects woman's manner and dress, and it is said he lives and cohabits with a man occasionally, but more I have been unable to learn."

Dr. Best, of Fort Berthold, Dakota, informs me that there are among his Indians, Gros Ventres, Mandans, and Rees, "a few bucks who have the dress and manner of the squaws and who cohabit with other bucks," but in what manner or for what purpose he is unable to say.

Dr. C. K. Smith, of Klamath, Oregon, writes: "There is but one 'hermaphrodite' in this tribe. She (?) has lived with a number of different men who claim that they have performed the sexual act with her. She has also cohabited with white men. The Indians claim that she has a rudimentary penis and that she used to cohabit with females. She dresses as a female, but is masculine in voice, features, etc."

One of the bote accredited to the Absaroke tribe is a Sioux, and I can assert, on perfectly reliable testimony, that among the Lower Gros Ventres there is a larger number of them than in the Absaroke tribe. A bote, a description of whom will be introduced presently, told me that the tribes of his acquaintance living in the Northwest had bote as follows: Flatheads, four; Nez Percés, two; Gros Ventres, six; Sioux, five; Shoshonis, one. There seems a species of fellowship among them, and I have no reason to doubt the correctness of his statement.

The bote wears the "sqnaw" dress and leggins, parts the hair in the middle and braids it like a woman's, possesses or affects the voice and manner of a woman, and constantly associates with that sex as being of it. The voice, features, and form, however, never so far lose masculine qualities as to make it at all difficult to distinguish the bote from a

woman. One of them does "squaw" work, such as sweeping, scouring, dish-washing, etc., with such skill and good nature that he frequently finds employment among the white residents.

Usually the feminine dress and manner are assumed in childhood, but the art to which they subsequently devote themselves does not generally become a practice till toward puberty. One little fellow while in the Agency Boarding School was found frequently surreptitiously wearing female attire. He was punished, but finally escaped from school and became a bote, which vocation he has since followed.

One of the bote of my acquaintance is a splendidly formed fellow, of prepossessing face, in perfect health, active in movement, and happy in disposition. Desiring that my knowledge should be positive, I had this bote brought to my office, and, by offering a moneyed consideration, induced him to submit himself, though with considerable reluctance, to a thorough examination.

He is five feet eight inches high, weighs one hundred and fifty-eight pounds, and has a frank, intelligent face—being an Indian, of course beardless. He is thirty-three years of age and has worn woman's dress for twenty-eight years. His dress was the usual dress of the Indian female, consisting of four articles—a single dress or gown of half a dozen yards of cloth, made loose with wide sleeves, and skirt reaching to the ankles, the skirt and body of one piece, very much like the "Mother Hubbard" *négligée* worn by ladies; a beaded belt loosely confining this at the waist; stockings from Government annuity goods; and buckskin moccasins extending above the ankles. The hair, twenty-four or twenty-six inches long, was parted in the center and allowed to hang loose in two masses behind the shoulders. Since among the Sioux and some other tribes it is usual for men to wear their hair in this way, it is well to observe that in this tribe (Absaroke) the men usually wear the hair in long braids and always part it on the side and "roach" the front.

Removing his dress, I found his skin smooth and free from hair, there being absolutely none on the legs, arms, or breast, or in the armpits. This, however, is of no special significance, as all Indians with whom I am acquainted, male and female, are free from hair on these parts of the body. The mammae were rudimentary, as usually found in the male.

Coming now to the more interesting parts, the sexual organs, I will state that when he removed his dress he threw his thighs together so as to completely conceal the organs, whether male or female; such a movement as I have frequently seen made by timid women under examination—a movement usually successful in the female, owing to the non-projecting character of the genitals and to the rotundity of the thighs, but not usually easy, for the reverse reasons, in the male. In this the bote—either from the conformation of the thighs, which had, really or to my fancy, the feminine rotundity, or from skill acquired by habit—succeeded completely.

When he was induced to separate his thighs, male organs came into view, in size perhaps not quite so large as the physique of the man would indicate, but in position and shape altogether normal. The penis, being flaccid, meas-

ured four inches and a half in length, three inches and a half in circumference. The testicles were of about the size of the shell of a small almond; the foreskin and glans were normal. On the pubes was a light growth of short hair, the usual amount found on the Indian male.

Before he would submit to the examination he had me promise that I would tell nothing to the authorities nor to any of his tribe. When I was done he asserted that no one had seen his genital organs from childhood till this examination. His constant associates are women, and I said to him, "You go swimming with women; how do you keep them from seeing your organs?" "Oh," he said, "I do this way," throwing his thighs together as he had done when he first removed his dress for examination, again completely concealing the penis and scrotum, and under direct inspection in this position it would be impossible to declare his sex. He denied ever having had sexual intercourse with a female, and pointed as evidence to his penis and groins—"no sore, no scar"; by no means bad evidence in a tribe so universally venereal. Other Indians assert that this bote formerly occasionally had sexual intercourse with women. Such, however, is rare, perversion of the function depriving them of the normal passion for the female. They have, however, for this perverse gratification a passion equivalent to the normal. I have heard a bote *beg* a male Indian to submit to his caress.

The bote described above lived constantly two years as the female party to a marital partnership with a well-known male Indian. It is not, however, the usual habit of the bote to form a "partnership" with a single man. He is, like the female members of this tribe, ready to accommodate any male desiring his services.

In habits the bote very closely resembles a class described by Hippocrates as found in his day among the Scythians of Caucasus, and called by the Greeks *ἀναρδητοί*, a word strikingly similar in meaning to bote. The *ἀναρδητοί* are described as males who—indirectly, from excessive horseback riding, and directly, in the opinion of Hippocrates, from the cutting of certain veins near the ears—have been rendered impotent and, in the words of the "Father of Medicine," "assume the attire of women, declare that they have lost their virility, associate exclusively with women, follow like occupations, and have a like pitch and tone of voice." The credulous assertion of the writer that "near the ears there are veins which render impotent those in whom they are cut" should be kindly forgotten along with the numerous errors of this great observer. The origin and perpetuity of these *ἀναρδητοί* is thus accounted for by Herodotus (Rawlinson's translation, "History of Herodotus," vol. i, p. 190): "When the Scythians were about leaving Syria and Palestine, which they had invaded, their rear guard pillaged the temple of Venus at Ascalon. The goddess was so enraged at the act of desecration that she caused the perpetrators to become like women, and further decreed that their posterity should be similarly affected."

Dr. William A. Hammond ("Impotence in the Male," p. 163 *et seq.*) describes with great minuteness two *mujerados* whom he found among the Pueblo Indians of New Mexico. These again closely resemble the bote in dress,

habit, and practice. "The Pueblo Indians," writes this author, "are in the habit of selecting some one male from among those living in a village and rendering him sexually impotent, reserving him at the same time for pederastic purposes. This person was called a *mujerado*, a corruption probably of the Spanish word *mujeriego*, which signifies feminine or womanish. There is no such word in Spanish as *mujerado*; but if there were, it would, according to the construction of the language, mean 'womaned,' or 'made like a woman.'" Of the use and manner of making the *mujerado*, Dr. Hammond writes: "A *mujerado* is an essential person in the saturnalia or orgies in which these Indians, like the ancient Greeks, Egyptians, and other nations, indulge. He is the chief passive agent in the pederastic ceremonies which form so important a part in the performances. . . . For the making of the *mujerado* one of the most virile men is selected and the act of masturbation is performed upon him many times every day; at the same time he is made to ride almost continually on horseback." From over-excitement comes abolition of the orgasm, the organs atrophy, the temperament changes, and he becomes assimilated with the female sex, perhaps at first with reluctance, but finally with entire complaisance and assent.

That the perversion of the bote is not due to excessive equitation is evident when it is known that the female dress is often assumed in childhood, and rarely at a later period than the age of puberty.

In the manner of making the *mujerado* and his importance in the traditional rites of the people among whom he is found, Dr. Hammond gives him a position of greater dignity than I can assign the bote, whose making I adjudge the work of his own perverted lust, and whose tolerance I attribute not to any respect in which he is held, but to the debased standard of the people among whom he lives.

There is, moreover, a difference in the method of the practice of their vocation. Pederasty is by no means unknown among the tribes of Indians where the bote is found, but the bote is less than any other a pederast. With him it is the oral and not the rectal cavity into which he admits the male organ.

It is interesting, however, to observe that Indian tribes vastly dissimilar in habits and as widely separated as the western half of the continent will allow possess each a class closely resembling and all markedly similar to the Scythian *ἀνδρόποιες* described centuries ago.

That the bote is a study of practical as well as scientific value to the surgeon is evident to one whose practice has brought him in contact with examples in the white race, not only of the *mujerado* but of his more disgusting cousin, the bote. With the former every specialist is familiar, and several cases are reported with graphic minuteness by Dr. Hammond in the little volume referred to above. Of the latter, a striking example was the case of an officer in the United States army, who was recently caught *in flagrante delicto*, the other party being an enlisted man, and allowed to resign from a Western post. He confessed the practice of the habit for years, showing that there is no bottom to the pit into which the sexual passion, perverted and debased, may sink a creature once he has become its slave.

## TALIPES EQUINUS.

BY C. W. BARRIER, A. M., M. D.,  
COLUMBUS, GA.

CONCERNING this deformity certain fundamental principles are conceded by all, while other principles and methods are still *sub judice*. Of this latter class alone I propose to write. As F. R. Fisher, F. R. C. S., of London, in Ashurst's "Encyclopaedia of Surgery," treats of this subject comprehensively, and represents a larger class of writers and operators, I will show wherein my views differ from his teachings.

To reduce the deformity he directs two operations, as though it could not be done at one. The mechanical treatment after each of these operations he describes as requiring two or three months, making four or six months necessary to complete a reduction. I have found in my practice that a large majority, if not all these cases, may be successfully treated at one as well as at two operations, and the patient may be well and walking about in at least two or three months, the time he directs to continue the mechanical treatment after each of his operations. I have found one operation preferable for the following reasons: 1. The patient and the parents are not horrified by the thought of two operations and such a long treatment. In one case, which I treated at one operation, the parents had been deterred from the treatment till the child was sixteen years old by the thought of two operations. 2. The patient is not helpless and does not require the attention of the surgeon more than half so long. 3. There is not half the danger that some unforeseen contingency may prevent the cure. The child may become sick; an epidemic may prevail; accident, sickness, or death may befall the surgeon in six months. 4. Some parents are very fickle and may conclude that, as so little has been accomplished at the first operation, another would not be worth while. I have seen more than one treatment cut short in this way. 5. One part of the deformity can not be entirely reduced while the other exists. 6. The danger, if any—and who can say there is none from the use of chloroform?—is only half so great. 7. Last, but not least, I object to two operations, because I have not seen their necessity, and I have operated in several cases extreme deformity and of long duration.

A. W., aged sixteen, with paralytic talipes equino-varus from birth, had made application to various surgeons, who advised two operations and frightened the patient from the treatment. On the 18th of last January, assisted by the accomplished physician, Dr. W. W. Bloodworth, I operated, accomplishing the whole at once, consuming in the operation and dressing only six minutes. On the eighth day the deformity was completely reduced. In three months the boy was walking on the foot all over town. In five months he was put to work at a job which required him to be on his feet twelve hours each day. The foot is still straight, with no tendency to return to its old position, although not strengthened by a brace.

W. W., aged ten years, of this city, having complete equinus, with slight varus from birth and with great displacement of the tarsal bones, was operated upon by myself, assisted by the efficient Dr. E. W. Jenkins, the two operations being performed at once. On the seventh day the deformity was entirely re-

duced, and on the ninth day the boy stood with the heel flat on the sole-piece of the splint, and bore all the weight of his body on the deformed foot. On the eighteenth day I discovered that the boy had thrown his crutches away and was walking on the foot in its splint, and I was compelled to devise means to keep him off of it.

Our author's method of cutting the tendo Achillis is no less objectionable than the two operations. I will enumerate the dangers attending the operation by his method in his own words. He says: "The division of the tendon in a healthy body, or when performed on a dead subject, is a very simple operation; but in the case of paralytic equinus it is by no means so easy to divide the tendon deftly; in the paralyzed leg all the tissues are very much wasted, there is, consequently, very little subcutaneous fat, and the skin folds closely over the tendon, etc., . . . but it renders the subcutaneous division of the tendon much more difficult than it would be if the superficial tissues were less closely adjacent to the structure which has to be divided. The dangers which have to be avoided are: (1) making a second puncture of the skin on the opposite side of the leg on which the tenotome is entered; (2) increasing the size of the first puncture during the section of the tendon so as to produce a gaping wound; (3) and, lastly, cutting through the skin over the tendon after the division of the latter is complete; all these accidents have happened in practice." All this is true, but he fails to enumerate all the dangers. However, I will do so in his own words. "If the tendon has not been perfectly severed, (4) the knife has probably pierced its deeper fibers instead of passing under it; (5) or else it has not been carried far enough to the side opposite to that of puncture and some of the fibers of the tendon have been left undivided; in such case the knife must be re-entered and section made complete; and the same must be done if the small plantaris tendon has not been severed."

These dangers are real, not imaginary, and certainly they are enough to attend any one operation. It seems to me that they all arise from the point of entering the knife—viz.: on the side of the leg, passing it anteriorly to the tendon—and they are augmented by the operator having to keep the sharp point of the knife in contact with the inner surface of the skin in passing around the curve to reach all the points of the tendon; and after the last fibers are cut the whole of the back part of the skin is drawn with force over the edge of the blade. To those who will reflect, I submit the following method of operating, which I think removes all these dangers: The patient being placed in the recumbent position on a table, the operator stands at the patient's feet and elevates the limb at a right angle to the body, which places the tendo Achillis directly before the eyes of the operator. Enter the tenotome on the median line of and posterior to the tendon, with the back of the blade directly toward the os calcis. When the knife has passed through the skin, with the thumb of the left hand on the side of the tendon opposite the point where the blade is entering, press the skin toward the blade; this will enable you to pass the tenotome between the skin and tendon, until the point of the knife is opposite the anterior surface of the tendon. Then turn the edge of the knife to

the tendon, and replace the thumb of the left hand by that of the right hand, with the handle of the knife in the latter. Now you have only the tendon and one layer of the skin between the edge of the knife and the thumb. With a few even sweeps of the knife, the thumb pressing the tendon firmly against the blade, while the tendon is put on the stretch by forcibly extending the toes, you sever it; the thumb feels the knife approaching the skin and warns you when to go slowly; and the tendon, being on the stretch, gives way with a distinct jerk, by which you know the work is complete; and you have no fear of having to re-enter the knife to cut around in search of undivided fibers or plantaris tendon. There is no curve to pass around in cutting the tendon, the point of the knife is not all the while in contact with and probably cutting the skin through, and there is no danger of pulling the skin with force over the edge of the knife when the tendon gives way, as in this case the skin is not pulled toward the edge, but down the knife. If there are any dangers attending this method, I have neither conceived of nor encountered them. There may be some danger of cutting the posterior tibial artery, but this danger is not so great in this as in the former method, as the thumb may press the edge of the tendon nearest the place of puncture more firmly against the knife, and cause the inner anterior surface of the tendon, which is nearest the artery, to be the last severed, and, as soon as this is done, we feel the tendon give way and take the knife out without cutting the artery. By the other method there is great danger of cutting the artery in moving the knife around to find uncut fibers or plantaris. I have practiced this method so successfully that my assistant, though a skilled physician, failed to discover the puncture until it was pointed out to him, it was so small.

Our author directs the use of Scarpa's shoe, as though the deformity could not be reduced without it. Aside from the economy, I prefer not to use it. I take two pieces of white pine, three eighths of an inch thick, and fit one to the sole of the foot, the other to the back of the leg. I cut a hole in the piece extending up the leg for the heel to fit into. I join these immovably at the heel, tacking on pieces of leather at the angle from one piece to the other, to act as braces. I make the included angle a little less than a right angle. I pad this with cotton, on which I place the foot and leg after having performed both operations at once and covered the punctures with iodoform ganze; then I place another pad of cotton over the limb and apply a roller bandage firmly yet comfortably, controlling muscular spasm and protecting the parts from shock on moving the body. Over this I apply a Martin's elastic bandage around the instep and anterior part of the foot, just tight enough to keep the bandage from falling off. When thus applied it produces no pain, and exercises a gentle traction sufficient to gradually draw the sole of the foot to the sole-piece of the splint, and causes the foot and leg to take the position of the angle of the splint. The bandage will accomplish this in from five to ten days, and the patient will not so much as know that a force has been applied. After this, I leave off the elastic bandage and replace it with a second roller bandage, making the parts immovable with the foot well set and at rest till the tendon is fully developed.

But let us hear how it is with Scarpa's shoe. "The whole success," says our author, "of the mechanical treatment of the case depends upon the skill with which the instrument is applied and used, and from a want of appreciation of this fact an imperfect result very frequently follows; and it is quite remarkable how one can blunder in his first attempt to apply a Scarpa's shoe." Again, "for the first twenty-four hours the limb is merely kept resting in its original state of deformity; then the instrument is taken off and the leg is examined to see if too much pressure has been exercised at any one spot from over-tightening the straps." "If such a strain is put on the foot as to give rise to swelling or pain, the pressure must be removed immediately, as otherwise the skin may be excoriated by the tightened straps, and the only remedy will be to give up treatment until the abraded surface is again sound."

Now, after it has required our author, an experienced hand, four days to apply the instrument, and after he has run such a great risk of excoriating the skin and of having to give up the treatment, he goes on to give directions how the cog-wheel is to be turned on from day to day for two or three painful months to complete the reduction. But why do we get so much better results from the use of the elastic bandage than from that of Scarpa's shoe? 1. Instead of narrow, hard leather straps, I use a three-inch elastic bandage, which exercises equal force on all parts. 2. Instead of using a force with which "it is quite remarkable how one can blunder," I use a force that the mother, after a little instruction, can apply as well as or better than the surgeon, which I actually leave for her to do. 3. I commence traction immediately after the operation, before the foot is swollen and sore. He waits four days, leaving the foot in its original state of deformity. I control muscular spasm with a firm dressing. He leaves the limb in a flexible dressing three days and then allows it to rest in its original state of deformity the fourth, while in my treatment, if on the fourth day the foot is left unsupported and is allowed to drop back into its deformed position, it causes great pain. 4. I apply a continuous force almost infinitely small. He applies a violent force probably one second in twenty-four hours, one second being about the time required to turn the cog-wheel. Let us estimate how much more a given force can accomplish by acting continuously than it can by acting only one second in twenty-four hours. The formula in mechanics applicable to this case is:  $rd = ft$ , in which  $r$  represents the resistance to be overcome to complete the reduction,  $d$  represents the distance through which the heel has to be pulled down,  $f$  represents the force applied; in the one case it is the force applied to the cog-wheel, in the other it is the elasticity of the bandage;  $t$  represents the time each force is applied; in the one case it is one second in twenty-four hours, in the other it is 8,640 seconds in twenty-four hours. Now, to find what a given force applied by means of the cog-wheel will accomplish in a day, we have  $f = rd$ , as in this case  $t = \text{one}$ . In the case of the elastic bandage we have  $f = \frac{dr}{8,640}$ , as  $t$  in this case is 8,640. Hence, we see, to accomplish a given work with a cog-wheel in one day the force must be 8,640 times as great as that required by

the elastic bandage. This is not overdrawn, for we have supposed the child to be perfectly passive while the cog-wheel is turned on, which is impossible, as he can not control the muscular spasm, nor the contortions of the limb, when he knows the dreaded force is to be applied. Indeed, it is impossible to obtain this minimum force with the bandage; but, happily, the child can bear, when applied in this way, a much greater force, which accomplishes the reduction in a far less time than two or three months, just as I have found it in practice, which time has in no case exceeded six or eight days.

But that he should postpone until the fourth day commencing the mechanical treatment, allowing the foot to rest in its original state of deformity, seems stranger to me than all else. If we will study the physiological method of repair in the case of divided tendons we shall see the tendency of such treatment. When tendons are divided their ends separate on account of their natural contractility. To fill up this gap, Nature, during the first four or five days, provides what we call plastic material. During the next ten or fifteen days this is converted into connective tissue, and during the next twenty or thirty days it is fully developed into tendon and supplied with nerve-force and contractility. The foot remaining the first four days in its original state of deformity, the tendons are only slightly separated, hence only a small quantity of plastic material is deposited. On the fourth day, after Nature has stopped supplying this plastic material, he commences his stretching process, by which he stretches this small amount of plastic material over a distance probably three or four times as great as Nature supplied it for. I prefer to apply the mechanical treatment immediately after the operation, increasing the space between the ends of the tendons so as to make room for the greatest possible amount of plastic material, which also lessens the distance through which it must be stretched. Thus, if the heel is to be let down two inches, and the cut tendon separates by its natural contractility one inch, he will have to stretch the small amount of material deposited in this one inch over the whole two inches, or twice the distance Nature has provided it for; while, on the contrary, if I, by commencing the mechanical treatment immediately, can increase this separation to an inch and a half by the fourth day (which I have never failed to do), I have this greater space to receive this plastic material, and it has to be stretched only half an inch, or one third the distance which Nature provided it for. But he continues the stretching through the whole time in which the material is to be converted into connective tissue, and while it should be taking on nerve-force and contractility. I prefer to complete this part of the treatment at least by the eighth day, while the material is yet plastic, and then leave the parts at rest to undergo physiological repair. Can we suppose that this stretching in no way impairs the natural process of repair? What other process of repair is not better accomplished by the parts being at rest? Is it any wonder that he complains of "imperfect results," and says that "the union will be weak and that the tissue will always be liable to stretch and leave the patient with the opposite condition of deformity, calcaneus"? It occurs to me that our author

is doing somewhat as the surgeon does when he leaves a broken limb half dressed and gets ligamentous instead of bony union.

## ERYTHROXYLON COCA; ITS VALUE AS A MEDICAMENT.

BY MARC LAFFONT, M. D., PARIS,  
PROFESSOR OF PHYSIOLOGY AT THE FACULTY OF LILLE, FRANCE.

DURING the last few years the therapeutic use of coca has been so greatly extended that it may be interesting and useful as a *résumé* to enumerate its many applications.

Although coca has, from its earliest introduction as a pharmaceutical product into France, enjoyed the highest professional recognition, this South American plant can hardly be said to have entered into current therapeutics. It is only since the discovery of the scientific application of the alkaloid of *Erythroxylon coca*, and since the important essays on the drug and the experiments made with it, that physicians generally have studied and recognized its therapeutic value.

It is well remembered how, in former years, the virtues of the salts of quinine were held to entirely supersede those of cinchona; in like manner this inevitable error has arisen with coca, its alkaloid, cocaine, only having been considered by many.

In consequence of the tests made with cocaine, which, from a physiological point, have established the dose and the limit of its toxic effect, and, from a medical view, have brought to light cases of abuse which have resulted in more or less serious accidents, many have been led to regard the plant coca itself as a dangerous drug.

The proof of the therapeutic value of the coca leaf is clearly shown by the many excellent results obtained in practice with such reliable preparations of the drug as have been furnished the profession by that worthy pharmacist, Mariani.

As to the comparison which many of our *confrères* make between the preparations of cocaine and of coca, we do not fear to state that, however sound may be the theory of preferring to administer certain alkaloids to administering a preparation of a plant of which the virtues vary according to where and how it was gathered, the place of its cultivation, its quality, and the constitution and nature of the preparation—we repeat, we do not fear to state that in the majority of cases, as the alkaloid does not contain all the active principles of the plant, it can not be preferred, except in special cases where the particular action of the alkaloid alone is desired.

The fact is well established that the salts of quinine can not replace the extract, the wine, or the powder of cinchona, the tonic principles and the essential oils of which have, without doubt, shown a special therapeutic value; and I need merely cite the indisputable success obtained by Professor Tronseau with the powder of cinchona in checking malarial fevers which had resisted even the largest doses of sulphate of quinine. More especially cocaine can not replace all the active principles and the essential oils of the

leaf of *Erythroxylon coca*, as has been proved from the time of the earliest discovery and use of this plant.

In 1887 at the Institute of France (Académie des sciences), and in 1888 at the Académie de médecine, I demonstrated that coca, by virtue of its active principles, had three very distinct separate actions (published in the "Proceedings"):

1. As an anæsthetic, acting upon the protoplasm of the terminations of the sensory nerves, preventing the transmission of painful sensations to the centers or the unconscious sensibility of Biehat.

2. As a nerve tonic, producing functional excitement of the cerebral and spinal nerve centers and increasing the intellectual and muscular activity.

3. As a tonic to the unstriped muscular fibers of the stomach, the intestines, and the bladder, producing functional excitement of the constrictor action of the great sympathetic nerve, with consequent functional exaltation of all the smooth muscular fibers or muscles of organic life.

The dissatisfaction produced and the complaints which are made that the plant is wanting in uniformity of quality and is unreliable in producing the desired effects, are due to the varying quality of the preparation.

An essential requisite to produce reliable uniform preparations of coca is a thorough knowledge of the origin of the leaf, its nature, and its quality.

Careful study and researches made by Mr. Mariani for many years as to the origin, the nature, the species, the culture of the different leaves of coca, and the care which he gives to his preparations, have been the means of placing at our disposal products uniform in quality and unvarying in their effects in those varied cases where their internal administration is called for.

I will cite but a few names among those of my many *confrères* whose recorded experience with the Mariani coca preparations coincides with my own, which I am about to set forth, based upon continued observation in hospital and private practice.

It has long been known that the natives used the coca leaves to lessen fatigue, to keep up the spirits, and to appease the cravings of hunger.

The first and main application of the "vin Mariani" is, therefore, as a general tonic for persons either physically or mentally overworked (Brown-Séquard, Germain Séé, Du-jardin-Beaumetz, Ball, Bouchut, A. McLane Hamilton, A. E. Macdonald, A. L. Ranney, L. C. Gray, L. Weber, Carlos F. Macdonald, H. M. Lyman, I. N. Danforth, P. S. Conner, J. K. Banduy, C. H. Hughes); in convalescence after lingering wasting diseases, where nourishment is needed and where it would be dangerous to overcharge the stomach; with all whose recovery is tardy from wasting or constitutional weakness; in chlorosis, anæmia, and rhachitis (Ch. Robin, Durand Fardel, Gubler, De Piétra-Santa, Fordyce Barker, Isaac E. Taylor, A. L. Loomis, W. T. Lusk, F. P. Foster, C. C. Lee, J. J. Henna, L. L. McArthur).

It is further used in diseases more specially referable to atony of the smooth muscular fibers, among which we class atony of the stomach. In dyspepsia, in those very common cases where this organ has become weak and torpid, is dis-

tended, and fails to secrete gastric juice, coca is well indicated (De Saint-Germain, Cottin, Dienlafoy, Salemi, Companyo, Rabuteau, A. J. C. Skene, P. A. Morrow, T. C. Giroux, Hunter McGuire, E. R. Palmer, O. O. Burgess, J. R. Leaming, Daniel Lewis, T. E. Satterthwaite, W. H. Pan-coast, D. F. Woods, J. N. Hyde, L. G. N. Denslow).

It is also serviceable in weakness of the vocal cords, in the case of ministers, singers, actors, teachers, and orators (Ch. Fauvel, Morell Mackenzie, Lennox Browne, Botkine, Cozzolino, Zawerthal, Poyet, Couvard, Fraenkel, Marius Odin, Labus, Massei, Lonis Elsberg, R. P. Lincoln, Beverley Robinson, W. C. Jarvis, H. H. Curtis, C. C. Rice, C. E. Sajous, E. Fletcher Ingals, H. Schweig, T. R. French).

It is, moreover, of value in weakness of the vascular organs, with the anæmic, the plethoric, where, principally on the face, the small blood-vessels show enlargement or venous arborescence which points to a similar state in the vessels of the nervous centers. The same vascular weakness is also observed with the varicose, in whom coca is indicated; likewise with the paraplegic, with whom it regulates the circulation of the nervous centers (Bernard, Béthancès, Landowski, Casenave-Delaroche, Gazeau, Rabuteau, V. P. Gibney, Robert Newman, E. B. Bronson, J. E. Janvrin, B. McE. Emmet, W. O. Moore, W. J. Morton, D. W. Yandell, J. H. Etheridge).

It may be also as a regulator of the nervous centers that the infusion of coca known as thé Mariani produces such marvelous results in mountain-sickness, in sea-sickness, and in the vomiting of pregnancy. It is well remembered how this preparation sustained the illustrious General Grant during several months (Cuffer, Letellier, Dérrécagaix, Trossat, Bouloumme, Dechambre, Fordyce Barker, G. F. Shrady, J. H. Douglas, H. T. Hanks, G. R. Fowler, J. M. Keating).

From a psychological point of view and from mental pathology it may be stated that coca is the only drug which successfully combats melancholia, low spirits, and all forms of depression of the nervous system, upon which it acts "like fulminate," to use the felicitous expression of Professor Gubler.

**Graves's Disease.**—"A case of Graves's disease in the Academic Hospital at Upsala, under the care of Dr. I. Aug. Hammer," says the *Lancet*, "tends to confirm Benedikt's view that the cervical branch of the sympathetic is not affected in this disease. *A priori* it seemed probable enough, as exophthalmos had developed more rapidly on the left side, and at the same time sensibility over the superior cervical ganglion of the left side existed, together with long-standing headache affecting the left side, and partaking of the character of paralytic hemianesthesia. The result of microscopic examination was, however, quite negative. In twenty-two post-mortem examinations in Graves's disease, published from 1860 to 1887, the sympathetic nerve was found quite normal in fifteen; in the other cases, either unilateral atrophy of the nerve elements—especially of the ganglion cells—was found, or the connective tissue was hypertrophied, or these two conditions co-existed."

**Ergot in Cholera.**—"Surgeon-Major Comerford, of India, has recently been using the fluid extract of ergot with marked success in the first stages of cholera and in severe diarrhoea. The drug was used hypodermically in ten-minim doses. In every instance its use was followed by complete success, the diarrhoea being quickly checked and collapse averted. These results were, however, only obtainable during the first stages of the disease."—*Medical and Surgical Reporter*.

## A CASE OF DIABETES MELLITUS IN A CHILD FIVE YEARS OLD.

By B. K. RACHFORD, M. D.,

NEWPORT, KY.,

DEMONSTRATOR OF BACTERIOLOGY IN THE MEDICAL COLLEGE OF OHIO.

THE rarity of diabetes mellitus in childhood makes the following case worthy of record. I saw the case with Dr. J. J. Youtsey, of Alexandria, Ky., in July, 1888, and am indebted to him for the following notes:

The child was five years and eleven months old when the symptoms of disease were first noticed. Dr. Youtsey saw the case for the first time on July 25th. Up to this date the parents, who were German farmers, had not thought their little girl seriously sick, although they knew she had not been quite well for some time. The mother remembered that in April, three months before, the child had begun to lose flesh, but nothing was thought of it at the time, as she had a good appetite and showed no other indications of sickness. She continued to lose in weight and strength, and during the past few weeks had had an unusual appetite and thirst, and had passed very large quantities of urine. During all this time the child had gone about and had not complained, and for this reason the parents did not think her sick enough to demand medical attention until July 25th, when the doctor was sent for. At this date her temperature was 99.75° F. and her pulse 112. She was not restless and had no pain, but was quite weak and very much emaciated. The voracious appetite which had characterized her sickness had disappeared two days before, but the insatiable thirst continued. She was passing daily from six to seven quarts of colorless urine, with a specific gravity of 1.035 and containing a large percentage of sugar. The child was given fluid extract of ergot and placed upon a diabetic diet.

*July 28th.*—Temperature 98°, pulse 116, amount of urine six quarts; child very weak and dull; no pain.

*29th.*—Died at 10 A. M.

## WHAT SPECIAL MECHANICAL TREATMENT HAS PROVED MOST SERVICEABLE FOR EACH VARIETY OF REDUCIBLE AND IRREDUCIBLE HERNIA?\*

By SAMUEL E. MILLIKEN, M. D.,

ASSISTANT SURGEON, HERNIA DEPARTMENT,  
HOSPITAL FOR RUPTURED AND CRIPPLED, NEW YORK.

At the Hospital for Ruptured and Crippled of this city I have had an opportunity to treat mechanically many cases of hernia, the average daily attendance being between forty and fifty patients. While it is found that the simple and inexpensive truss of Dr. Knight, the founder of the hospital, is satisfactory in a large proportion of cases, it is necessary occasionally to resort to other forms. The management is liberal enough to permit the use of any truss that the medical staff may approve.

Last year's observations, like those of previous years, have demonstrated that no special form of truss is applicable to all cases.

**Inguinal Hernia.**—The great majority of cases being inguinal, my remarks will for the present be directed to

---

\* Read before the New York State Medical Association, September 26, 1889.

this variety. For convenience and practicability I have divided it into three degrees, as follows:

1. A simple bubonocele, where the viscus remains in the canal.

2. The hernia is without the external ring, but the canal remains oblique or intact.

3. When the canal is obliterated, and the external ring is enlarged. This last degree is practically a direct hernia.

The difficulty with which herniae of the first and second degrees are retained is usually not great when any form of truss is employed. The most satisfactory treatment has been accomplished by the following five forms of truss:

1. The spiral spring, of which there are many modifications, is too well known to call for a description. This style is especially adapted to patients that require perfect freedom of the abdominal walls, as only a leather strap is in front. In cases of the third degree it is often necessary to attach a perineal strap; even with this procedure a few exceptionally difficult cases can not be retained.

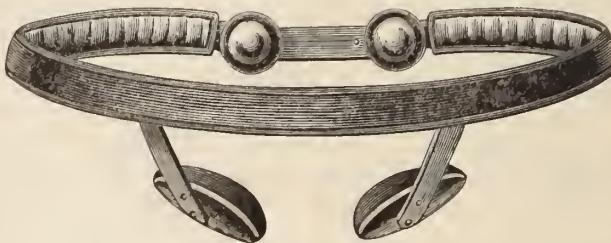

2. The Knight has a band that is almost elliptical and extends about three fourths around the body; on the end is attached a malleable shank, with a round or oval pad. The band should be so tempered that it can be fitted to the body after it is covered. The mechanism is very simple, and, with the proper adjustment of the shank, there are very few cases even of the third degree that are unmanageable. The addition of a perineal strap assists greatly in keeping the pad in position. A double truss can be made by attaching another shank about four or five inches from the end of the band that crosses the abdomen.

3. This differs from the foregoing in that it has no shank. The Seeley, which is covered with hard rubber, and the celluloid of Pennfield, are the most durable ones of this form. This truss is better suited to the first and second degrees, because pressure does not have to be made so low. It is also applicable to the third degree, but is somewhat less efficient than the Knight.

4. The complete band is represented by the Hood. This truss has a tempered bar on each side that extends from the sacro-lumbar joint to the inguinal region, where it is attached to a slotted steel plate, and these are connected by a bar that is considerably heavier than those of the side. The pads being also slotted, allows the truss to be modified to suit most all forms of inguinal hernia. With a well-fitting band, the antero-posterior pressure can be regulated by the thickness of the pad. Only in extreme cases of the third degree does a large pad have to be employed.

5. A truss that has been quite efficient in cases with corpulent abdomens and large rings is the complete band with a shank. This is simply a combination of the Hood and Knight (See cut.) The band, which is a single piece of bar steel, is fitted to the pelvis and abdomen with the patient standing. It is especially important that the band should come just beneath each anterior superior spinous process to prevent upward displacement. Although the band crosses the lower portion of the abdomen, it need not restrict its movements, because it can be arched forward without decreasing the usefulness of the truss. The shank has to be slightly longer than on the Knight, but otherwise

it is identical. The band has about the same dimensions as that of the Hood. The use of this truss has been limited to

those cases that were especially difficult to retain, and care has been taken to get a perfect fit in each instance. But for the ordinary cases of inguinal hernia it is quite unnecessary to make a truss for each when such varieties of form are at our disposal.

*Femoral Hernia.*—As the anatomical relations are much less varied in femoral than inguinal hernia, it is unnecessary to make any subdivision. This form of hernia is very rarely difficult to retain, however simple the appliance may be.

The two styles of truss that are best adapted to its treatment are the spiral spring and the Knight.

*Umbilical Hernia.*—The most satisfactory treatment of umbilical hernia in children has been with rubber adhesive plaster and a small pad. The plaster should not be changed more frequently than once a week, and should be allowed to remain two weeks if no excoriation is produced. In patients past three years a French umbilical truss can be applied, but difficulty is often encountered in keeping the pad in position. The percentage of incurable cases in children is very small, while with adults it is the reverse. As only palliative measures are usually attempted with the latter class, it is found that the abdominal supporter answers this purpose admirably.

*Irreducible Hernia.*—In the majority of cases of irreducible hernia of the inguinal and femoral types operative treatment is advised; but there is a certain number of cases of epiplocele whose symptoms are slight and who decline to be operated upon. In this class of cases the application of a simple spica with a soft pad, reapplied every day, often accomplishes partial or complete reduction after a week or ten days. This method has been chiefly effective in cases of femoral hernia.

*Irreducible Umbilical Hernia.*—As irreducible umbilical hernia is almost exclusively met with in the adult, rarely are any more than palliative measures attempted. Should no symptoms of incarceration be present, the application of an abdominal supporter usually partially reduces the mass, and this can be still further assisted by adding a large flat pad.

**A New Cure for Headache.**—“Several Moorish envoys have arrived in France. They are accompanied by a native doctor, who, judging from an account received of his *modus operandi* from the Phœcian city, seems rather given to the adoption of heroic remedies. A negro servant had a headache, and, as he had vainly applied slices of lemon to his throbbing temples, the medical gentleman took him in hand. Violently seizing the skin between the patient's eyebrows, the ‘doctor’ bit it till it bled, and then, taking hold of the man’s ears, he nearly pulled them off. But he worked a rapid cure. The headache was gone, at least so said the unlucky patient, and he ought to have known.”

FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, DECEMBER 7, 1889.

THE SENSE OF SMELL.

THERE is no other cranial nerve which presents so much to puzzle the physicist, the anatomist, and the physiologist as the olfactory. The course of its fibers from the nasal mucosa to the cortex in the temporo-sphenoidal lobe is devious and obscure, but the phenomenon of matter of various kinds imparting the sensation of odor by contact with the periphery of the first nerve is still more mysterious. With regard to light and color and all the sounds of the octave, we have long been able to conceive of their reception and differential appreciation by the cortex as due to vibration and variation in vibration rates. The wave-theory accounts satisfactorily for these visual and auditory phenomena.

There are some well-known facts concerning the olfactory sense which have always been matters of daily familiarity, but which we have not as yet scientifically interpreted. For instance, some odors, though mingled together, can still be dissociated and recognized by the olfactory nerve-ends, whereas others, on the contrary, overwhelm one another, so that one only may be perceived, the other being completely suppressed. This antagonism has been little studied, and has been generally dismissed by the physiologist under the assumption of a chemical process occurring in the mixture. As illustrating this internecine warfare among smells, the odor of almonds conquers that of musk; certain ethereal oils destroy the unpleasantness of iodoform; orris-root is employed against bad breath; sulphuric ether overcomes Peruvian balsam; camphor makes the odors of the oils of lemon and juniper, of petroleum, of cologne, and of onion disappear; and coffee and cloves have the reputation in our drawing-rooms of being inimical to certain spirituous exhalations.

There seems, then, to be a sort of strife between odors of various kinds—a strife inexplicable upon any simply chemical theory; and it is more than probable that the vibratory hypothesis must needs be accepted to account for the sensation of smell as well as for those of light and of sound. Not long ago Professor Haycroft ("Brain," July, 1888) made some investigations upon the olfactory sense, from which he drew the conclusion that the sense of smell as well as that of taste depended upon the rate of vibration of gaseous particles, and he found, moreover, a relation existing between the molecular weights and vibrations of bodies and the odors which they exhaled.

More recently Dr. Zwaardemaker, of Utrecht ("Fortschritte der Medicin," Oct. 1, 1889), has been studying the same subject in a manner to throw additional light upon the difficult problem. He has constructed an instrument which he calls an olfactometer. It consists simply of a glass tube, one end of

which curves upward to be inserted into the nostril. A shorter movable cylinder made of the odoriferous substance, or a cylinder of filter-paper moistened with any redolent matter, fits over the straight end of this glass tube. When one inhales through the glass tube no odor will be perceived so long as the outer cylinder does not project beyond the inner tube; and the further we push forward the outer cylinder the larger will be the surface of scented substance presented to the in-rushing column of air, and the stronger will be the odor perceived. The cylinder may be made, for instance, of ordinary yellow wax, balsam of Tolu, gum benzoin, cacao-butter, paraffin, Russia leather, vulcanized rubber, etc.; or it may be fashioned of porous earthenware, which may be saturated with a known solution, either in water or in oil, of any odoriferous compound whose qualities it is desired to investigate. Whatever sort of cylinder is used, it should be of a fixed size, graduated in millimetres, 10 centimetres long by 8 millimetres in diameter.

In employing the instrument one inhalation is taken at a time. A normal sensory organ under ordinary circumstances and at 15° C. will always require the same quantity of scented material for the production of the minimum of perception. This normal perceptible minimum can be accurately determined and mathematically expressed by means of the graduated cylinder. In this manner one odor may be compared with another. The unit of olfactory irritability may be termed an olfactor, its value being equivalent to the number of millimetres of the cylinder necessarily exposed in order to obtain the faintest smell from the substance used. Thus, at 15° C., the olfactor of cedar-wood has been found to be 20 mm., and that of paraffin, Russia leather, and gum benzoin each 10 mm., etc.

Should one desire to study the effect of mingling two odors, it is only necessary to saturate the cylinder of the olfactometer with one scented body and another cylinder with another. By the juxtaposition of the ends of the two cylinders, the lengths being accurately determined, the air rushing in upon inhalation through the tubes must take up and mingle the two odors. The author found by this means that whenever one outweighed the other, he perceived the one or the other smell, but that when both were in exact equilibrium, either no odor at all was perceived or at most a very weak and uncertain impression was made, which partook of the qualities of neither of the two substances employed.

But as some sort of union of the gaseous molecules could not be altogether excluded by this method, such as an indifferent osmotic or physical combination preventing sensory perception, it was deemed expedient to make use of a double olfactometer in experiments of this character. This instrument consists merely of two of the olfactometers described above, one for each nostril. The difficulty that the two nasal organs may differ in their sensitiveness must be borne in mind, and the olfactor of each determined. We may then employ different scented substances, either in minimal quantities or up to two or three olfactors. By the use of the double olfactometer one may easily convince himself that even in this procedure one odor will overwhelm another, rubber, for instance, causing the

smells of paraffin, wax, and Tolu balsam to disappear. Even with very strong excitants there is never a mingling of sensations. Either the one or the other odor is distinguished by one or the other nostril, until, by careful equilibration of the two, no sensory effect is at all perceived. Sensibility is absolutely eliminated. Each nasal half becomes in this manner completely insensible to the odor inhaled through it, although its sensitiveness is really the same as before.

A striking example of this may be observed in making use of a two-per-cent. solution of acetic acid in one cylinder and a one-per-cent. solution of ammonia in the other. Both are powerful sensorial excitants. By pushing first one and then the other cylinder forward on the nasal tubes, first one and then the other odor is strongly perceived, while at one position, the point of equilibrium, no smell of any kind is noticeable. Were such a disappearance of the effluvia observed to take place in the open air, it would naturally be supposed to be due to a chemical combination of the two substances in the form of an odorless salt of ammonium. But under the circumstances such an explanation is out of the question, and the phenomenon is explicable only upon physiological grounds analogous to the well-known compensation occurring in the gustatory sense. Dr. Zwaardemaker is, however, averse to offering any hypothesis in elucidation of the problem.

We are constrained to believe that there is something in the vibratory theory, already applied to sight and hearing, to account for these remarkable facts in the domain of smell, and that is the interference of molecular waves with each other, producing in the former cases darkness and silence and in the latter temporary anosmia.

#### MEDICAL PRACTICE IN OLD TIMES.

It is not in reading the works of ancient medical authors that one has glimpses of the general practitioner or specialist of that day in their relations to the people. From the works of Hippocrates and Galen, and from those of the skilled Arabian physicians, we learn many interesting medical and surgical facts, some of which, to tell the truth, have only recently been rediscovered and relabeled by modern practitioners unfamiliar with the experiences of their ancient *confrères*. But it is to popular writers—the poets and philosophers of the past—that we must turn for those side-lights which show us the doctor himself in his various practical attitudes. In the course of some desultory reading we may meet with such passages as abound, for instance, in the works of Epictetus. He was born toward the end of the reign of Nero, somewhere in Phrygia, and, although a Greek and a philosopher, was the slave of a Roman captain, as it was fashionable in those days for prominent Romans to add living poets, wise men, and athletes to their anthropological collections acquired from every zone.

Epictetus pictures the general practitioner in Rome in this wise: "Going about as a physician does and feeling pulses, saying to one you have a fever, to another you have a headache

or the gout; to one, abstain from food; to another, eat, or do not use the bath; to another, you require the knife or the cautery." (Book iii, chap. 22.)

Here is a little side-light upon household remedies, those familiar crotchetts of the old ladies of Rome: "Eye salves are not useless to those who use them as they ought and when they ought. Fomentations are not useless. Dumb-bells are not useless. Let him who is suffering from dysentery ask me if vinegar is useful. Seek first for the discharge to be stopped and the nleers to be closed." (Book ii, chap. 21.)

Antisepsis was exceedingly popular, as the following bears witness: "For this reason, water, oil, hands, towels, scrapers, nitre, sometimes all other kinds of means are necessary for cleaning the body." (Book iv, chap. 11.)

Here is a query for the ophthalmologist: "What is more paradoxical than to puncture a man's eye in order that he may see?" (Book i, chap. 25.)

The climatologist had also his place in Rome: "Thus also physicians send those who have lingering diseases to a different country and a different air." (Book iii, chap. 16.)

We have an occasional glimpse of the obstetrical service of those days: "To say nothing of the rest, he mnst have a vessel for heating water to bathe the child; wool for his wife in labor; oil, a bed, a cnp." (Book iii, chap. 22.)

The allusions to the aliptic art are exceedingly numerous, for the *aliptæ* were the *massieurs* and *masseuses* of that day. Massage and inunction were far more widely employed then than even now.

It seems that, through some defect in the laws perhaps, diploma mills must have been run very fast in Rome in the time of Nero and his successors. There must have been more doctors than were actually needed, and the struggle among them for practice must have presented the same edifying spectacle that we behold to-day in various places. Otherwise, how are we to explain the following? "What physician invites a man to be treated by him? Indeed, I now hear that even the physicians in Rome do invite patients, but when I lived there the physicians were invited." (Book iii, chap. 23.) "If you like, take your place in the agora and proclaim your syllogisms for sale like dealers in physic!" (Book iii, chap. 24.)

Were the foregoing passages written eighteen centuries ago or yesterday? Coming down to a little over two hundred years ago, to London, Mr. Samuel Pepys, among his famous commentaries upon the life and fashions of that time, especially at court, does not forget to mention the great representatives of our profession with due respect and honor. What color could he have added to this sketch to bring the doctors in a more-life-like manner before our mind's eye? It was written in his "Diary," September 19, 1664: "Dr. Pierce tells me, when I was wondering that Dr. Fraizer should order things of the Prince in that confident manner, that Fraizer is so great with my lady Castlemaine, and Stewart, and all the ladies at court, in helping to slip their calves when there is occasion, and with the great men in curing of them, that he can do what he please

with the King, in spite of any man, and upon the same score with the Prince; they all having more or less occasion to make use of him."

### MINOR PARAGRAPHS.

#### DEEP INCISIONS INTO THE SOFT PARTS IN DIFFICULT CASES OF LABOR.

A BOLD operation is proposed by Dührssen in the "Prager medicinische Wochenschrift," which he professes to have performed ten times. In each case the mother was saved, but all the children had died during the prolonged labor. Two of the mothers were in danger from eclampsia at the time of the operation. It is said to be indicated in old primiparae where there is great rigidity of the parts with weak pains, when there is danger from eclampsia, after premature rupture of the membranes, when the pelvis is flattened so that the head of the child will not engage in the superior strait, and when the cervix is rigid or cicatricial as a result of venereal disease, carcinoma, ulceration, or operation. The technique is as follows: No speculum is required. The cervix is seized with the fingers or with forceps, and when the tissues are well stretched an incision 3 ctm. deep is made toward the tuber ischii on each side, extending 4 ctm. up the vagina. The child is then easily removed. The hemorrhage is slight and easily controlled. After the birth of the child the wounds are drained and treated with iodoform. In cases of eclampsia an anaesthetic is not necessary. The chief danger seems at first to be that of the wounds being torn to a greater depth, but Dührssen asserts that there is no danger of this, inasmuch as the canal thus formed is sufficiently large to allow of the passage of the child's head without causing sufficient tension to tear the wounds any deeper.

#### "BISULPHATE OF MORPHINE."

A LAWSUIT interesting to the members of the medical profession as well as to apothecaries is now before the courts in Montreal. A French Canadian practitioner, wishing to prescribe quinine for a young child, through absent-mindedness wrote upon his prescription *bisulphate of morphine* instead of *bisulphate of quinine*. The paper was taken to the shop of a well-known apothecary, whose assistant, perceiving an error, at once, after the manner of inexperienced dispensers, attempted a substitution, and made up the powders with sulphate of morphine. The result was fatal. And now a curiously complicated question has to be settled by the judges. The father of the child has sued the doctor because it was through his absent-mindedness that the child lost its life. The doctor has sued the apothecary for all the damages to which the father's suit may put him. It is true, he pleads, that he ordered bisulphate of morphine, and that, if such a substance existed and if the apothecary had sent it to the child, he would be responsible, but he never ordered sulphate of morphine, and it was the sulphate of morphine that killed the child. It will be interesting to know the result of the trials.

#### LEAD POISONING FROM GINGER ALE AND SODA-WATER.

SEVERAL cases of lead poisoning have occurred within the last few months in Montreal which have been traced to the use of soda-water and ginger ale kept in bottles with metallic stoppers. A patient in the Montreal General Hospital, who is at present the subject of wrist-drop and other saturnine manifestations, acknowledges having indulged very freely in soda-water at the bar where he was serving. There was a distinctly marked lead line, and lead was found in the urine. Samples of

the "cream" soda have been analyzed by Dr. Ruttan at the university laboratory, and found to contain a very large quantity of lead.

#### A LARGE GIFT FOR HOSPITAL PURPOSES.

A VALUABLE bequest has befallen Pittsburgh, Pa., for hospital purposes, under the will of John H. Schoenberger. Eight hundred thousand dollars and a valuable block of ground have been bequeathed to establish the St. Margaret's Memorial Hospital for Incurables, to be administered under the auspices of the Episcopal Church. This large endowment will, in all, reach to nearly a million dollars in value.

#### CHRIST HOSPITAL, JERSEY CITY.

A NEW hospital building was dedicated in Jersey City, on November 13th, by a notable company of bishops and other clergy, the Governor of the State, and the mayors of two cities, along with many medical men. This hospital will be superintended by the sisterhood of St. Margaret, of the Episcopal Church, but its charities will be dispensed regardless of creed or denomination. There will be an out-patient department, a contagious disease isolation ward, maternity wards, eye and ear wards, and an ambulance annex. Dr. A. C. Post and Dr. Joseph Hilton are among those newly appointed to the consulting staff.

#### RETINAL CHANGES IN CHRONIC ALCOHOLISM.

THE "British Medical Journal" records, in its report of the Ophthalmological Society of the United Kingdom, the following results of ophthalmoscopic and microscopic examinations (made by Mr. Edmunds and Mr. Lawford) of the retinae of a man who had died of alcoholic paralysis and heart disease. The ophthalmoscopic changes consisted of widespread haziness of the retinae, without hemorrhage or localized exudation. Sections of the retina revealed slight oedema of the nerve-fiber layer in the immediate vicinity of the optic disc and well-marked oedema spaces in the outer granule layer. In these spaces there were round and oval masses of clear homogeneous effusion. The only other recorded similar case, so far as the authors know, is one reported by Dr. Sharkey.

#### THE PENNSYLVANIA "UNIVERSITY PRESS."

THE friends of the University of Pennsylvania are about to form a syndicate of publication, under the name of "The University Press." Their purpose is to control the present publications in the interests of the University and issue such new ones as seem to be needed. Four magazines will probably be on foot at the beginning of the new year. Among the supporters of this undertaking are Dr. D. Hayes Agnew, Dr. H. C. Wood, Dr. James Tyson, Dr. John Marshall, Dr. Edward Martin, Dr. J. H. Musser, and Dr. S. D. Risley. Dr. O. W. Holmes is named as having promised to contribute to the magazines.

#### MEDICAL LIBRARIES IN THE WEST.

A CHICAGO correspondent of the "Medical News" complains that that city has no good medical library. He shows that, although a large sum is presently to be invested in the Newberry and Crerar libraries, medicine has no part in the matter; and the Chicago Public Library seems entirely ready to get rid of its medical "incubus." The only important medical collection within the valley of the Mississippi, he says, "is located at Milwaukee, and is a private institution." The Chicago profession must, he thinks, rely wholly upon themselves and must

sink all other differences and antagonisms in order to build up their newly proposed Medical Library Association.

#### THE DOCTOR IN GENERAL LITERATURE.

UNDER the title of "The Pardon of Ste.-Anne d'Anray, and other Breton Pictures," Dr. William Perry Northrup contributes to the current number of "Scribner's Magazine" an exceedingly clever portrayal of some of the peculiarities of the people of Brittany, interspersed with brief but telling comments. We have before had occasion to speak of Dr. Northrup's work in general literature, and we hope that opportunities of referring to it in the future will not be lacking.

#### THE CHILDREN'S AID SOCIETY.

THE thirty-seventh annual report of the New York Children's Aid Society shows that 38,850 children were under observation and cared for, more or less, during the year; 4,500 children were received at the Summer Home at Bath, and 1,400 received the aid afforded by the Sick Children's Mission; 850,000 meals and 220,000 lodgings were supplied at the six lodging-houses and thirty schools.

#### A FIREMAN'S WARD.

A MOVEMENT is on foot to raise a fund for the establishment of a ward in some prominent hospital for sick and injured firemen and fire-patrolmen. Mr. Chauncey M. Depew and a number of well known citizens are reported to be interested in this beneficence, and its success is probably assured.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending December 3, 1889:

DISEASES	Week ending Nov. 26.		Week ending Dec. 3.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	30	6	24	10
Scarlet fever.....	53	7	40	2
Cerebro-spinal meningitis.....	1	1	0	0
Measles.....	41	5	30	5
Diphtheria.....	81	21	73	17
Varicella.....	6	0	5	0

**The "Lehigh Valley Medical Magazine."**—The Medical Association of the Lehigh Valley is about to publish a quarterly journal, of about two hundred pages annually, to further the interests of the profession in that part of Pennsylvania.

**The "Country Doctor."**—Dr. J. T. McColgan, of Arco, Tenn., has a journalistic conception under consideration and expects to bring out a new monthly, to be called "The Country Doctor," on or about January 1, 1890.

**The Death of Professor Richard Volkmann, of Halle,** is announced. He was well known in this country, not only by his personal work as a surgeon, but also by his exceptionally valuable collection of variorum "Klinische Vorträge."

**The late Dr. Walter De Forest Day.**—Dr. Day, whose death occurred on Wednesday of last week, had for many months been known to be the subject of an aortic aneurysm, and had been unable to continue his meritorious career in the service of the Health Department and as a teacher in the College of Pharmacy. His industry, precision, and amiable quali-

ties will be much missed by those with whom he was brought into contact.

**The Medical Microscopical Society of Brooklyn.**—At the meeting of Wednesday evening, the 4th inst., the order for the evening was a paper on "Technical Methods for the Central Nervous System," by Dr. E. H. Wilson.

**Change of Address.**—Dr. L. Bolton Bangs, to No. 31 East Forty-fourth Street.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 18 to November 30, 1889:*

LORING, LEONARD Y., Major and Surgeon. By direction of the Secretary of War, the extension of leave of absence on surgeon's certificate of disability granted in S. O. 241, October 16, 1889, from this office, is still further extended one month on surgeon's certificate of disability. Par. 3, S. O. 268, Headquarters of the Army, A. G. O., November 16, 1889.

MOSELEY, EDWARD B., Captain and Assistant Surgeon, is relieved from duty at Whipple Barracks, Arizona, to take effect upon the expiration of his present leave of absence, and will report in person to the commanding officer, Fort Clark, Texas, for duty at that station, reporting by letter to the commanding general, Department of Texas. Par. 4, S. O. 268, A. G. O., November 16, 1889.

FISHER, WALTER W. R., Captain and Assistant Surgeon, is relieved from duty at the Presidio of San Francisco, Cal., and will report in person to the commanding officer, Fort Assiniboine, Montana, for duty at that station, reporting by letter to the commanding general, Department of Dakota. Par. 4, S. O. 268, Headquarters of the Army, A. G. O., November 16, 1889.

EBERT, RUDOLPH G., Captain and Assistant Surgeon. The leave of absence on surgeon's certificate of disability granted in S. O. 109, May 11, 1889, from this office, is extended six months on surgeon's certificate of disability. Par. 13, S. O. 270, Headquarters of the Army, A. G. O., November 19, 1889.

HARVARD, VALERY, Captain and Assistant Surgeon. By direction of the Secretary of War, the extension of leave of absence granted in S. O. 240, October 15, 1889, from this office, is further extended one month. Par. 1, S. O. 272, A. G. O., November 21, 1889.

BALL, R. R., First Lieutenant and Assistant Surgeon, Fort Riley, Kansas, will proceed to Fort Sill, Indian Territory, and report to the commanding officer for temporary duty at that post. Par. 2, S. O. 173, Department of the Missouri, November 21, 1889.

PILCHER, JAMES E., Captain and Assistant Surgeon, is relieved from duty at Fort Ward, New York Harbor, by direction of the Secretary of War, and will report in person to the commanding officer, Fort Clark, Texas, for duty at that station, reporting also by letter to the commanding general, Department of Texas. Par. 3, S. O. 276, A. G. O., November 26, 1889.

COCHRAN, JOHN J., Captain and Assistant Surgeon. Leave of absence for fifteen days is granted, to commence about December 1, 1889. Par. 8, S. O. 272, Division of the Atlantic, November 27, 1889.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the two weeks ending November 30, 1889:*

RUSH, W. H., Passed Assistant Surgeon. Ordered to the U. S. Steamer Saratoga.

URIE, J. F., Assistant Surgeon. Detached from the Coast Survey Steamer Gedney and ordered to the U. S. Steamer New Hampshire.

BRYANT, P. H., Assistant Surgeon. Detached from the Norfolk Hospital and ordered to the Coast Survey Steamer Gedney.

SMITH, GEORGE T., Assistant Surgeon. Detached from the Army and Navy Hospital, Hot Springs, Ark., and ordered to the Naval Hospital, Norfolk, Va.

STONE, E. P., Assistant Surgeon. After examination for promotion, to await orders at Boston, Mass.

GUNNELL, F. M., Medical Director. Placed on the retired list November 27, 1889.

GAINES, J. H., Surgeon. Ordered to duty at Army and Navy Hospital, Hot Springs, Arkansas.

#### Society Meetings for the Coming Week:

MONDAY, December 9th: New York Academy of Medicine (Section in Surgery); New York Ophthalmological Society (private); New York Medico-historical Society (private); New York Academy of Sciences (Section in Chemistry and Technology); Lenox Medical and Surgical Society (private); Boston Society for Medical Improvement; Gynæcological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private); Baltimore Medical Association.

TUESDAY, December 10th: New York Medical Union (private); Medical Societies of the Counties of Chemung (quarterly—Elmira), Oswego (semi-annual—Oswego), Rensselaer and Ulster (quarterly), N. Y.; Newark, N. J., and Trenton, N. J. (private), Medical Associations; Morris, N. J., County Medical Society (semi-annual); Baltimore Gynæcological and Obstetrical Society.

WEDNESDAY, December 11th: New York Surgical Society; New York Pathological Society; American Microscopical Society of the City of New York; Medico-legal Society; Medical Societies of the Counties of Cayuga (semi annual), Cortland (semi-annual), and Montgomery (quarterly), N. Y.; Pittsfield, Mass., Medical Association (private); Philadelphia County Medical Society.

THURSDAY, December 12th: New York Academy of Medicine (Section in Paediatrics); New York Laryngological Society (annual); Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society; South Boston, Mass., Medical Club; Pathological Society of Philadelphia.

FRIDAY, December 13th: New York Academy of Medicine (Section in Neurology); Yorkville Medical Association (private); Medical Society of the Town of Saugerties.

SATURDAY, December 14th: Obstetrical Society of Boston (private).

#### Letters to the Editor.

##### DANGER IN THE RHEOSTAT.

50 N. FOURTH STREET, COLUMBUS, O., November 29, 1889.

To the Editor of the New York Medical Journal:

SIR: A rather unique and painful accident happening in my practice a few days since opened my eyes to a new element of danger in the use of electricity, and I make haste to lay it before the profession. Nearly all writers and teachers of electro-therapeutics on this side the Atlantic denounce the collector and advise the substitution of the rheostat. They maintain that the successive turning on of cells through the collector is accompanied by disagreeable shocks to the patient, and that, as certain

cells are habitually used to the exclusion of others, the battery becomes unevenly exhausted, and will require more care. Furthermore, the leash of wires running from the individual cells to the collector multiplies the chances of derangement and adds to the uncertainty of action. All this is true, and, although I was possessed of a new and elegant sixty-cell Leclanché-Gonda battery with a collecting board of the most approved pattern, I was much annoyed by these self-same conditions and added hydro-aluminium rheostat. It worked admirably, and I was seriously contemplating the entire abandonment of the collector when my rheostat began to work imperfectly. I first noticed that, owing to the increased resistance caused by its interposition, my milliammeter did not register much more than half as much with the same number of cells as without it, so that greater battery power was needed to produce the same effect. I next noticed irregular and erratic excursions of the needle and simultaneous complaints on the part of the patient that the electrical flow was irregular. I now gave the rheostat a thorough overhauling and cleaning, as I supposed; and at this juncture a young lady whom I had been treating for stenosis of the uterine canal presented herself for treatment. The electrodes being adjusted and the full force of the battery being made available, the current was turned on through the rheostat until the needle stopped at 70. All of a sudden the patient complained, and, seizing the wheel of the rheostat to turn off the current, I was horrified to see the needle bound up to nearly 350 millampères. Simultaneously the patient uttered a series of shrieks, cried out that she was dying, and lapsed into unconsciousness. Turning off the rheostat had no effect on the electrical current, and, stepping to the collector, I turned off the current as rapidly as might be without creating too much shock. Addressing myself to the patient, who lay pale and death-like, it was fully two minutes before she gave evidence of returning consciousness. Fortunately, she was a woman of good physique, and the effects soon passed off. Had she been a subject of heart disease or other serious organic lesion, it is problematic what the result might have been. On examining the rheostat critically, I found that a small flake of the smegma-like deposit that forms on the aluminium plates had floated out and adhered to the central plate, thus forming a connection that allowed the almost full force of the battery to flow through the patient independently of the immersion. I have for the time being discarded the rheostat, preferring the inconveniences, but greater safety, of the collector. Should I return to its use, I shall only turn on so many cells at once as I think the case may need.

D. TOD GILLIAM, M. D.

##### THE TYPHOID SPINE.

189 GREEN LANE, MANAYUNK, PA., December 1, 1889.

To the Editor of the New York Medical Journal:

SIR: Your issue of 30th ult. contains an article by Dr. V. P. Gibney entitled "Typhoid Spine." Less than one year ago a case came under my care which can be justly placed under that title. The history is briefly as follows:

Ella S., aged twenty-two, single. Mother living, the subject of diabetes mellitus. Father and one sister dead, cause unknown. One brother living and healthy. January, 1889, attacked with typhoid fever. The fever ran its usual course with no marked irregularities. Indeed, the only complaint made was of rather an unusual amount of pain in the loins. The temperature was normal at the end of the fourth week. She complained of nothing except excessive pain in the lumbar region on movement. Toward evening the pain would become almost unbearable—so great that anodynes were used. Careful examination was made of the lumbar region. There was no

fullness and there was no marked tenderness, but great pain on movement, always referred to the right lumbar region. The urine was normal. Vaginal, rectal, and abdominal examinations were negative. There was no pain on movement of either hip. No tenderness along the sciatic or crural nerve. Blisters over the seat of pain and continued counter-irritation were tried without much effect. After four weeks' rest in bed or a reclining chair, she was able to be out and rapidly improved. About the ninth or tenth week from the beginning of the fever she went to work. She is a finisher in a paper mill and stands all day. After one week's work she was suddenly seized with severe pain in the old situation, which again confined her to bed. She was again examined carefully with entirely negative results, except that pain was excessive in the lumbar region on attempting to rise.

Rest was enjoined, potassium iodide was given with apparent benefit, and it was suggested to fit a jacket in order to enable her to be about. She became dissatisfied and passed into the hands of a "worm doctor." After several weeks of rest in bed, however, she again recovered and has been at work for the past three or four months and is apparently well.

A diagnosis of a low grade of inflammatory trouble about the ligaments of the lumbar spine was made.

M. H. FUSSELL, M. D.

#### OCULAR DEFECTS AND THE NEUROSES.

NEW YORK, November 29, 1889.

*To the Editor of the New York Medical Journal:*

SIR: I find myself very much surprised by a leading article in your Journal of November 30th. I refer to one entitled "Ocular Defects and the Neuroses." I was present at the meeting of the Neurological Society there referred to. I heard the report of the committee, the protest and answer of Dr. Stevens, the evidence of the extra-official commission chosen by Dr. Stevens himself, and yet I failed to understand, as stated by your editorial, that six patients out of fourteen had been improved by ocular tenotomy. Now, if such a complete misapprehension has occurred on my part, it is possible that a similar one has affected other minds. I write this to ask, if it be not already the attention of your Journal so to do, that you will publish the report of the commission and the reply of Dr. Stevens in full. I hope I am not seeking too much, for it seems to me to be in the interests of fair play that those of us who have been assailed as being behind the age, because we have never been able to accept the doctrine that epilepsy and chorea are cured by operations on the muscles of the eye, should not now be deprived of the support of evidence of an impartial commission, which has presented a report overwhelmingly in favor of our side of the question.

D. B. ST. JOHN ROOSA, M. D.

##### NEW YORK ACADEMY OF MEDICINE.

###### SECTION IN NEUROLOGY.

Meeting of November 8, 1889.

Dr. LANDON CARTER GRAY in the Chair.

**Chronic Delusional Insanity; Paranoia.**—Dr. MATTHEW D. FIELD reported the histories of cases of this affection as follows:

**CASE I.**—W. E. L., male, aged twenty-nine, a photographer. The patient was committed for examination as to his sanity by Judge Murray on July 3, 1888. The history was obtained from his sister. The patient was the youngest child of a family of four children. His father was twenty years older than his mother, being fifty-six years of age when he died. The patient's father had suffered from consumption for several years, and had died a few months after the birth of the patient. During pregnancy with this child the mother had been severely taxed physically by the care and nursing of a consumptive husband. The patient had been a weak and sickly baby, and, until after the age of two years, had not been expected to survive. He had received a fair school education, but had never displayed any force of character. The only intimate friend he had ever had became insane some years ago, and was now an inmate of the Bloomingdale Asylum. On account of his delicate health the patient had been petted and indulged, and had never been able to support himself. From boyhood he had been solitary, moody, and irritable, having outbursts of passion from slight causes. Shortly after attaining his majority he went West, where he had remained some eighteen months. His family had known little of his life during this time. When he came home he brought some photographic apparatus, and said that he had acquired that art while away, and had the ambition to become an artist. He stated that he had been victimized and cheated while away. He became more moody than ever, and was sociable with no one, except one of his sisters. At times he would become much excited and harangue, his theme being usually religion. Curious pictures of his own production were found in his room, representing heavenly visions he had seen. He talked to his sister about the star of Bethlehem, and was often found gazing at the sky. He would point out a star and say: "That is the star of Bethlehem; that is my star." He frequently refused food, and said that God fed him. He asserted that he was ordained to perform certain things for the good of the world. He now began to talk more strangely, and the family learned that he had been arrested for creating a disturbance on the street. The patient had a weak face and a silly and pompous manner, poor physique, narrow and highly arched palate. The patient stated that he had been arrested for preaching on the street and attempting to stop the street cars. He had not directly interfered with the cars, but had shouted to the drivers that they were breaking the Sabbath and that the wrath of God would descend upon them, and that he had been commanded to warn them. In 1886 the patient saw three visions. He said they were revelations from God, and that in these visions it was revealed to him that he was to reform the world. These three visions had appeared early in 1886, and had never been repeated. His description of the visions was much confused, but he said he could represent them better by drawings. [The sketches made by the patient were exhibited to the meeting.] In the corners of the drawings the patient had written an explanation and description of the visions. The patient's family took him home and cared for him until September, 1887, when he was again committed for examination. His mental condition had changed but little. The same delusions existed, and the connection with the three visions was just as apparent.

This case had seemed to Dr. Field to be an interesting one of systematized delusions occurring in a feeble-minded individual, where the delusions followed and were built upon vivid visual hallucinations that had never been repeated. It was the experience of the reader that visual hallucinations were rare in cases of paranoia, and it was still more rare to find them the standing-point of delusions not yet repeated. It was more usual to find auditory hallucinations, and to have them continue and to be

come prominent factors in the delusions. He recalled, however, one other case—that of a man who had attracted considerable attention in New York a few years ago. In his case there had been a single vision, not repeated. This man could give not only the date, with the hour and minute of its appearance, but its actual duration. From the moment of this single vision he had been an altered man.

CASE II.—S. D., aged thirty-eight, married, an inventor. The family history on the paternal side was good. The father was a man of education and marked ability, but was intemperate. On the maternal side the mother was consumptive, and the grandfather and grand-uncle insane. The patient was the youngest of four children. The elder sister was a rounded character in everything—educated, refined, and practical. The next was a brother, who was odd, a good thinker, but, from his family connections, noticeably weak in character. This brother's children were markedly bright and capable. The next sister was certainly peculiar. She made much of little matters and was very erratic in actions and conversation, but was at times very entertaining. The patient was a man of magnificent physique. He had displayed marked ability from early childhood. He was considered a genius, was eccentric in some ways, and was always a poor business man. His inventions had given him a world-wide reputation. He was an erratic worker. It was difficult to get him to perfect his inventions, as, after demonstrating the principles, his interest would diminish. Some four years ago he had undertaken the management of a company where he had had much executive and business work to do, as well as the exercise of his own profession. This work had greatly harassed him and he became very irregular in his mode of living. Sleep was interrupted and he drank freely, though rarely, if ever, to intoxication. He became much run down physically, and it was thought best that he should take a rest. He started for Europe with his wife early in December, 1885. Almost as soon as the steamer left the dock he exhibited delusions of persecutions. He became suspicious of everything and everybody, and declared that there was a conspiracy to destroy him. He interpreted every action of his fellow-passengers as relating to himself. When several would be conversing anywhere he would feel sure that they were talking about him. He continued to travel, and every new sight and face suggested some new idea of persecution. After a few weeks his wife induced him to return home, which he seemed glad to do. On the return voyage his delusions became so active as to attract the notice of the other passengers. The patient was seen immediately on his arrival by the speaker, who found him almost completely given up to the contemplation of these delusions. When confined to his own home, where everything was familiar and where no strangers were allowed to see him, he was quite calm and free from these ideas, was a pleasant companion, and ate and slept well. One day the patient called at the office of the speaker and wanted the roof of his mouth examined, which was done, and a small sore discovered, the nature of which was explained to him, but he declared that it was a chancre and he knew just how he had contracted it. While on shipboard he had observed that his cigars were always given him out of a particular box, and that those cigars, infected with syphilis, had been prepared for him. He had been suspicious of the cigars, but had not been able to divine their designs until now. The explanation of this delusion was that the patient had seen a copy of the "Medical Record" that had contained an editorial on the lewd pictures of cigarette girls that were then conspicuously displayed in all of the cigar stores, and remarked that girls who would allow themselves to be photographed in such positions would be likely to acquire venereal disease, and added that it was well known that syphilis had been conveyed in

cigars. This was sufficient to convince the patient that the sore in his mouth was a chancre. When it was found that the patient was much more comfortable in his own home, a young man was found to act as a companion and keep a constant watch over him. A workshop was built at home, and here he continued his inventions and made his own models. He had continued to improve up to the present day. The speaker had observed the progress of this case, and no sensory hallucinations had been manifested; there had never been delusions of grandeur.

CASE III.—H. F., aged fifty-eight, married, clerk. This patient came to Bellevue Hospital on May 4, 1888, and asked to be sent to the Island. He was much agitated and declared that he had syphilis and had infected his family and visitors to his house. He declared that he had lost all his manhood and that he had the "blot on the brain." He wanted to be sent to the asylum, for he was sure his sons would murder him when they found out how he had wronged them. His sons had taken him home and tried to care for him. On May 22, 1888, the patient had again come to the hospital and begged to be sent to the asylum. He had expressed all the delusions as on the first occasion. He was again taken home. In July, 1888, the patient had come again to the hospital and fairly begged to be taken in. He had told how he had escaped from home by climbing out on the roof and making his way to the street. When it was decided to admit him, he quieted down and seemed much relieved. The patient had declared he was about to die, as the syphilis was consuming him. He believed that his sons had general paresis due to infection from him. The patient probably had had syphilis, but there was no physical evidence of the disease. He was sent to the State asylum at Middletown, N. Y. Under the date of November 26, 1888, Dr. Taleott wrote the speaker that the patient had not changed very much in the character of his delusions until within the past two or three weeks, when he had become more irritable and suspicious, and thought there was a conspiracy to keep him in the asylum. The delusions in this case were systematized and had existed for a long time, certainly six months, almost unchanged. Though hypochondriacal in character, they were logically reasoned out from his false conceptions of syphilis, and upon this all his delusions were founded.

Morel in 1852 had given some observations on the transformation, among the hereditary insane, of hypochondriacal ideas into ideas of persecution and afterward of grandeur. Kraft-Ebing distinguished two kinds of paranoia. First, that with delirium of persecution, which he fully described with its three stages of hypochondria. Second, that of persecution and grandeur and its sub-variety, "quarreling insanity." The speaker thought it would be interesting to learn if this patient developed ideas of grandeur in the future. He did not want to be understood as advocating the classification of this case under the name of paranoia, as he thought the term was being made too comprehensive by some. The patient's age was certainly against paranoia. It was to be regretted that the family history could not be given.

CASE IV.—Mary L., aged fifty-six, single, domestic. No family history. On admission to the hospital the patient was in a filthy, neglected condition. She resisted all interference. She said that "her husband was an officer in the upper land." "He first presented himself to me on October 1, 1868." She did not see him when he first presented himself, but was told by God's voice that on the next Sunday he would sit beside her in the pew in church. The next Sunday, October 4, 1868, she saw him in the seat with her, and she described his personal appearance. She had been and was still waiting for her husband to come with a procession and carry her away, as he had

promised to do. At times she was quite incoherent, and spoke of her father being the Heavenly Father's grandfather, etc. In this manner, and by her indifference to her surroundings and neglect of her person, she displayed much dementia. When the duration of the delusions was considered—*i. e.*, twenty years—the dementia was slight. In this case the hallucinations were auditory and were the foundations of the delusions, and continued to form a very important feature of the disease.

CASE V.—James M. D., aged thirty-three, single, canvasser. No family history, except from the patient. From his account there was no hereditary insanity. He said that he had always been considered eccentric. A lineman who had known the patient some three or four years ago stated that D. then talked much of one of the leading actresses, and believed that she, as well as many other ladies above his station in life, was in love with him, and that they were constantly making overtures to him. He was suspicious and egotistical, and would think that the actions and conversations of others related to himself. He seemed to have a fear of detectives, and would often leave his work and disappear. His own account of his life was that he had received a common-school education, and when a mere boy had started out to care for himself. For some time he had worked in a factory, and finally went West and was a prospector, and then a miner. In the mines he had made a few thousand dollars, but asserted that he had been cheated out of a fortune. Then he was a telegraph operator, and then a lineman, and lately had been canvassing for Appleton's "Cyclopædia." For years he had been trying to study and explain all natural phenomena, and was writing a work that was to elucidate all such subjects—such as the creation of the world, geology, astronomy, chemistry, etc. He believed that he had been very attractive to ladies, and that they had followed him about in disguise. He assured the speaker that he could have married ladies of rank and fortune. After the presidential election four years ago the patient had sent to Mr. Cleveland a long congratulatory telegram and volunteered his services. The patient had said that he had first seen Miss A. some six years ago, and that he had fallen in love with her and she with him. He had followed her about, as her protector he said, from place to place, and two or three times to Europe. He had never attempted to speak to her but once, and that was when she returned from Europe last September or October to fill her professional engagement in New York. The patient began at once to besiege the lady with letters and frequent calls at her hotel. On the 14th of November he was arrested, and was seen on the following day by the speaker. The patient conducted himself with quite an air of importance, and was much puffed up by the space the newspapers gave to him. He wrote a long statement for publication, which he desired to appear just as he had written it, and he wanted to correct the proof himself. When arrested he was armed with a self-cocking revolver, with five chambers loaded. There was also found in his pocket a sheet of letter paper, at the top of which was the word "Notice," and below was written, "Some time I may be found dead or in a trance; if so, you can safely say I have met with foul play at the hands of A. and that gang. P. S. No matter where my body may be found, ship it to Miss A. She will see that it is interred, and will attend to all the funeral arrangements." The speaker exhibited to the Section the photograph of the patient, and also tracings of his head, which had been made by Dr. Frederick Peterson.

The speaker then read some abstracts from the patient's statements of his own case.

"Piqued Jimmie & Mainic. M. A. visits this country on the sly to see D. After her Jimmie, while supposed to be in a convent in London. Passing over the earlier portions of our

love affair, which, tho interesting to us, might weary the reader. While in Liverpool, on my last trip to England, I was severly poisoned in a glass of liquor in the 2nd Class Refreshment Room of Northwestern R. R., Line St. Station, its effects were very severe but I managed to cure it well enough to take care of myself. The impared stomach caused by this drugging run me so low in vitality that I fear'd that I would not live to see this November So I wrote Miss A. bidding Her good bye, telling Her I probaly would not Live to see Her again. This was some time about the latter part of July last. About the middle of August I attended St. Paterick's Church in Washington to vespers. As I came out after services a womans voice sounded: 'OH! what can I do when he wont speak to me.' I may here state that from the first Miss A. refused to be formally introduced to me or answer my letters. But seemed anxious to form my acquaintance in a More Romantic way. \* \* \* I now felt certain of her, but made up my mind to let Her run awhile, as she did me in London. That night I was sitting in my room when I heard the gruff' voice of a man outside the door of the House opposite say 'You can't ever Make anything out of That dude; let 'em go.' a voice like Miss A's answered 'Cheese it. He's onto us watching Him. She evidently was standing with HIm as He uttered his advice, and She spoke Her reply as She dodged into The House. I at the Time Turning to look at Them. It was quite dark so I could not recognize what the Man was like, but from his voice believe He was a short thick-set Florid, 'Duffer like' Man, such as I seen with Her afterward in the Temple Cafe'. She then evidently took a trip away for a few Days for I heard the same young womans voice whch did The Mantering in the carriage say the following evening 'I dont know what she wanted to go away for. Shes just as crazy after Him as She can be' adding 'of course she is' to a grunt from an Elderly Man, Her Companion. This Man then in an irritable old Honest Farmer like voice said 'These actresses are a poor lot, Theyr Frauds all of Them, not only that but Theyr mean' following it up with a Tirade against acting in general. 'The next I heard of Her was Three or four evenings afterward. while sitting in my Room. picking up Her picture, gazing at it for a time, finally ending by kissing it. as I did so There was a couple of little Jesting Laughs from two females in The House opposite. and 'ha My picture. maybe He wont like Me when he sees Me,' in a sort of Happy uncertauin subdued voice from our M., who evidently was sitting with Them watching us. . . . I Then went to the Sisters orphan School near by and asked one of them to undertake the task of arranging a meeting between us. But the Sister only looked incredulous and said it was worse than a Fairy Tale, and said if Miss A. had come to Washington it would surely be in the papers. I Tried to explain to her that under The circumstances it snrely would not be in the papers, and that I would pay Her for The Trouble. \* \* \*

"The last I heard of Her she said 'Ill speak to HIm any way and if he loves me Ill take HIm Home with me.' I thought I had conquered but she evidently changed her mind or it may be that the opportunity did not occur and That she was forced to go in a hurry to attend to business or catch the ship to retrrn and fill her Provincial Engagements in England, and upon sober thought coupled with the urgent advice of Friends concluded That as I was broken the best thing to do was to give me up or she may be suffering from a bit of pique at my seeming intentional slights. I meant the Most Honorable in The world toward M. but sought to break Her Terrible Self Will. I have broken Myself instead, while Mary Sails on as of yore as a 'Ajax Defying the Lightening.' \* \* \* After this Terrible exposé I feel That all must ever be over between us, and fully realize my great loss. She has Trivial vices that cling to Her from Her

surroundings as a smoky odor. To the one who Works among it but the mind of the woman is as far Her surroundings as Heaven. Purgatory. The current belief that Mary is a piece of Marble is all wrong. She appears as cold as the cloud crested volcano to the verdant grassy Hillock as is M. compared to other women. She has possessions as Herself so far above The ordinary That the ordinary cannot understand. They watch and like but dont understand, passion, she is filled with passion and riven unknown, but the surges of the woman Heart can never do more than gurgle through and soften Her nature. The wondrous mind is ever in control. I shall feel My loss and believe M. will remember Jimmie. D.

"If the mere fact of my Running after my sweetheart without the formality of an introduction constituted a sufficient reason for my being considered insane. I am satisfied that More than Half of the now married men, have deserved this punishment at some period of their lives, also if such were the Case Mary as I show above should be sent to the Island in the same Boat with myself. if however She is suffering from a fit of Pique over my supposed slights, in Justice the statements here made should be looked into and if found True, I can only see that I have err'd more in omission than commission. That she was recognized by many during her stay in Washington I feel assnred. \* \* \* If however all that I have stated are conjured phantoms of a diseased Brain Then I am only too Thankful that I live in a country where such good institutions are provided for my welfare and shall only be happy to avail myself of the privilege of entering such. If my Brain is really affected it is probaly due to excessive study in trying to raise myself to position that would enable me to make my advances towards my M. from at least a somewhat equal station, as during the last five years I have been furthering a set of discoveries that will mark an epoch in the advance of Natural Sciences, in a Book which I am now preparing. I will give a Theory on the probal forms of Atoms. An Hypothesis on the struture and action of Molecules together with an explanation of the causes of Molecular Motion. \* \* \* \* My Manuscript as it now exists in its unfinished state will lead the easual investigator to but more thoroughly believe in my insanity. I humbly ask That it May be saved and given to me if I be put in the asylum That I may finish it before my Brain is totally gone. My private letters from my Friends and relatives have been destroyed as 'Trash.' They appear so to the authorities bnt They were not Trash to me. If my Investigators will but give me the benefit of the doubt till proven iusane, if They will look through History and find examples numerous where men not understood, were termed 'Cranks' subjected to various tortures, although they helped posterity, which now Honor Them with monuments for my own part I would much sooner have the grasp of a Friendly Hand now than a Million Dollars Monument by posterity. J. M. D. Bellevue Hospital, November 17, 1888."

In this case the delusions of grandeur had been developed slowly and had continued for years with bnt little change. Delusions of persecutions had appeared, but they had developed from those of grandeur and were in every way conditional upon them. The late appearance of the hallucinations was rather unusual. The exaggeration of the *ego* displayed throughout was very characteristic of paranoia. This case was not unlike Esquirol's estomania, a subdivision of monomania. According to Esquirol, this perversion was not necessarily accompanied by animal sexual desire, and the adjective erotic was here used in the classical sense. The patient noted in his adolescence for his romantic tendencies, construed an ideal of the other sex in his day-dreams, and subsequently discovered the incorporation of this ideal in some actual or imaginary personage, usually in a more exalted social circle than his own.

NEW YORK ACADEMY OF MEDICINE.  
SECTION IN THEORY AND PRACTICE OF MEDICINE.

*Meeting of November 19, 1889.*

Dr. R. C. M. PAGE in the Chair.

**The General Therapeutic Action of Electricity.**—Dr. A. D. ROOKWELL read a paper on this subject. He thought that few who were now using electricity in the treatment of disease stopped to consider the effects of the passage of currents through living tissues, or upon what was based the *rationale* of every electro-therapeutic result. The literature on this subject had accumulated beyond measure, but still showed so little correct appreciation of its physics that it was necessary to emphasize the statement again and again that electricity was not a simple, single manifestation of natural force, but that it was a generic term, which included complex phenomena with wide variations and manifestations. Electricity was, according to the speaker, a stimulant of the most powerful character, and an irritant when this side of its nature was sought after. As a sedative, in some cases it was unequaled. Admitting the recognized significance of the word tonic, and that remedies for improving the tone of the system still held an important place in the classification of the *materia medica*, it was the opinion of the speaker that electricity should be classed as a tonic of very high order. It possessed varied influences of this kind, according to the kind of current used and the method of its application. To produce that tension of the nervous system and of the muscular fiber generally, so as to enable them to respond to their natural stimuli, the mechanical effects of the faradaic current seemed to be especially applicable. This was a current of alternation, with a to-and-fro motion, dependent on the closing and breaking of the current. Unlike the galvanic current, it possessed no chemical action which need be feared, and no powerful reflex effects need render one unduly cautious in its use. In the passage through the body of a current interrupted with the requisite degree of rapidity, it need produce no appreciable muscular contractions, yet it gave passive exercise to all the deeper layers as well as to the superficial muscles. Aside from the purely mechanical effects of the induced or faradaic current, there seemed to be a more subtle influence upon the nerves themselves. No purely mechanical influence could produce the numerous phenomena that followed its use in some diseased conditions. In the tedious period of convalescence from the protracted fevers, electricity in some of its forms had done good service. It gave passive exercise to the muscles; it promoted and rendered more natural the processes of secretion and excretion; it corrected circulatory disturbances, and gave tone and strength to both nerve and muscle. The writer said that those who had failed to get good results in the use of electricity were either deficient in experience, or were not sufficiently persistent, or had somehow failed in the technique of application. Some of the results in electro-therapeutics were due in a measure to physical effects. Judging from analogy, as well as from facts, there could be little doubt but that an appreciable degree of heat was excited. All conductors of electricity became heated more or less, according to the degree of their resistance. As the body offered great resistance, a certain proportion of the electrical force must be converted into heat. The physical effect of electricity on metals was well known. It was said by some writers that the copper wires used to conduct the faradaic current broke more frequently than when used to conduct galvanic currents. The chemical or electrolytic action was practically confined to that form of dynamic electricity that was termed galvanism. Its visible effects occurred in the department of electro-surgery, when needles or pointed electrodes

were used. A distinction had been made, and justly, between electrolysis and galvano-chemical cauterization. The former was a disintegrator and separator of the constituent elements of organized structures. The latter produced its effects by means of the acids and alkalies that were liberated at either end of the pole by electrolytic action. It was the chemical galvano-cauterization, and not the electrolysis, that accomplished most of the good results that followed intra-uterine applications in cases of endometritis. The action of either current modified the physiological functions in various ways. It had been readily demonstrated how the secretion of salivary glands could be increased. Mucous secretions were very quickly increased by either current. In the writer's own experience, the electrical treatment had sharpened the appetite, quickened digestion, and relieved constipation so rapidly and decidedly as to make it evident that the gastric and intestinal juices were all made to secrete more liberally, and that the action of the current was on the nerves that supplied these organs, rather than on the tissues of the organs themselves. Among the affections of the bowels where electricity was quite certain to exercise a beneficial effect were those of defective innervation; also those diseases comprehended under the names of hypochondriasis and neurasthenia. Its influence over the circulation, on the arteries, veins, and capillaries was due to its power to increase the quantity and quality of innervation received by them.

Dr. C. L. DANA, in opening the discussion on Dr. Rockwell's paper, said that he should like to make special allusion to the therapeutical value of static electricity. In this form the electrical fluid, or ether, was in a state of stress or strain, and might be likened to a thin rubber band stretched to its utmost. When the strain was relieved, a disruptive discharge took place. According to another analogy, static electricity was like a thimbleful of water raised to an immense height; when spilled it gathered such momentum in its fall that a severe blow was struck. If the thimble was continuously filled and as rapidly emptied, we had a succession of static discharges which formed an intermittent electrical current. The electro-motive force produced by the fall was immense, being over 33,000 volts, but the resistance met was very great, and the quantity of the fluid small, so that the total effect, or current strength, was ordinarily not great. The static current, so called, was made up of successive and almost infinitely brief discharges from the positive to the negative, with accompanying numerous oscillatory discharges. A single disruptive discharge consisted of a principal discharge, or current from positive to negative, with numerous minor oscillations. By using small Leyden jars which filled and discharged quickly, this current could be made almost continuous, and could cause chemical effects. The intensity or current strength was the amount of electricity passing through a given space in a second of time. The static discharge occupied such a fraction of a second that its intensity or current strength was hardly measurable. But its voltage or electro-motive force was, as already stated, immense. The intermittent current produced was therefore a peculiar one. The muscular contractions caused by static electricity had been stated to be due to a purely mechanical effect. This was, in the writer's opinion, a wrong view to take, for the reason that the sparks caused contraction when applied directly to the muscle, while mechanical irritation sufficient to cause contraction of a whole muscle must be, under clinical conditions, applied to the motor points. Also because there was no apparent mechanical irritation in the ordinary sense when the static current was applied with wet electrodes. In the case of the spark there was a sudden expansion of the skin at the point of contact from heat, but no deep mechanical disturbance. It was thought the spark acted like the secondary current of a faradaic battery, causing no measurable electro-

tonic effects. The static electricity was applied in the form of a disruptive discharge or spark, in the bath and breeze, and by the current. The effects of the spark were well known, but the effects of the bath and the breeze had been inadequately stated heretofore. When a patient was seated on an insulated stool and charged, a series of discharges was going on from all points of the body. This produced a cutaneous stimulation and a mental effect. The cutaneous stimulation had in some cases a peculiar physiological and therapeutical effect. It was by no means psychical, but belonged to the same class of physiological phenomena as those of metals. The static current could be used with moist sponge electrodes directly through the clothes, or with wet electrodes upon the skin. This current caused contraction of the muscles. The special advantage of the static battery was in paralyses with some spastic element, and in monoplegias and paraplegias. Outside of this, its best results were in chronic muscular rheumatic and myalgic conditions, also in sensory disorders.

Dr. J. H. GUNNING said that he did not propose to enter into the mysteries of electricity, but would simply give his experience as to its therapeutic action. His work in this direction had been principally confined to the use of static electricity. The faradaic current he believed to be very valuable as an emmenagogue and also as a sedative. Excellent results were got from its use, especially when given in conjunction with drugs in some forms of peritonitis and in some forms of obstinate vomiting. The results of his observations in the use of static electricity corresponded with those of Dr. Dana. He found that from the application of static electricity with the wet sponge directly to the nerve in certain forms of facial paralysis, instead of a treatment extending over five or six months, as necessitated by other electrical methods, the patients were entirely restored at the end of six weeks. He thought that the static form would prove most serviceable to the general practitioner. The galvanic method was of value as an emmenagogue and in cases of weak uterus where stimulation of that organ was indicated.

**The Auriculo-ventricular, Presystolic, Sound.**—A paper on this subject was read by Dr. H. D. CHAPIN. The presystolic, auriculo-systolic, or auriculo-ventricular murmur had been the subject of much discussion and acrid controversy. In 1841 Gendrin had called attention to a presystolic murmur, and Fanvel in 1843 considered it to be due to mitral obstruction. This view seemed to have been accepted at that time, but some years later Dr. Barelay advanced the idea that a mitral obstructive murmur had no existence in fact, the sound usually attributed to this condition being really due to regurgitation. This dispute had recently been renewed by Dr. Dickinson, in the columns of the "Lancet," in 1887, who denied that the so-called presystolic murmur was indicative of mitral stenosis. The latter gentleman regarded the murmur as covering the first portion of the systole up to the point of closure of the valve, and named it rather an early systolic murmur. Gairdner, Balfour, Bristowe, and others had vigorously replied. Dr. Bristowe had summed up the arguments in favor of the presystolic nature of the murmur as follows: 1. That it accorded with the physiological fact of the auricular contraction running with the ventricular systole, the beginning of which was indicated by the very sound that terminated the murmur. 2. That the murmur preceded the pulse and ended with the apex beat. 3. That the presystolic murmur did not differ in quality from the earlier mitral murmurs which were acknowledged to be direct. 4. That all the direct mitral murmurs were characterized by consonated noisiness and lack of penetrating power, and were audible over a curiously restricted area, but were not conveyed into the axilla as all regurgitant mitral murmurs were. Finally, post-mortem examinations not infrequently revealed a condition of stenosis of the mitral valve.

Dr. Chapin's conclusions had been derived from clinical studies alone, and were intended to be suggestive rather than dogmatic. He said a presystolic or auriculo-ventricular murmur was produced by some interference with the normal and easy passage of blood through the auriculo-ventricular septum or valve. The murmur was rough in quality, beginning at the end of diastole and ending abruptly with the systole. In rhythm it might be considered metadiastolic as well as presystolic. One of the most characteristic points about this murmur was its abrupt termination. This quick stop of the abnormal bruit was very different from the gradual ending of a mitral regurgitation murmur. Almost all of the authorities the speaker had been able to consult considered that the presystolic murmur was invariably due to organic disease at the mitral valve. There was a class of cases, however, in which this sound was distinctly heard, which the speaker believed to be entirely free from organic heart disease. The class referred to was that of growing children, especially girls, who were pale and hydramic and suffered from various digestive disturbances. These cases were not only subject to palpitation of the heart, but at times, especially after exercise, a more or less rough presystolic murmur might be heard at the apex. Many of these children had been confined for a long time in crowded or badly ventilated school-rooms. Possibly they were over-anxious in their studies, but, at any rate, were in a condition of defective nervous equilibrium. Under treatment with iron, cod-liver oil, nutritious and easily digested food, with plenty of fresh air, the abnormal heart sound had often disappeared. It had seemed to the speaker that the trouble in these cases was due to an irregular muscular action, dependent upon a defective innervation of the heart. Weak children had an especial tendency to a faulty, over-irritable action of the muscles, both voluntary and involuntary. This might show itself in the incontinence of urine, or by twitching of certain muscles of the face, or it might eventuate in general chorea. Why might not the innervation of the heart be affected with or without any of the disturbances just mentioned? In such a case an irritable, strongly acting auricle, with a mitral valve whose muscles were too tense, might be a cause of a blubbering sound just before the systole. The sound produced by any such irregular muscular action would be intensified by the watery condition of the blood. Undoubtedly a large proportion of cases of presystolic murmur were due to organic valvular trouble. Meigs and Pepper stated that mitral obstruction was comparatively frequent in childhood. Goodheart considered that in children under eight years of age this lesion was almost unknown, but with advanced years the affection became more common, and was one of the most frequent affections of adult life. Eustace Smith considered that mitral stenosis unaccompanied by insufficiency of the valve was not common in the child. The speaker had in his possession the histories of forty cases of mitral stenosis that he had been able to keep under observation for different lengths of time, varying from a few weeks to several years. The ages varied from two years to that of adult life. In thirty-one of the cases there was simple mitral obstruction, while in nine cases there were combined murmurs. Of the latter, five were double mitral, three were double aortic and double mitral, and one was a combined mitral and pulmonic obstructive murmur. The commonest symptom of slight degrees of mitral obstruction that the speaker had noted was that of pain and dyspnea on exertion. The pain was directly referred to the region of the heart. It seemed as if the labored action of the heart to pass the blood through a partially constricted auriculo-ventricular septum produced a neuralgia in some of the adjacent nerves. A slight dry cough was more or less frequent. The speaker thought that a careful examination of the heart would explain a certain proportion of cases of obscure developmental trouble and poor

vitality in children that could not otherwise be accounted for. It was interesting to note the connection of this murmur with rheumatism. Out of thirty-one of the speaker's cases, twenty presented evidences of rheumatic taint. From the records of the London Hospital for 1880, only fifty-eight per cent. of the cases of mitral stenosis presented a history of rheumatism, while seventy-seven per cent. of the cases of mitral regurgitation were rheumatic. In 1886 the speaker had read before the Academy his conclusions based upon a study of seventy-six cases of rheumatism in children. Of this number, twenty-six patients had had valvular disease of the heart. Of the twenty-six, only four had presented evidences of mitral obstruction, while eighteen had had mitral regurgitant murmurs. In making a diagnosis of the mitral direct murmurs, it was well to remember that they often varied in intensity according to the action of the heart. It was the custom of the speaker to have the patient jump up and down in a vigorous manner before auscultation in any suspected case. If we regarded the prognosis of mitral stenosis from a theoretical standpoint, it would not be good, owing to the comparatively limited compensation that was possible; but, as a matter of fact, the prognosis was believed to be exceedingly good. The only instances of death in these cases that the speaker knew of were in those who had had regurgitation combined with the stenosis. But most of his cases had been in young children, when death from any form of cardiac disease was not common. The treatment should be hygienic, with tonics if required. These patients had best be kept under observation so as to meet indications as they arose, just as in any other form of cardiac trouble.

It was frequently the experience of physicians to be called upon to treat cases of valvular disease of the heart when it was impossible to trace back to the inception of the trouble. The patient might not be able to give a history either of rheumatism or endocarditis, but sought advice for dyspnoea, swelling of the extremities, or other symptoms of failing circulation. It was the opinion of the speaker that a large proportion of the cases of valvular disease in the adult had begun in childhood. The beginning of the trouble, which was the most hopeful period for treatment, was overlooked for a number of reasons. The nature of the rheumatism that attacked children was often obscure, and several attacks of wandering or so-called "growing pains" might be overlooked. In most of the histories of valvular disease in children the cardiac affection seemed to come on after several attacks of rheumatism. Great care should be exercised to make an early diagnosis, and vigorous measures taken to combat the first manifestations of rheumatism in children, fearful that, although the heart might escape the first mild attack, it might suddenly and unexpectedly become affected by an equally light manifestation of the disease. When endocarditis ensued, the symptoms were apt to be very obscure. Palpitation, slight pain, and breathlessness, with a dry cough, might not be particularly noticed by the parents, although the child would seem sicker than before. These patients were often taken to the dispensaries, and the mother would be quite surprised to learn that her child had incipient heart disease. Just at this juncture rest was indicated above all things. If this was not procured, the delicate, softened heart muscles quickly underwent dilatation, followed by permanent damage to the valves. Dilatation very readily took place in early life. Compensative hypertrophy, however, quickly ensued, although there might be no sign of it until years later. By recognizing the endocarditis at the start and keeping the child quiet, we might reasonably hope to avoid dilatation and consecutive crippling of the valves.

Dr. ANDREW H. SMITH said he was not one of those who believed that there was any essential difference between a dia-

tolie and a presystolic murmur. He thought the same conditions existed in both, the difference being only in the degree or character of the obstruction at the auriculo-ventricular opening. If this was greatly narrowed or irregular, a murmur would result which would be audible in diastole. If, on the other hand, the obstruction was not very great and the irregularities were not marked, and there was a comparatively easy flow of blood during the quiet part of the diastole, no murmur would exist until the current was quickened by the auricular systole. A great many murmurs were credited with being presystolic which were in reality systolic. The difficulty lay in defining at what instant the systole began. It was now universally recognized that normally the first sound of the heart occurred at the first instant of systole. It had been said that before the first sound there was still another murmur, but this did not necessarily precede the initial action of the systole. Frequently this was of a soft character, and disappeared after a brief duration. It occurred in cases where the muscular walls of the heart were defective, and where there existed a certain amount of dilatation, and it was not difficult to arrive at a definite explanation of the condition of things. If the normal diameter of the ventricle was represented by four and the length of each of the opposite chordæ tendineæ by two, then, in the event of any weakness in the heart muscle, the diameter of the ventricle was increased to five, while the sum of the length of the chordæ tendineæ remained four at the moment of systole. When the chordæ tendineæ were tense, a space would be left equal to one; so that, with the diameter of the ventricular cavity as five and the combined length of the chordæ tendineæ as four, coaptation of the valves could only take place when, in the progress of the systole, the former was also reduced to four. The resultant reflux of blood would then give rise to a murmur which would have the character of a presystolic murmur, though really systolic, and he believed many of these murmurs were of this character. It had been asserted that in these cases there existed a permanent systolic murmur due to dilatation of the auriculo-ventricular ring, so that the curtains could not reach across the increased diameter of the auriculo-ventricular opening. That applied more to permanent cases, and in that class it would be found that the murmur was distinctly systolic—a first-sound murmur. He had been much interested in what the author of the paper had termed the tolerance of children to this grave lesion. As an instance of this he would cite the case of a boy of three years and a half of age in whom the murmur was so loud and harsh that it could be heard two or three inches away. He had apprehended the most serious results, but as time went on nothing happened, and the boy was now about ten years old and seemed to be very little inconvenienced by his heart lesion. The murmur was still there, however, but very much modified in intensity, and could not be heard unless the ear was applied to the chest.

Dr. W. H. KATZENBAUGH said that as to the frequency of mitral obstruction murmurs his experience accorded with that of the reader of the paper. He had lately analyzed carefully murmurs occurring with the systole of the heart. He had found that out of one hundred and twenty-eight cases of mitral obstruction murmurs, sixty-seven were in combination with mitral regurgitation. He had met with this murmur in comparatively few young children, but it was frequent in young women averaging about twenty-three years of age. He thought when doubt existed as to diagnosis, comparison of the aortic and pulmonic sounds would sometimes aid in forming a conclusion. Change of position or a moderate amount of exertion would frequently make this murmur quite intense. In mitral stenosis one symptom was often met with—namely, spitting of blood; in advanced cases especially this often took place.

Dr. A. L. LOOMIS said he had not supposed that any doubt existed in the minds of experimenters on the question of presystolic murmurs. There had been a time when this point might have been raised. He had been accustomed to divide presystolic murmurs into three classes—the anaemic, the congenital, and those that were due to chronic endocardial conditions. The anaemic murmurs were unquestionably produced in the same way as in the cavity of the heart. These murmurs would be present for a time, disappearing to return again. Congenital mitral stenosis was not of infrequent occurrence. He remembered an instance where a murmur from this cause, with a purring thrill, was quite distinctly present in each of three sisters, whose ages ranged between eight and sixteen. From neither of them had he been able to elicit anything which would lead to the conclusion that the murmur was developed after birth. It seemed then that there certainly did exist a congenital mitral stenosis which did not interfere with the comfort of the patient. In children the heart sounds, it must be borne in mind, were intensified and slight murmurs would sound very loud, from the thinness of the chest walls and the comparatively greater area over which the sound was distributed. Consequently, murmurs heard in children sometimes seemed very terrible. As to the murmurs due to endocarditis, it seemed to the speaker that any one who had observed these during life and noted carefully the post-mortem appearances would not hesitate to conclude that the adhesions of the valves giving rise to the "button-hole" slit was sufficient pathological change to produce them. There were several varieties of systolic murmurs—the presystolic, systolic, and metasystolic. A pure systolic murmur was the one which we had in mitral obstruction with regurgitation, whereas in pure mitral regurgitation without any obstruction, the first part of the systole would probably be heard, and then the murmur came later, and was metasystolic. After all, it seemed to the speaker that a great deal was heard about cardiac murmurs, but the really essential point for consideration was the cause of cardiac diseases. Still, as had been stated, some conditions of the heart seemed to exist, giving rise to heart murmurs, which, however, did not in any way interfere with the patients and which did not appear to have any pathological significance. Every family practitioner was familiar with the occurrence of endocarditis in children of rheumatic habit or heritage, and who developed the endocarditis before the signs of the rheumatic dyscrasia manifested themselves. Pericarditis and endocarditis occurred frequently and simultaneously in some children. When the possibility of infectious diseases was considered as a cause in producing endocarditis in children it would be seen how common it must be for them to have inflammatory heart complications. If the nutrition and general health were preserved, and adequate compensation was established, many of these patients went on to middle life before any symptom arose indicating valvular changes.

Dr. H. N. HEINEMAN gave the statistical results of a large number of cases in which he had made careful analyses as to the exact character of the murmurs. The observations had included 300 adults and 153 children. He found that  $\frac{2}{5}$  of the cardiac murmurs in cases of the children were mitral obstruction murmurs, while in adults the proportion was only  $\frac{4}{5}$ . He would like to know what became of the patients with these presystolic murmurs. He thought that no cardiac affections should be diagnosed by the character of the murmurs present, but rather by combined signs, such as changes in the size of the heart, changes in the valves, and the sphygmographic tracings. He thought that from what had been said it must be accepted that there existed such a thing as a presystolic murmur, that it occurred most frequently in children, and that though it apparently disappeared, it did not really do so, but became, in

later life, merged into some mitral and aortic lesion and thereby lost its identity.

Dr. E. G. JANEWAY said there was no serious doubt as to the existence of a mitral stenosis and of a mitral presystolic murmur indicative of it. After describing the theories as to the production of the cardiac murmurs under discussion, the speaker said that those cases in which mitral stenosis was marked and in which the murmur ceased had given rise to a great deal of argument. Any one who had watched patients with mitral stenosis for years would have noticed that they came and went from the hospitals, until they came in finally with various symptoms and complications, such as cirrhosed liver, dilated right heart, and dropsy. The presystolic murmur was, however, gone, and in its place would be heard a mitral regurgitant murmur. As regarded the murmurs due to dilatation of the ventricle, he was in the habit of classing these under the head of mitral systolic rather than mitral presystolic, as they occurred with the systole. Whether due to anaemia or to some weakness of the heart walls, causing temporary inefficiency, the prognosis in mitral stenosis was, in the speaker's opinion, by no means hopeful. It seemed to him that these cases disappeared because the patients died. Where it was possible to follow them up it would be found that many died suddenly.

The question was then further discussed by Dr. J. L. SMITH and Dr. THOMPSON.

The CHAIRMAN remarked that, while he would not dispute the fact that some of these many murmurs of which they had been hearing might be functional, still he felt bound to say that his experience led him to the conclusion that they were always associated with some organic lesion.

#### ROYAL ACADEMY OF MEDICINE IN IRELAND.

##### SECTION IN PATHOLOGY.

*Meeting of Friday, November 1, 1889.*

The President, Dr. E. H. BENNETT, in the Chair.

**Fracture of the Skull with Hernia Cerebri.**—Dr. T. EVELYN LITTLE made a communication on a case of fracture of the skull, with hernia cerebri, in a child. The patient died on the fourteenth day in an attack of convulsions, there having been no symptom whatsoever pointing toward a fatal result until a few hours before death. At the post-mortem meningitis was found over both hemispheres, with an excavation in the frontal lobe corresponding to the seat of the injury.

The PRESIDENT said the disproportion between the injury to the bone and the injury to the brain was fully borne out by experiments, which had demonstrated the great elasticity of the skull in children.

Dr. SWANZY said the feature of the case which had interested him most was the symptom of the turning of the head toward the side on which the injury was situated. As Dr. Little had mentioned, that was generally associated with rotation of the eyes in the same direction. There was a conjugate deviation of the eyes and head toward the same side. But there might be one part of this duplex symptom without the other. In health a very discursive motion of the eyes to one side was usually associated with a motion of the head in the same direction; nevertheless, by a slight effort of the will it was possible to turn the eyes while the head was kept steady, or to turn the head while the eyes were kept fixed. Consequently one need not be surprised if in any diseased condition he occasionally found one part of this duplex symptom without the other. With regard to the position of this center of motion of the head and eyes, Ferrier,

by experiments made some years ago on monkeys, had satisfied himself that it was in the superior and posterior parts of the middle frontal convolutions. Some time afterward Grasset had argued from clinical observations that the site was in the inferior parietal lobuli. Later still the site had again been placed by Horsley in the frontal lobe. A few months ago Wernicke had ascertained to his complete satisfaction that it was situated in the inferior parietal lobuli; and now Dr. Little placed it in the frontal lobe.

DR. LITTLE, in reply, admitted that there were different theories with respect to conjugate deviation of the head and eyes. As to the deviation in this case having been due to some more distant lesion of the brain, he felt some difficulty in adopting that supposition. Although the amount of brain substance lost was very considerable compared with the injury, still it was remarkably definite and remarkably local; and these circumstances were of importance in connection with the question of localization. To say that the lesion here might have produced symptoms of interference with centers in other parts of the brain was no more than what could be said with respect to any lesion, traumatic or from disease, in any part of the brain.

**Renal Calculus.**—Dr. J. K. BARTON communicated a case of renal calculus which had been successfully removed by operation. The calculus had been tightly wedged into the calices of the kidney.

DR. FOOT asked if there had been any history of hæmaturia in the case. That symptom was an obvious one in the diagnosis of renal calculus; still he should not have thought it likely to occur here, on account of this being a fixed calculus.

DR. BARTON, in reply, said the patient had no hæmaturia. The urine was faintly acid, but became alkaline after it had stood for some time.

**Conjunctival Cyst.**—Dr. J. B. STORY submitted a conjunctival cyst which had been removed from the eye of a baby aged six weeks. It was attached to the cornea and sent a band backward to the internal rectus muscle, from which it had to be raised by a strabismus hook. The cyst was a dermoid, and Mr. Scott exhibited microscopic sections of its wall.

Mr. Story commented upon the presence of these dermoid cysts in cases of coloboma of the lids, and dermoid bands uniting the globe to the skin of the face, and stated his approval of the theory of Van Duyse, who attributed all these defects to the existence of amniotic adhesions in embryonic life.

THE PRESIDENT remarked that adhesions between the amnion and the surfaces of the embryo were the greatest cause of these congenital defects.

**Tubercular Kidney.**—Dr. HEUSTON submitted an example of tubercular kidney in a boy aged thirteen, which had been successfully removed by operation, and said there were microscopic specimens of the kidney on the table showing the giant cells and other evidences of tubercular disease. He had been unable, however, to detect in these specimens the *Bacillus tuberculosis*.

## Miscellany.

**The New York Academy of Medicine.**—At the next meeting of the Section in Surgery, on Monday evening, the 9th inst., Dr. George E. Brewer will read a paper entitled "Accidents, Complications, and Results following Internal Urethrotony in 120 Cases of Stricture," the subject to be discussed by Dr. F. N. Otis, Dr. R. F. Weir, Dr. F. R. Sturgis, Dr. A. G. Gerster, Dr. R. W. Taylor, Dr. L. B. Bangs, and Dr. Eugene Fuller; Dr. George G. Hopkins, of Brooklyn, will present a

eurette for the male bladder, and Dr. F. N. Otis will demonstrate the finished litholapaxy evaeuator.

At the next meeting of the Section in Pædiatrics, on Thursday evening, the 12th inst., Dr. L. E. Holt will read a paper on "The Anatomical Characters, Nomenclature, and Treatment of the Diarrhoeal Diseases of Infancy," the subject to be discussed by Dr. W. P. Watson and Dr. A. Caillé (the dietetic treatment), Dr. H. Koplik and Dr. A. Seibert (the mechanical treatment—irrigation), Dr. J. H. Fruitnight (the use of opiates), Dr. S. Baruch, Dr. H. D. Chapin, Dr. G. B. Fowler, Dr. J. E. Winters, Dr. A. Jacobi, and others.

At the next meeting of the Section in Neurology, on Friday evening, the 13th inst., Dr. Graeme M. Hammond will read "A Contribution to the Study of Exophthalmic Goitre," and show a patient; and Dr. M. Allen Starr will read a paper on "The Relation between Peripheral Irritation and Nervous Phenomena."

## ANSWERS TO CORRESPONDENTS.

**No. 301.**—We think the board is not now in session. Notices of the times and places of its sittings are published by us from time to time.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inscribed when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

## Lectures and Addresses.

### THE CARTWRIGHT LECTURES

ON

### VITAL AND MEDICAL STATISTICS.

DELIVERED BEFORE THE ALUMNI ASSOCIATION OF  
THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK,

November 14, 20, and 22, 1889.

BY JOHN S. BILLINGS, M. D., LL. D., D. C. L.,  
U. S. ARMY.

#### LECTURES III AND IV (ABSTRACT).

THOSE of you who are familiar with the history of medicine in the early part of this century will remember the great anticipations which were formed and expressed by prominent physicians as to the results which might be expected from what was called the system of statistical medicine, introduced in the Paris school by Louis and his contemporaries. This was not exactly a new system, but rather an attempt to methodize an old one—*i. e.*, to present the experience of different physicians in such a way that comparisons might be accurately made and the results mathematically expressed.

In this so-called numerical method all the details of each case observed are to be noted as far as possible without any special regard to whether these details may appear to the observer to have any special connection with the course of the case or its termination, or not. When a number of such cases have been collected, they are to be compared in all their details, showing in round numbers how many present such and such particular circumstances and how many do not.

In order to make a useful application of this method, it is of course necessary that the different observers shall be describing substantially the same thing; that is to say, the disease to be observed must present a definite series of symptoms, so that a person properly qualified will recognize its existence without any liability to error. It should also be a disease which follows a tolerably regular and definite course, having a commencement which can be recognized. Such forms of disease include the so-called specific diseases and acute affections of particular organs. The method is most applicable to surgical cases of all kinds, including those which come under the domain of the various specialties.

As regards details of pathological anatomy, it has been pointed out by Dr. Flint that the statistical method can only apply to those changes which can be appreciated by the senses after death, and that, there being but one constant lesion found in typhoid fever—viz., the softening of Peyer's patches in the small intestine—the statistical method gives us little assistance in the investigation of the pathological condition of this disease.

We may note, however, that—if it be admitted that typhoid fever is due to a specific bacillus, as seems now to have been fairly demonstrated, and that this bacillus has been discovered and verified mainly by the application of

experimental methods—it is nevertheless true that the results thus obtained have met with a general and prompt acceptance, mainly because the application of statistical methods to the circumstances of outbreaks of this disease in different communities are in perfect accord with the bacillus theory of its causation.

This merely illustrates the general law that the experimental and the statistical methods must be used together, and that their results must be in accord to produce full confidence in the results obtained by either alone.

It must be admitted that the probabilities of error are much greater in medical than in vital statistics, and this for a number of reasons. The first is that no two observers examine or interpret a disease in precisely the same way, and hence it is extremely difficult to collect a mass of observations sufficiently large to form a basis for statistical reasoning. Those who wish to be scientifically accurate in the use of such material are usually compelled to deal with a very limited number of observations, because they can not obtain a large number upon which they can fully rely.

The best data are, for the most part, those which lie in the field of surgical observation, since here the symptoms observed, the methods of relief applied, and the results obtained are tolerably definite, and there is not likely to be much difference in the methods of recording them.

The methods of medical statistics differ fundamentally from those used by the vital statistician in that they usually have no relation to the phenomena observed in the normal, healthy, living population. The physician inquires, out of a thousand cases of children or of old persons that have been treated, how many times this particular disease has been met with; or, in a given number of cases of this disease, what proportion have died. This method is in fact practically the only one which is available to the physician, but the vital statistician, if dealing with disease, will want to know the probabilities that a male between twenty and thirty years of age will contract a given disease, such as phthisis or typhoid fever, and for this purpose he wishes to know the whole number of cases observed in a given population, and the number of the population furnishing those cases, in order to establish the ratio.

The fact that in each case of sickness there are many different circumstances which combine to produce the result is not, as Louis remarks, a valid objection to the use of statistical methods for the purpose of estimating the influence and relative importance of each of these influences; it is rather an argument in favor of their employment. Counting is better than guessing, and when it gives contradictory results as applied to two groups of cases, it indicates that some circumstances have not been taken into sufficient account, and that further inquiry is necessary. In the body of the sick man, as in the test tube, like causes under like circumstances will produce like effects.

Admitting that the chances of error in medical statistics are very much greater than in those relating to vital statistics, it does not follow that they have no value. It simply increases the desirability of collecting a large number of facts before proceeding to draw any definite deductions.

In statistics in regard to therapeutics we have to take account of the various influences which the condition of the organism exerts upon the results before we can fairly estimate the action of the new and special influence which has been introduced in the shape of an action of a drug, or a particular mode of treatment. In any event, such statistics, even when derived from a small number of cases, serve to indicate lines of investigation and to ask questions, if they do not answer them. As Legoyt remarks, two pneumonias do not resemble two dice, each having the same number of faces and of numbers, but rather dice with an unequal number of faces and different numbers.

The greater part of our pathology and therapeutics has not been derived from statistical observation. It is not by this means that the diagnosis of small-pox, or of scarlet fever, or of rheumatism, has been worked out, or the fact that the ulceration of the intestinal glands belongs to typhoid fever, or the presence of gummy tumors to syphilis; nor has it been by this means that the transmissibility of certain forms of disease by contagion has been proved. Whenever a necessary and logical connection between a particular cause and the resulting phenomena has been established, statistics are of little or no value in demonstrating the connection. In every case the result must follow the cause, as it does in a chemical experiment, and a few repetitions of such experiments give as great a degree of certainty as a thousand or more.

The chances of the occurrences of a certain event in relation to cause can only be mathematically calculated when the totality of the possible causes of the result remains the same under the different circumstances investigated. This is one of the chief reasons for the impossibility of drawing positive conclusions from medical statistics properly so-called.

The results of medical statistics will not apply to the treatment of any particular case. They can never prove that bloodletting should be employed in all cases of pneumonia, or that it should never be applied in any case of pneumonia. Even the results obtained from the most satisfactory medical statistics will only be found useful to the physician in directing his treatment in the absence of any special indications in the particular case which he has before him.

The data upon which to base medical statistics must be obtained either from published records, from unpublished memoranda collected by means of correspondence, or by the so-called collective investigation methods, or from personal experience. The published data include such records of private practice as are given in journals, transactions, monographs, etc., records and statistics of hospitals, statistics of public medical services and of medical and life insurance societies.

Detailed reports of cases such as are suitable for use in statistical work are not over-plentiful. In the majority of cases the individual data are not given. We have only summary statements of tables of results. This is the case with regard to much the larger part of the great mass of reports of results of hospital and asylum practice which have been published during the last hundred years, either in the form

of separate annual reports or in summaries for journals or societies. These reports give some information as to the prevalence of certain diseases in certain places at certain periods of time, and in this way have some historical value, but they do not show the proportion of cases of disease or death to the living population in which these occur, and very few of them give the data by sex and age in the manner required by the statistician. Some of these calculate death-rates with reference to the total number admitted during the year, others to the total number treated, which includes those remaining on hand at the beginning and those admitted during the year, and others to the total number disposed of during the year by discharge, transfer, or death. A few of them give the average daily number under treatment during the year and the average number of days' treatment for each case, sometimes making a distinction of sex, but almost never of race or age.

Comparisons of gross death-rates of different hospitals, however calculated, are of little value for the purpose of determining either the sanitary condition of the place, the skill of the medical staff, or the merits of the particular system of treatment, owing to the great variations in the class of patients admitted. Of course the statistics of hospitals for special classes of diseases can only be compared with those of the same kind; and even for general hospitals, the fact that the gross death-rate of one is higher than that of another proves very little.

In comparing hospital death-rates, it is now generally agreed that it is best to make use of the death-rates in relation to the total number of persons disposed of by discharge, transfer, and death for a series of years. Comparison of the number of deaths with the admissions only is apt to give very misleading results. A better method than this is that of Bertillon, who adds to the number at the beginning of the year one half the sum of those admitted and of those going out. It is also desirable to know the ratio of deaths and discharges to the mean population of the hospital, which is obtained by dividing the number of days of treatment by three hundred and sixty-five; but in this connection it is to be remembered that when the mortality is calculated with relation to the number of days' sojourn in the hospital, those physicians who keep their patients the longest will show the lowest death-rates.

From what has been said in these lectures it will be seen that no form of hospital statistics can be considered as satisfactory which do not give the distinctions of sex and age, and this not only for the total of all the patients, but for each of the several forms of disease treated.

Prior to the discovery and employment of antiseptic methods in obstetrics the records of lying-in hospitals were very unsatisfactory. It is true that we have no very definite standard of death-rates in child-bearing in private practice with which to compare them, but this rate is given by the Registrar-General of England as being at the rate of five per thousand children born alive for the twenty-eight years 1847 to 1874.

The summary of the returns of the externe maternities in connection with Guy's, Bartholomew's, and St. Thomas's Hospitals for the twenty-one years 1856 to 1876, compris-

ing an aggregate of 74,580 cases, give a mortality of 4·1 per 1,000.

The largest lying-in hospital and the oldest is that known as the Rotunda, or Dublin Lying-in Hospital. In 198,481 cases of confinement in that hospital, the death-rate was 13·9 per 1,000.\*

It is not an easy matter to determine what may be called the normal or average mortality of women in childbirth in order to determine the probable utility of a particular mode of managing cases of labor, as, for example, the so-called aseptic method. From the mortality statistics of the late U. S. Census ("Report on Mortality and Vital Statistics," Pt. II, lxx) we find that in 1,577,173 births 5,646 deaths of the women are reported, being in the proportion of 3·57 per 1,000 births. This proportion was higher in the rural districts than in the large cities, and in negroes than in whites.

For the same year (1880) the Registrar-General of England reports the death-rate of women in relation to births as 2·07 per thousand. If now we compare these figures with those given by obstetricians and physicians, we shall find that the latter give death-rates from two to four times as great. Thus, Duncan gives the death-rate in private practice as from 8 to 10 per 1,000 births, while Le Fort gives the figures from maternity hospitals as 30,594 deaths in 888,312 births, or over 34 per thousand, while Ehlers, using the statistics of Prussia from 1816 to 1886, gives the rate as from 5·8 to 9·4 per thousand.

How are we to explain these differences? Is the reported greater mortality in rural districts, in certain races, or in physicians' reports due to peculiarity in the cases reported, or to the surroundings, or to the method of making reports and collecting data? Evidently the latter is first to be considered. In the data furnished by the census and the English registration reports, the cases attended only by midwives and wise-women are included as well as those attended by physicians, and it is among the negroes and the Germans that the proportion of cases thus attended is the greatest. Moreover, in the cities, where there is a regular registration of deaths upon physicians' certificates, there is less tendency to give the vague term of childbirth as the cause of death than in the rural districts, where the cause of death is returned by non-professional persons; but this does not apply to England, and it is not probable that it greatly influences the results in this country.

The deaths reported in the census as due to childbirth are those which occur during or soon after labor, including those due to haemorrhage, exhaustion, acute uremia, etc., while those which occur at a later period may be reported as due to peritonitis, septicæmia, etc., although the physician, in reporting the results of his private practice, would include all these as deaths due to labor.

While the physician will usually consider only the relation between the number of cases of labor and the number of deaths in childbirth, the vital statistician will study the relations of deaths in childbirth to the number of women

living between the ages of fifteen and fifty years, or to the total number of deaths from all causes. The figures of the last United States census show that of every 100,000 women between the ages of fifteen and fifty living in our large cities, 16·21 died in childbirth during the year, while in the rural districts the corresponding figure is 51·58.

If, then, we are to judge as to whether the death-rate in childbirth in the practice of a particular physician is to be considered as high or low, we must first know whether the figures relate to hospital or to private practice, and, if the latter, whether it was in the city or in the rural districts. To obtain some standards for comparison we may use the numerous reports found in medical literature in which physicians have given the statistics of their private obstetrical practice, and compare the results with those given in the statistics of maternity hospitals.

Suppose that, for the sake of testing the relative efficiency of two different modes of treatment or of the general progress made during a series of years in therapeutics, we take the statistics of a particular disease, which should be one having a tolerably definite train of symptoms so as to be easily recognized. A disease which it is common to select for this purpose is acute lobar pneumonia. Suppose, now, that in a given group of cases of pneumonia subjected to one method of treatment the mortality or the proportion of death is found to be greater in another series of cases subjected to a different treatment; are we thereby authorized to conclude that that mode of treatment connected with the lowest mortality is really the cause of the low mortality? By no means. Before we can do this we have to settle the character of the cases, the proportion of those in each group occurring in advanced age or in intemperate persons, or in those affected with other diseases, or in certain races, because all these circumstances influence the death-rate. We have also to take into account the total number of cases in each group in order to make an allowance for the probable error due to small numbers. If the two groups of cases have occurred in different localities or have been treated in different institutions, we have then to take into account the special influences of the locality or institution, as far as it is possible to do so, and not until all these corrections have been made can we fairly estimate the relative influence of the treatment.

In the absence of statistics of cases and deaths by ages, we can get very little information from statements of death-rates from pneumonia. For example, the death-rate in United States hospitals from pneumonia from 1877 to 1888 was 18·72 per cent. of the cases treated. Was this a high or a low death-rate? We can only say that it was probably rather below the average, since the average death-rate for males between twenty and fifty years of age is 19·9 per cent. of cases treated. The need of such considerations is well illustrated in a paper by Dr. C. W. Townsend and A. Coolidge, contained in the "Medical News," July 27, 1889, p. 85. This paper is a discussion of all the cases of acute lobar pneumonia treated at the Massachusetts General Hospital from 1822 to the present time, the figures being divided into periods of ten years, making seven decades in all.

\* Summarized from the "Dublin Medical Journal," 1869, and from Dr. Johnston's "Annual Reports" from 1868 to 1875.

The conclusions arrived at by the authors are as follows:

1. In the thousand cases of acute lobar pneumonia treated at the Massachusetts General Hospital from 1822 to 1889 there was a mortality of 25 per cent.

2. The mortality has gradually increased from 10 per cent. in the first decade to 28 per cent. in the present decade.

3. This increase is deceptive for the following reasons, all of which were shown to be a cause of a large mortality:

(a) The average age of the patients has been increasing from the first to the last decade.

(b) The relative number of complicated and delicate cases has increased.

(c) The relative number of intemperate cases has increased.

(d) The relative number of foreigners has increased.

4. These causes are sufficient to explain the entire rise in the mortality.

5. Treatment which was heroic before 1850, transitional between 1850 and 1860, and expectant and sustaining since 1860, has not, therefore, influenced the mortality rate.

6. Treatment has not influenced the duration of the disease or of its convalescence.

Suppose we try to estimate the relative value of a particular treatment of rheumatism, say, by salicylates. We find several tables in medical literature giving the results treated by this and other methods. As a type, take the analysis of 1,200 cases treated at Guy's Hospital, given by Dr. Hood ("Brit. Med. Jour.", Dec. 31, 1881, p. 1119), in which he gives the average duration of illness, number of relapses, and number of cases of cardiac complications in 350 cases treated with salicylates and in 350 cases treated without them, and concludes that relapses and cardiac complications were more frequent under the salicylate treatment, but that the pain ceased sooner and the average length of stay in hospital was less. But the cases are not tabulated by sex, age, race, etc., so that we can estimate the bearings of these circumstances on the results, nor in any tables are these results thus classified.

An important point in medical and vital statistics is to keep the current record, or what may be called the day-book account, entirely separate and distinct from the classification or modes of tabulation. The current record must be made complete at the time, for if any items are left out they can never be replaced. But this record, once made, may be used in various systems of classification and comparison for many years afterward. If an attempt be made to put this record into the form of a classified return primarily, it is certain to be defective, and will not be applicable to researches of another kind.

In the reviews of the progress of medicine, of which we already have a large supply in the shape of annual addresses and centennial literature, and to which extensive additions will no doubt be made at the close of the present century ten years hence, you will find more or less elaborate statements of the advances which have been made in diagnosis, pathology, preventive medicine, and surgical therapeutics in all its branches. Also, it is easy to show that we

have made great advances in the art of relieving pain. But, when we seek by statistical methods to determine what advances we have made in the prevention of death by the internal use of drugs, it must be confessed that the data are, for the most part, wanting, and that the optimist and the pessimist can propound their theories and beliefs upon nearly an equal footing—*i.e.*, that of ignorance of the real facts in the case.

It is easy to see that the statistics of fevers collected in the last century—before typhus, enteric, and relapsing fevers were distinguished from each other—are of little use now, and modern bacteriology has destroyed, to a great extent, the value of the old statistics of tubercular diseases, typhoid fever, cholera, etc., and of the statistics of surgical operations. They have rendered some service in their day, but their value is now chiefly historical. There is, however, in existence in medical literature a very considerable number of cases which have been recorded with sufficient detail to be available for statistical treatment which they have not yet received. Death-rates in relation to number of cases of special forms of disease, showing relations of mortality to sex, age, and race, are yet to be calculated, and there is material for some good and useful work in this direction.

Within the last twenty-five or fifty years in civilized communities the gross mortality has diminished, there has been a prolongation in the average expectation of life, and the mortality of the years of infancy has greatly diminished; but how much of this is due to preventive medicine, how much to improved conditions of habitation and to the lowering of the price of food, and how much to improved methods of treatment? Dr. Zweifel endeavored to answer this question in a lecture on the influence of medical knowledge on the life of the people, delivered in Leipsic in 1887. ("Der Einfluss der ärztlichen Thätigkeit auf die Bevölkerungsbewegung.")

Taking as a basis for his calculations the figures of Bavaria for ten years and those of Saxony for thirteen years, he found that, for 100,000 living population, the average number of deaths from tuberculosis increased from 250 to 258; from inflammation of the lungs, from 222 to 270; from croup and diphtheria, from 98 to 123. He remarks that these are saddening figures, in spite of the sanitarians and health resorts, in spite of ventilation, new methods of treatment by inhalation, compressed air, etc. The number of men who die from diseases of the respiratory organs is steadily increasing, and he queries whether Süssmilch was not right in his phrase "Göttlichen Absterbeordnung" ("Divine law of death").

On the other hand, he shows that the mortality from typhus has fallen from 62 to 34. But the question is whether this is due to a diminished prevalence of the disease, or to a diminished mortality in the same number of cases of the disease due to improved medical treatment. It may be noted in this connection that the chief effect of improved sanitation appears in the lessened mortality in children under five years of age, and that it is chiefly in the mortality occurring after these ages that we are to look for the influence of improved medical treatment. In examining this, how-

ever, it is to be remembered that improved sanitary conditions, affecting chiefly infants by preserving a number of feeble and sickly children, tend to produce a higher rate of mortality in succeeding years. In cases admitting of surgical treatment, and in childbirth, there can be no doubt as to the diminished mortality in the practice of those who use the best accepted modern methods, but these methods are not yet used scientifically by half of the profession, and the results are not perceptible in the general death-rates thus far collected.

It must be admitted that the greater part of the increased expectation of life is probably due to better food, purer water, greater cleanliness, and improved methods of preventing the spread of contagious diseases. If we look at the curves representing the loss of life in large masses of people at different times and places we see that the laws of life and death have but a narrow range of variation after the age of infancy has passed, and that improvements in therapeutics have lifted the lines but very little. They have lessened suffering greatly, but they have not greatly deferred death.

In our present state of knowledge there are certain forms of disease and derangement of organs whose tendency is to recover without any treatment, or in spite of bad treatment. There are also certain diseases and derangements which are incapable of cure by any known method of treatment. Otherwise, man would not be mortal. Between these two classes is a small number of cases of disease the result of which depends on the treatment. In order that medical statistics may give us any information in regard to this last class, we have got to have some idea as to the proportion of each of the two other classes.

A very good illustration of some of the ways in which lies can be told with statistics may be found in the various books and papers which have been produced in connection with the anti-vaccination controversy.

In order to understand the relations between vaccination and small-pox it is necessary to have the death-rates from small-pox given for different periods of life—that is, by age. In this country and in Great Britain we have no data as to the deaths by small-pox by different ages prior to the introduction of vaccination, because the registration of deaths by ages has only been carried on for a little over fifty years. We can, however, for Great Britain, compare the statistics of vaccination for three different periods—the first, from 1847 to 1853, in which gratuitous vaccination was provided for the people, but it was purely an optional matter with them whether they should make use of it or not; from 1854 to 1871, when vaccination was obligatory by law, but this was mainly theoretical, since the law was practically not enforced; from 1872 to 1880, when the vaccination was rigidly enforced.

Before the introduction of vaccination there were but few persons who did not have the disease at some time in their lives. It appeared in epidemic waves over Europe, usually at intervals of from five to seven years, being about the period of time required to accumulate by births a sufficient amount of susceptible persons to enable an epidemic to make headway. Of course, then, the great majority of

persons had the disease in infancy, or in early childhood, and a large proportion of these died. So that in those days the small-pox mortality in the early years of life was high, while those who survived were either protected from future attacks or presented a certain amount of immunity to the poison of the disease, so that the small-pox death-rate of the higher ages was then low. When vaccination came to be general, the young were protected, but were not protected as permanently and completely as would have been effected by an attack of small-pox. The result of this was that the death-rate from small-pox under five years of age fell eighty per cent., while from five to ten years of age it fell forty-five per cent., and in the older ages it may even have increased where revaccination was not systematically and thoroughly carried out. Taking the English records for 1872 to 1874 and 1877 to 1880, it is found that the proportion of deaths under and over fifteen years of age, per thousand deaths, from small-pox differs according to whether the persons were vaccinated or unvaccinated, as follows: Of 1,000 unvaccinated persons dying from small-pox, 672 were under fifteen years of age and 328 over fifteen. Of 1,000 vaccinated persons dying from small-pox, 834 were under fifteen and 666 over fifteen, the proportions being, as will be seen, almost precisely reversed under the two conditions.

If we compare the death-rate per 1,000 of living population in an epidemic of small-pox occurring in a city in the United States in recent times with that of an epidemic occurring in a city in the last century, we shall probably find that the death-rate was greater in the modern city than in the ancient one. Perhaps two thirds of the people in the modern city were properly vaccinated; in the ancient city none were vaccinated. Are we to conclude that partial vaccination increases the death-rate from small-pox? Yes, for a single epidemic year; but if we take a period of twenty years or more for our comparison, we shall find the death-rate much lower in the vaccination than in the ante-vaccination period, because in the ante-vaccination period the adults had been through several epidemics of small-pox, and had either had the disease and survived, or had proved insusceptible to the virus, being in either case protected. The only class of the population in much danger from small-pox in those days were the young children born since the last epidemic, less than ten years ago. But in the modern community, partially protected by vaccination, there has accumulated a considerable number of unprotected adults during the long periods which now elapse without an outbreak, and these increase the death-rate. Comparisons of small-pox statistics for single years are therefore almost worthless.

In vital statistics, as in other branches of social science, it is not true that the effects of causes acting in combination are equal to the sum of the effects of each of the causes acting separately. Different causes of death having no relation to each other do not have a joint effect which is equal to the sum of the effects of each cause taken separately, and it is therefore difficult to bring the phenomena of vital statistics within the boundaries of mathematical formulae. In the doctrine of this kind of averages time and number are not convertible terms.

Statistics applies to masses of men, to communities, not to individuals. We find a mass of matter moving in a certain direction with a certain velocity and endeavor to calculate the direction and amount of the forces which have produced this result. In like manner we may consider the tendency to death in a community as a resultant of several forces as indicated in the diagram, and endeavor to estimate the influence of each of these forces in producing the result.

In studying medical and vital statistics one is somewhat in the position of a man on the deck of a large Atlantic steamer, out of sight of land and gazing on the troubled ocean. He sees many waves, large and small, apparently moving in very different directions, and it is not until he has, by careful examination and repeated comparison, learned to distinguish the ripples due to the wind now blowing, the larger cross-seas resulting from forces which were acting a few hours before, and the long rolling swells which indicate to some extent the direction and force of the tempest of yesterday, that he can begin to understand the roll of the ship on which he stands; while to appreciate the force and direction of the great current which is sweeping with it all the troubled water and the ship itself requires skilled observation with special instruments, and the use of charts which embody the experience of hundreds of voyages. So also in viewing the records of human life, disease, and death, the variations which are at first most perceptible are often those which are most superficial and which give little or no indication of the magnitude and direction of the movement of the great masses beneath.

The following works will be found useful for reference:

In addition to the census and registration records we have another important source of information in vital statistics—namely, the records of life and health insurance companies. These are not so well known to physicians generally as they should be, and I wish therefore to call special attention to the two most valuable compilations of them now in existence—namely, the "Insurance Cyclopædia," commenced by Cornelius Walford, of which five volumes have now been published, and the "System and Tables of Life Insurance based on the Experience of Thirty American Life Offices," by Levi W. Meesh, published in 1881.

### CONGENITAL ABSENCE OF FIVE RIBS, WITH RESULTING DEFORMITIES.\*

BY HOMER GAGE, A. M., M. D.,  
WORCESTER, MASS.

THE subject of the following sketch was referred to me in May last by Dr. O. H. Everett, of Worcester, Mass. I have been unable to find any similar case in my own reading, and Dr. R. Lorini, of Washington, who has made at my request a very careful search, reports that he can find no reference to any like deformity in the library of the Surgeon-General. I have thought, therefore, that these photographs,† with a brief sketch accompanying them, might prove of interest to you.

Susie S., born in Worcestershire, England, aged seventeen years and two months, is the oldest of nine children, none of whom present any peculiarities of growth or development. While pregnant her mother fell down stairs, injuring her side, but had never attached any significance to the injury. The absence of part of the bony wall of the thorax on the left side was noticed at birth. There was not, however, any curvature of the spine, nor was anything noticed with regard to the position of the heart. While she was yet a baby in long clothes, a little bunch was observed in the left side, which appeared only

\* Read before the American Orthopædic Association, September 19, 1889.

† For the photographs I am under great obligations to Dr. E. V. Seribner, of Worcester. The lines indicating the position of the ribs and viscera were drawn upon the body with soft crayon.

when she was coughing or crying, was about as large as a walnut, and seemed not unlike a rupture. She was carried daily to

the hospital in the vicinity, where a bandage was applied to keep the bunch from coning out. These measures were, however, unsuccessful, and it gradually grew larger, attaining its present size about four or five years ago. The spinal curvature was first noticed when she was five or six years old, but received no treatment until four or five years later, when plaster jackets were applied, and these four years ago were discarded in favor of a corset made of mill-board stiffened with fish glue. The corset has not provided any proper support for more than a year, and in consequence her

ing prominence of the costal cartilages in front on the left. Upon inspection, the left side presents very much the appearance often observed after severe empyema, when the cavity has been closed by the retraction of the chest wall instead of by the expansion of the lung. But closer examination shows that the appearance is due not to the retraction of the chest wall, but to the congenital defect in its development. As indicated in Fig. 2, the first, second, third, fourth, and fifth ribs are found in their natural positions and relations. Just below the fifth costal cartilage is a sixth cartilage which is connected with the end of the sternum and can be traced outward and upward until it joins the extremity of the fifth rib. There is no trace of the sixth, seventh, eighth, ninth, or tenth rib, and in the gap thus left the muscular wall can easily be pushed in until the pulsations of the aorta can be felt from the side. In this gap, too, as is shown in Fig. 4, can be readily made out and felt the upper half of the spleen. Across the middle of the spleen can be felt the eleventh and twelfth ribs, smaller and in much closer proximity to each other than normally.

Pulmonary resonance and the respiratory sounds are lost below the border of the fifth rib in front and below the angle of the scapula behind. The area of cardiac dullness begins at the middle of the sternum, and extends to below the right nipple in the fifth interspace, as shown in Figs. 2 and 3. The first sound of the heart is heard loudest at this point, and the second sounds along the opposite side of the triangle. There is no murmur. Pulsation can be seen and felt all over this area, but more distinctly along what seems to be the basal line. Figs. 3 and 5 are instantaneous photographs taken while the girl was in the act of coughing, and afford a very accurate representation of the bunch to which I have already alluded. It can

not be produced or maintained by any ordinary muscular effort, and subsides almost at once with the expiration which completes the cough. It has a firm, elastic feel, and, as it is thrown out against the hand, gives a sensation exactly like the impulse of a hernia. Percussion over the whole area reveals a resonance decidedly stomachic in character. When once thrown out it can be partially held in position by the hands, and if at such times a little water is swallowed, it can be distinctly heard to fall into the stomach. Unless this bunch can be prevented from appearing by firm pressure of one sort or another, she says that she is in constant distress, which is aggravated by eating or drinking.

For her relief I applied a plaster jacket, from which I made a cast of the body from the axillæ to the trochanters. Upon this cast I had a leather corset molded, and I endeavored to give it additional strength by incorporating four steel stays. She has worn this corset now for about two months with very

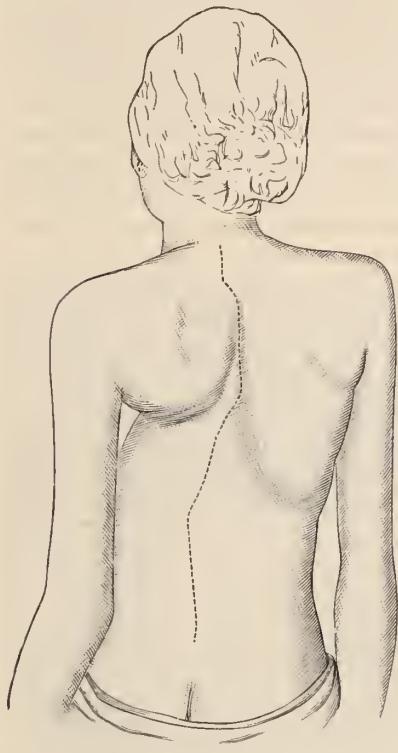

FIG. 1.

curvature has increased very rapidly, and her general health been very much impaired.

She has never had any serious illness, has met with no accident, and until within a year past has been obliged to assume, to

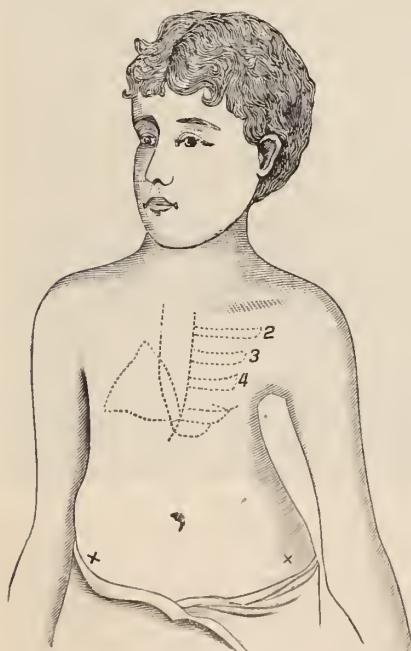

FIG. 2.

puberty. She has a lateral curvature of the spine in the mid-dorsal region, with the convexity to the right, and a long compensatory lumbar curve. There is considerable horizontal rotation of the vertebrae, as indicated by the prominence of the angles of the ribs on the right side, but there is no correspond-

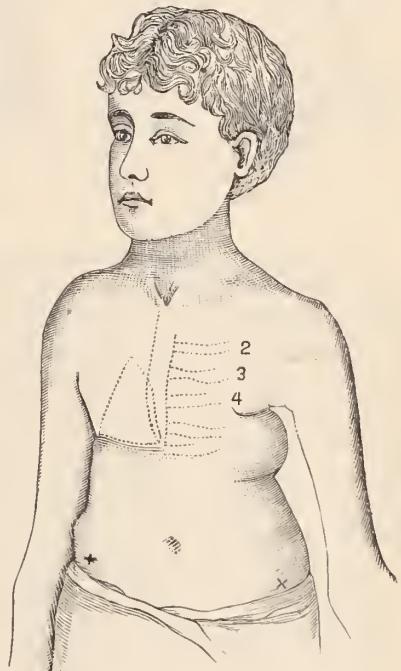

FIG. 3.

satisfactory improvement. She has gained in flesh and strength, has a better appetite and better color, and is once more able to attend to her household duties.

FIG. 4.

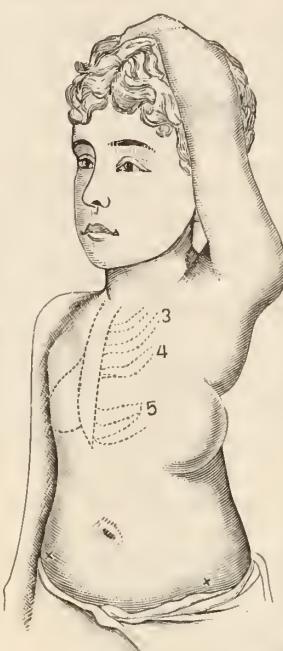

FIG. 5.

Coexistent with these anomalies in the number of ribs there is very often, almost as a rule, a corresponding defect in the development of the vertebrae, as in the very remarkable case reported to the Royal Medical and Chirurgical Society by Willett and Walsham in 1880, in which five ribs on the right side, four on the left, and four and a half dorsal vertebrae were absent. There was a lateral curvature with convexity to the left which was believed to be due to the absence of the right half of the third dorsal vertebra. I feel very confident that in the case which I have just described there are twelve dorsal vertebrae. How many, if any, of them are imperfectly developed could be determined only by post-mortem dissection. Repeated and very careful examinations have, however, failed to give any evidence of asymmetry in their development. Moreover, I fail to see why such a supposition is necessary to explain the subsequent deformities. The absence of five ribs upon one side must cause a very serious disturbance in the arrangement of muscles and fasciae. What has become in this particular case of the attachments of the serratus magnus, of the lumbo-saeral division of the erector spinae, of the latissimus dorsi, and the great muscles of the abdominal wall, is of course impossible to determine; but, whatever their attachments may be, these muscles must work at a disadvantage as compared with their fellows of the opposite side. In consequence thereof, as soon as the child began to assume the erect position the superincumbent weight of head and upper extremities was transmitted to a spinal column whose supports were seriously crippled on one side. The result has been the gradual development of a lateral curvature with its convexity toward that side whose supports were strongest.

The position of the heart on the right side is very much

indeed like that observed in cases of left-sided pleurisy with large effusion, or in cases of left pneumothorax, and I am strongly inclined to the belief that it is the result of similar mechanical conditions. The left pleural cavity is diminished very much by the absence of so many ribs, and has been wholly occupied by the growth and expansion of the lung. In some way or other it seems to me that this growth and expansion of the lung with the sinking in of that side of the thorax and the increasing lateral curvature have forced the pericardium and its contents to the right. The only alternative is to assume that the position is an anomaly of development, and that seems to me hardly necessary. A congenital displacement is usually associated with a general transposition of viscera, and that is certainly not true of this case.

There remains only the peculiar tumor which appears with the act of coughing. I have already indicated briefly my idea as to its probable nature, and will only add that the evidence obtained from its shape and position, from auscultation and percussion, and from the manner of its appearance, leaves in my own mind no reasonable doubt that the tumor is a hernia of the stomach.

## AN EXANTHEMA AFTER THE USE OF RHUBARB.\*

BY HERMAN GOLDENBERG, M. D.

I. W., German, aged sixty-four years, a sailor, was taken sick last November with cough, bloody expectoration, and a swelling of both ankles, which was regarded as rheumatic and treated with a solution of salicylate of sodium. The amount taken could not be ascertained. He stated that, after having taken about thirty teaspoonfuls of the mixture, he awoke on the morning of the 6th of January with a violent beating sensation in the head and a burning in the face. He found, on examination, a number of small nodules on the face, which, in the course of the day, became larger and at the same time pustular. The number of nodules then increased, and others appeared over the hands, which also underwent the same pustular change.

When I saw the patient, on January 8th, he was suffering from frequent epistaxis, and presented an anaemic appearance, suggestive of some general disturbance. Temperature normal, urine scanty, specific gravity 1.011, containing two per cent. of albumin.

The face was quite disfigured, and showed perfectly symmetrical lesions on both cheeks. They extended not above a line drawn from the upper end of the concha auris to the lower eyelid, and below they were limited by a line drawn from the lower end of the concha auris to the angle of the mouth; on the outer side they were found up to the ear, and on the inner side to a line joining the middle of the cornea to the angle of the mouth. The scalp and hairy parts of the face were not affected. The eruption was confined to the region supplied by the peripheral branches of the facial nerve, involving especially the zygomatic and the buccal. It consisted of from fifteen to twenty brownish-red, irregularly-shaped pustules, varying in size from that of a pea to that of a bean, or larger. The lesions seemed to be deeply infiltrated at their bases, and were

\* Read before the American Medical Association at its fortieth annual meeting.

surmounted by a superficial pustular formation, the whole being surrounded by an inflammatory area. On pressure, a quantity of pus exuded, followed by blood, the lesions retaining their original size. Below and to the outer side of the middle of the eyes, protruding tumor-like, two large pustules were found. They were much infiltrated, of about the size of a fifty-cent silver piece, and elevated about an inch from the level of the face. The surface of the tumors presented a number of cribriform openings, out of which pus, sebaceous matter, and blood could be pressed in the same way as in the smaller pustules. On the surface of these tumors the pus had dried, forming

good, and that the eruption had appeared suddenly, consisted of infiltrated nodules and pustules, and was confined to the face and hands.

I concluded that we had here to deal with an artificial eruption, as I had previously seen a similar case caused by the use of bromide of potassium, and, furthermore, the eruption resembled the one described by Dr. R. W. Taylor and Dr. C. W. Cutler as dermatitis tuberosa after the use of the iodides.

His physician had reported to me, as I have already mentioned, that the patient had taken large doses of salicylates, but, as I had never heard of any similar eruption occurring from their use, it occurred to me that there might have been an error on the part of the apothecary. This was proved, however, not to be the case on analyzing the medicine. I believed myself, therefore, justified in regarding the exanthema as one caused by the salicylates, and was confirmed in this belief through the reports of Dr. Lauriston E. Shaw, of 1886 and 1887, and, still more recently, his recorded cases in the "Lancet" of January 19, 1889, in which hemorrhage occurred in rheumatic patients after the use of the salicylates. He says that the epistaxis during salicylation is mentioned by nearly all writers on the subject. In order to determine if the salicylates were the real cause, I continued giving the patient a mixture containing the salicylate of sodium during the following four weeks, without, however, producing any eruption or causing any disturbance in the general health. My conclusion, therefore, seemed to have been at fault, as it hardly appeared probable that this medicament would not have produced a result similar to the last eruption, even if not to the same degree.

It is well known that affections of the kidneys have an influence on artificial exanthemata in such a manner that those drugs which are well borne in a normal state of the kidneys produce a toxic effect upon the skin if they are affected, owing to the fact that the perspiration takes vicariously and to a certain extent the place of the kidney secretion. On the other hand, the same drugs are well borne when the normal kidney function is restored. In the case of my patient such a tolerance of the drug could not be assumed, since the amount of albumin during this period was not only not diminished, but rather increased. Although forced to exclude the salicylates as the causal agents, I yet adhered to the opinion that the eruption was produced by some artificial means.

I must here mention that the patient had informed me that before the appearance of the eruption he had been subject to constipation, for which he had been in the habit of taking rhubarb and Hamburg tea containing also rhubarb. I had noted these facts, but had not considered them of any importance. I also read about the same time of a case presented by Dr. Litten, at a medical meeting in Berlin, of a rhubarb eruption resembling a very severe pemphigus and which could be reproduced at will. I was therefore led to try the effect of this drug.

After a week's rest from all medication I gave the patient a mixture of rhubarb and soda. Having taken about an ounce and a half of the mixture, containing about two drachms of the pulvis rhei, the patient awoke on the morning of the 12th of March with a burning sensation in his face, and he noticed on both cheeks an eruption consisting of small, hard blisters, peau-sized, of tubero-pustular character, surrounded by a red inflamed area. The lesions increased to such an extent that, when I saw the patient the next morning, almost the entire face was covered

ing a thick crust. After their removal there appeared a moist, bleeding, fungoid, ulcerated surface. A similar nodular and pustular eruption was present on the dorsum of either hand. The lesions gradually disappeared without any treatment in the course of a few weeks, leaving a bluish pigmentation, but no cicatrices. The albumin remained constant during the whole time that I observed the patient. The eruption had been looked upon by the physician who sent the patient to me as pemphigus. Although at first glance it resembled pemphigus very strongly, closer observation and the clinical course, together with the nature of the lesions, excluded this affection. I need only refer to the facts that there was no fever, that the general health was

with thick yellowish crusts, beneath which there was an accumulation of pus. The eruption was symmetrical, the scalp and hairy part of the face being free. The characters of the single lesions were the same as in the first attack: pustules on an infiltrated base, and also a tendency to bleed on the removal of crusts. On the extensor and the flexor surfaces of the hands and somewhat on the fingers there was the same eruption as on the face.

The patient discontinuing the medicine, the lesions gradually faded in a few days and the ulcers began to heal. On the fourth day, through a misunderstanding, the patient again took two or three teaspoonfuls of the mixture, and a few hours later a decided effect of the drug was again noticeable upon the skin. The reproduction of the eruption by rhubarb thus occurred three times, and I would consequently conclude that that drug was the cause.

I regret that I was unable to continue my observations on this interesting case, as his death ensued not long after from purulent peritonitis following a suppurating embolus of the spleen.

107 EAST FIFTY-NINTH STREET.

#### REPORT OF A CASE OF PERNICIOUS ANÆMIA.

BY E. R. AXTELL, M.D.,

RESIDENT PHYSICIAN TO ST. LUKE'S HOSPITAL, DENVER, COLO.

G. S., aged thirty-four, of normal weight (one hundred and seventy-five pounds); nativity, England, northern part; in Denver five months; came here from Massachusetts, where he had resided one year. He was in Canada two years ago; he had been there five years; occupation, ditcher, laborer. Three months ago, while ditching, he worked in water up to his waist. He worked in this water for a week, and dates all his symptoms from that time.

The patient was always strong and healthy. He had a slight bilious attack last summer; was sick only four days. He denied syphilis. Never was a great drinker nor a regular one. Has been drunk, however, a number of times.

He was admitted to St. Luke's Hospital August 12, 1889. He states that last winter he felt excellently; never had better health. In June last the patient worked for a week at ditching. Was compelled to stand in water up to his waist. During this week he had numerous chills, with languor and fever. Since that time he has never been well—has never been able to do a full day's work. Always felt tired—"played out." For a week or two after, he was on a ranch putting up a wire fence. He found that he could not do a day's work; would have to quit. No dyspnea, but a sense of extreme weakness. Then he came to Denver and found that he still could not work. Appetite began to fail, he had repeated vomiting, looseness of bowels, few chills, and some fever. He states that he con-

sulted a doctor about July 25th, and that the doctor visited him for some time, but that he got no better. He states that about July 24th he had a very severe nose-bleed, which continued for an hour without ceasing. It was stopped, he says, by ice being applied to the back of his neck. An hour later his nose bled for the second time, and continued to bleed for half an hour. He states that his nose had bled several times before this, but not freely. Was now confined to bed. When the patient was brought to the hospital he was thought to have typhoid fever. Placed on a solution of quinine and listerine. Quinine, five grains every four hours. He was kept on this for a week without effect; the case in the mean time was studied with the following result:

*Nervous Symptoms.*—Great languor, with weakness of limbs. Much dizziness upon arising from bed. Subjective noises in head and ears. Backache at times. Slowness of memory; no headache; sight and hearing good; distressing feeling of being "tired out."

*Respiratory Symptoms.*—Some cough at times; nose feels "stopped up"; free discharge; has catarrh; while lying in bed has no dyspnoea. Respires 15 to 18 times a minute. When out of bed has just the slightest amount of "air-hunger," hardly sufficient to be noticed; has nose-bleed almost daily; hardly able to blow nose without some epistaxis.

*Circulatory Symptoms.*—Pulse weak, compressible, and ranging from 60 to 100; no cardiac palpitation; none during the whole term of observation.

For temperature range, see below.

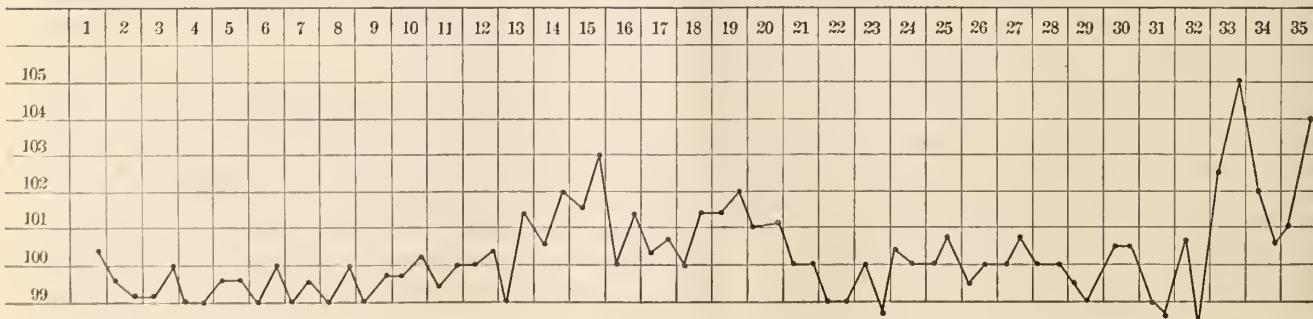

*Digestive Symptoms.*—No appetite; nausea and vomiting frequent; bowels very loose; painless; has had from ten to twelve stools during several nights; medicines exert but little effect; stools dark-brown, thin, watery, and speckled with lumps of yellow faeces and mucus; states that he has passed a small quantity of blood by the bowel on several occasions; no piles; mucous membrane of mouth pale; tongue large, soft, light in color, with a light coating of whitish fur at times; no great thirst.

*Genito-urinary Symptoms.*—Had gonorrhœa a month ago; passes water freely at present. Urinalysis: Urine clear, amber-color, specific gravity 1·018, ranging to 1·024, reaction acid, no albumin, no sugar.

*Tegumentary System.*—Skin dry, harsh; exposed parts a dark, faded-leaf yellow; forearms especially darkened; other parts slightly tinged; conjunctiva slightly yellowed at inner canthus; at times patient sweats a great deal.

*Muscular and Osseous Systems.*—Nutrition fairly good; fair amount of fat; patient stated that he had lost twenty pounds since the commencement of the disease, or after working in that ditch of water; has tired feeling in body and limbs at all times; no pain or tenderness in bones.

*Physical Examination.*—Skin of a mulatto-color, earthy yellow; forearms darker than chest; slight sore on lobe of left ear; conjunctiva partly jaundiced, the rest pearly white; gums, tongue,

lips, and nails anaemic; nails very slow in growth; superficial veins never prominent; chest well developed; no sinking of spaces; expansion good; palpation and percussion normal; auscultation reveals dry wheezing râles over right lung anteriorly; left lung normal; heart dullness normal; impulse feeble and diffused; haemisystolic murmur heard over both pulmonary and aortic orifices; this loud and clear; abdomen of good size, flabby, not distended; liver dullness lessened; splenic outlines greatly enlarged; can be felt below ribs as a hard rounded mass; extends upward to sixth rib; some pain on pressure; limbs normal, except for discoloration of skin.

Ophthalmoscopic examination of fundus oculi revealed numerous small haemorrhages irregularly scattered over both discs. One large haemorrhage in lower outer quadrant of left retina.

*Course.*—The patient, after being on quinine for a week without any perceptible effect, was then placed on Warburg's tincture, a half ounce every three hours, to which was added later tincture of digitalis and tincture of chloride of iron. Diarrhoea in the mean time continued, but was partially checked by bismuth and opium, only to commence if the medicine was omitted for a half-day. Gradually patient got weaker and weaker. Nose bled more frequently. Appetite became very poor, and tired sensation became very distressing. Patient seemed to realize that he was to die and was very low-spirited.

At this time the blood was examined as to its physical character, and also microscopically. Quite a pin-thrust was necessary to draw any blood at all. The drawn blood was red, but paler than normal, and was of less consistency, being thin and watery. Power and rapidity of coagulation lessened. Under the microscope the number of red cells was found to be greatly diminished, as compared with a specimen of blood drawn from a healthy man. No count was made, no haematocytometer being obtainable. The red corpuscles were very small, irregular in shape, crenated, and paler than normal. They did not form rouleaux, and but few presented a side-view. The white corpuscles or leucocytes were also very scarce, and their diminution was clearly as noticeable as the diminution of the red cells. Clearly a leucæmia also prevailed.

Warburg's tincture was continued for over two weeks with no result. Some stimulation also administered. Patient then placed on Fowler's solution of arsenic; five drops after each meal. All other medication was then discontinued except stimulation.

For eight days the patient was kept on this treatment. No apparent change occurred. On September 13th the patient had two severe chills—one in the early morning, one at 3 p.m. These were followed by fever, severe pain in the right side, and the next day by "rusty sputa" and typical signs of croupous pneumonia, from which the patient died at 4 a.m., September 16th.

*Autopsy.*—Body that of a well-developed, well-nourished man; skin of a light, earthy-yellow color; post-mortem rigidity well marked; autopsy made sixteen hours after death; fair amount of subcutaneous fat; no post-mortem staining of skin; both lungs free from pleuritic adhesions; whole lower lobe of right lung and lower part of the upper lobe in first stage of croupous pneumonia; pleura over affected surface intensely inflamed; left lung normal; no hydrothorax; heart normal in size; no excess of pericardial serum; muscular tissue soft, flabby, pale in color; cavities filled with soft, brown clots; auricles and ventricles thinned; ventricles more degenerated than auricles; valves normal; spleen markedly enlarged in all directions; about two pounds in weight; substance intensely reddened and harder than normal; small supernumerary spleen, size of a marble, in omental fat; liver slightly contracted and

markedly *cirrhotic*; gall-bladder contained but little bile; pancreas normal; kidneys normal, slightly paler than usual; suprarenal capsules normal, as regards size and shape; intestines very pale and flabby; mesenteric glands not enlarged; brain not examined.

#### Points of interest centering in the case:

*Sudden Onset.*—The patient stated positively that he was well and hearty until he began ditching in June, during which time he worked for a week in water up to his waist.

*Definite Cause.*—Working in cold water. Prolonged application of cold, with no means of recovering heat during the resting hours. As a definite cause, this seems to be pretty well established in this case. Just why it should produce in him this trouble I know not. Whether others working with him were similarly affected could not be ascertained.

*Tired Sensation.*—This was a most prominent symptom, and patient could lie in no position without experiencing it. Sleep brought no rest. Limbs always felt as though they had been used for some time.

*Absence of "Air-hunger."*—As a symptom, dyspnœa is considered almost pathognomonic or essential, but in this case it was never marked. On exertion the patient would have slight dyspnœa, but it was hardly noticeable.

*Absence of Palpitation of the Heart.*—This was a special point of inquiry, but the patient always denied its existence. Why it should be absent when the heart and blood changes were so marked is hard to fathom.

*Presence of Leucæmia*—for clearly a leucæmia was present, there being but a few white cells present in any specimen examined. The estimated proportion of the cells, as seen, was one white to one hundred red.

*Inadequacy of Treatment*—quinine, Warburg's tincture, iron, and arsenic proving of no avail. If the disease had been recognized early, the arsenic would have been pushed, but it was not, and the pneumonia supervened so early that no manifest change was noticeable from its limited use.

*Duration.*—This was about thirteen weeks. But the disease was complicated by the pneumonia, and it was the immediate cause of death. But the patient was so weak, pulse so thready, that it would seem a question of but a few weeks with him when the disease itself would have killed. A duration, then, for this case of from fifteen to twenty weeks would seem to be most reasonable.

*Presence of Post-mortem Rigidity.*—This was hardly expected. The patient had been sick so long and the blood was so poor in coagulability that the muscle-clot (myosin) and muscle-plasma were hardly expected to contract at all. Yet a very decided rigor mortis was present sixteen hours after death.

*Presence of Chronic Interstitial Hepatitis.*—This pathological change was one of the most prominent changes present, and it was quite marked. Large "hob-nails" studded the entire liver surface, and new fibrous tissue traversed the liver in all directions. The presence of this condition is significant, and our case requires careful study. Could it be one of cirrhosis of the liver and not pernicious anaemia? Many of the symptoms were those of cirrhosis—

gastro-enteric catarrh, pyrexia, enlargement of the spleen, and jaundice. Yet there were present many symptoms which could not be dependent upon cirrhosis—diminution of red and white corpuscles, profuse losses of blood, haemorrhages into the retinae, and haemic murmur. This condition complicating the trouble makes an interesting case, and I would call attention to the fact that the two diseases can make a very similar array of symptoms, and care must be taken in separating them. In this case cirrhosis was never suspected, as no clear history of drinking could be obtained.

## PRELIMINARY NOTE ON THE STUDY OF EXOPHTHALMIC GOITRE.

BY LOUISE FISKE-BRYSON, M.D.

CAREFUL observations in a certain number of cases of exophthalmic goitre would seem to indicate that, however inconstant and variable the presence of symptoms hitherto considered pathognomonic of this strange and unexplained disease, distinctive, fixed conditions prevail, and that these perhaps afford the only rational basis for prognosis.

Such a condition is diminished chest expansion. This is accompanied by increased respiration and frequently by cough. In all the cases examined—the examinations in several instances being repeated at regular intervals for many months—this symptom was constant, varying only in degree. In severe cases the chest expansion on forced inspiration was half an inch, and sometimes less. A chest expansion of one inch or more, on forced inspiration, was considered sufficient ground for a favorable prognosis, in spite of persistent loss of strength and the presence of classical symptoms. Every case examined, with possibly a single exception, gave evidences of present or previous disease of the respiratory tract, usually chronic rhinitis, pharyngitis, or bronchitis. Appropriate measures directed to this locality have been followed by marked improvement in the general condition. Dampness increases the respiratory difficulty and aggravates other symptoms, notably the depressive symptoms of the mental state.

*Respiratory Tract.*—Diminished chest expansion, frequent respiration, cough, evidences of past or present chronic pharyngitis and rhinitis, of bronchitis; and certain conditions resembling those that prevail in angina pectoris and asthma. Peculiar catching of the breath at regular intervals when reading aloud.

*Digestive Tract.*—Excessive thirst; sudden hunger; nausea; vomiting; characteristic diarrhoea (sweating of the intestine), coming on suddenly and lasting a few days, a few weeks, then disappearing, possibly returning again at irregular intervals throughout the course of the disease, and remaining as a constant symptom toward the close of life in fatal cases.

*Skin.*—Perspiration, urticaria, eczema, petechiae, local or general pigmentation. Transient brown spots, isolated or in groups, appear during the course of the disease, and sometimes bronzing of the skin. A woman of the German peasant class—neck measurement seventeen inches and three quarters, chest expansion on forced inspiration less than

half an inch—presented complete bronzing of the skin, with darker areas about the neck, temples, and chest. Whatever abnormality of the skin may exist, the irritation caused by it is out of all apparent proportion to the lesion. In a late stage of fatal exophthalmic goitre in a woman every trace of hair had disappeared from the entire body, with the exception of the eyebrows and a fairly good-sized oval-shaped growth partially covering the vertex and occiput. The hair being long, it was possible to conceal the denuded spaces. There was every reason to suppose that in time the alopecia would have become general. The patient stated that she was always wringing wet from perspiration, and the hair had rotted out in consequence.

*Genital Tract.*—Leucorrhœa, menorrhagia, metrorrhagia.

*Muscles.*—Tremor. A kind of paresis—sudden loss of power—of the lower limbs that causes stumbling and falling; von Graef's symptom absent in the case of two negroes. A slight increase in the size of the muscles of the left side, making the measurements equal to those of the right.

*Ophthalmoscopic Examination.*—Practically negative.

*Mental State.*—At first and for a short time there is great depression of spirits, with tearfulness, irritability, specified fears or general apprehension. This gives way to a condition of hopelessness that eventually becomes "desperate cheerfulness" as the disease progresses. L. S., a few days before her death, enjoyed making plans for a short stay in some hospital, to be followed by a trip to the mountains. Her symptoms at that time were of the most exaggerated type, together with weakness so profound that the patient could not raise herself or turn over in bed. M. R. reported that when ill-health compelled him to give up business the previous year he had been melancholy beyond expression. "But now," he added buoyantly, "I believe I could spend all my capital, and borrow money if necessary, without feeling it so very much." Accompanying or growing out of this desperate cheerfulness there often exists an absurd and perfectly useless mendacity. Commonly it has no more reason for being than the mendacity of hysteria, though there may be some foundation in fact for what the patients say about themselves. Whoever studies carefully and persistently the characteristics of persons suffering with exophthalmic goitre will be struck with the fact that, whatever the degree of their natural or acquired timidity, they all have a remarkably good opinion of themselves and a strong desire to impress others with a realizing sense of their virtues and accomplishments, and urge their claim to special consideration on the ground of some cherished quality that seems to raise them above their natural station in life. A young girl of the German peasant class replied, in answer to varied and apparently off-hand questions extending over a period of weeks, that she could play and sing extremely well, could read aloud in a fascinating manner, and dance charmingly. The only accomplishment the writer had an opportunity to test was that of reading. This proved to be clear in point of enunciation, but expressionless and non-intelligent, performed with the same regular catching of the breath that characterizes this disease (and perhaps others). M. R. said he could play on every known musical

instrument. W. F. says that she sings, plays, dances very well, and speaks German. She belongs to a social class in which such accomplishments are not common. S. L., a negress, is forty-five years old, and looks fully twenty years younger. She is very proud of this distinction, and of her neat, stylish appearance, and of her correct views of life. L. S. was, according to her own statement, a linguist and a musician. Dreams (which the patients are unwilling to speak about) are not the least of the many annoyances that appear in the complex of symptoms known as exophthalmic goitre. Persistent and tactful questioning, repeated at intervals, will serve at last to elicit about the same history of dreams, which are terrifying in their nature, of harmful black objects—rats, toads, reptiles, animals, men—in pursuit of prey. Sleep is disturbed and unrestful. There are jerking of the limbs, sudden starts, and occasional outcries.

Exophthalmic goitre may exist simultaneously with some other constitutional trouble, such as migraine, hysteria, Addison's disease, diabetes, and myxœdema. Often there is a history of infectious disease during childhood that seems to have been the starting-point of marked alteration in nutrition, as scarlet fever, inflammatory rheumatism, etc. There is but little reason to imagine that exophthalmic goitre starts up out of space and hits its victim like a thunderbolt out of a clear sky. It is more reasonable to suppose that the way has been prepared earlier.

When exophthalmia is absent, it is possible—more than that, it has been done—to mistake Graves's disease for tuberculosis or malarial fever, especially when the latter is of an irregular type. The following general comparison of symptoms makes the differential diagnosis somewhat apparent:

Tuberculosis.	Exophthalmic goitre.	Malarial fever.
Chilliness now and then.	Tremor.	Chills.
Fever.	Fever.	Fever.
Cough.	Cough.	
Increased respiration.	Increased respiration.	Increased respiration during fever.
Dyspnoea on exertion.	Dyspnoea on exertion, or in damp weather, or coming on suddenly without apparent cause.	
Sweats.	Sweats.	Sweats.
Diarrhoea.	Diarrhoea.	
Pallor and hectic flush.	Pale yellow tint; bronzing of skin; pigmentation; eruptions.	Jaundiced hue; pigmentation.
Hopefulness and courage.	Desperate cheerfulness; easily cowed.	Melancholy.
Loss of flesh.	Loss of flesh.	
Pulse: No uniform relation to temperature; always feeble, varying rarely in rhythm, and accelerated by slight causes.	Pulse: No uniform relation to temperature; often feeble, varying frequently in rhythm, and accelerated by causes so slight as to be almost inappreciable.	Pulse: Bears a somewhat regular relation to temperature.
Anæmia.	Anæmia.	Anæmia.

*Treatment.*—General hygienic measures, the first of which is to get the patient as far away from the ground floor as possible and from all sources of dampness. Inland—especially a mountain region of moderate altitude—seems emphatically the choice location for vacations or a change

of air. The common report is that a stay at the sea-shore makes life a perfect burden, increasing the respiratory difficulty and bringing back depression of spirits. Damp days have the same unfortunate effect. A salt sponge bath, followed by friction—lower limbs first, upper limbs, trunk, neck, and head—two or three times a week, induces a more healthful action of the skin. Alcoholic and malt liquors must, as a general thing, be discarded, together with sweets and fried food. Regular rest and regular exercise should be prescribed according to careful direction, like any other medicine.

*Drugs.*—The iodides, nux vomica, carbazotate of ammonium, and strophanthus have given good results. The iodides are contra-indicated when there is much respiratory difficulty. Jaccoud gives arsenious acid night and morning, and bromide of potassium between meals. Friedreich advocates quinine for an indefinite period.

Strophanthus (Kombé arrow-poison) was first presented to public notice by Professor T. R. Fraser, of Edinburgh (see "British Medical Journal," November 14, 1885). "However introduced into the body, it increases the contractile power of all striped muscles, and renders their contractions more complete and prolonged. . . . As a result of the action on muscle, the heart is early and powerfully affected. It receives a larger quantity in a given time than any of the other muscles of the body, and therefore it is probable that strophanthus affects its action more distinctly and powerfully than it does that of the other striped muscles." Strophanthus is without cumulative effect, is antipyretic, diuretic, and promotes appetite and digestion (Bartholow). It has a marked central effect upon the vagus ("Reference Hand-book of Medical Sciences").

The following interesting items are copied from the history and the report of the autopsy of Dr. J. West Roosevelt's case, which he has courteously furnished for the greater completeness of this preliminary note :

Patient, woman, aged forty-seven years; father died of phthisis, maternal uncle insane; no knowledge of other neurotic trouble in family. . . . Over lungs, resonance of exaggerated type. There are places where coarse and fine liquid râles are heard. . . .

DATE.	Pulse.	Respiration.	Temperature.
May 25. . . . .	120	38	100°
May 26. . . . .	128	48	98
May 27. . . . .	120	40	100
May 28. . . . .	120	38	98
May 29. . . . .	112	38	98·6
May 30. . . . .	118	32	98·8
May 31. . . . .	108	34	98·4
May 29. . . . .	116	32	99
May 30. . . . .	116	32	98
May 31. . . . .	108	34	98·4
May 30. . . . .	112	32	98·6
May 31. . . . .	100	28	98
May 31. . . . .	100	28	99·2

*Autopsy.*—Diaphragm on right side rises to the fourth space; on the left to the fifth space. Lung: Small, dark-pink in color; left lower lobe is oedematous and shows commencing red hepatization; pleural cavities normal. . . . Bronchial and mediastinal glands enlarged and deeply pigmented. . . . Heart: Normal size; muscle looks normal; coronary arteries somewhat thickened; mitral and aortic valves slightly but distinctly thickened.

. . . Stomach and intestines: Mucous membrane throughout thickened and coated with mucus. . . . Liver: Smaller than normal, dark in color. . . . Brain: Vessels at the base somewhat thickened. . . . In pia mater over middle peduncle of the cerebellum, small, flat new growth about the size of a filbert, which does not seem to have pressed on anything. . . . Pneumogastric and sympathetic nerves look normal.

*Microscopic Examination.*—Negative.

The study of a special subject has convinced me that the medical profession is a fraternity full of generosity and *esprit de corps*. While I have been the recipient of the greatest kindness from many physicians, in New York and elsewhere, in regard to opportunities of observing and investigating cases, to Dr. Edward C. Seguin I am indebted for special courtesy.

38 WEST THIRTY-EIGHTH STREET.

## A CASE OF POISONING BY COAL GAS.

*SLOW RECOVERY. HEROIC TREATMENT.*

By JEFFERSON C. CROSSLAND, A. M., M. D.,  
ZANESVILLE, OHIO.

In vol. I, No. 17, of this Journal there appears an article on poisoning by illuminating gas from the pen of Dr. W. C. Kloman. This article is written partly to correct some false impressions contained in Dr. Kloman's article, but especially to record a case which the writer considers interesting, instructive, and in some particulars exceptional. Illuminating gas, no doubt, produces death by the carbon monoxide of the gas combining with the haemoglobin of the blood.

As to the comparative amount of carbon monoxide in water gas and coal gas I am uninformed, and therefore accept Dr. Kloman's statement.

However, the case of Dr. Kloman, and that shortly to be described by the writer, do not seem in accord with the comparative amounts of carbon monoxide in the two gases.

On November 20, 1888, Mary S., a muscular young woman of excellent physique, applied at the Kirk House, at 10 p. m., for lodging. It was subsequently learned that she had been employed as a domestic for about a year in the western part of Ohio, and was on her way home, having stopped here for the night, and intending to take the morning train for her home in a coal district in an adjoining county. She was unable to write, and the clerk placed her name on the register, with a call for 5 a. m. She was assigned a room, and immediately retired. At 5 a. m. the clerk went to her room to call her. On approaching her room, the clerk found the hall fragrant with the odor of gas, and, recalling the illiteracy of this guest, suspected she had blown out the gas. He made violent raps on the door, and, receiving no response, broke it open. There on the bed lay the young woman, apparently hopelessly asphyxiated by the gas. The stop-cock was examined and found to be turned on full. The gas was shut off. The door was opened and a window raised. The room was a very small one, not exceeding 10 by 10. Dr. C. Draper was called, and when he arrived found the patient in the following condition: Respiration stertorous, shallow, and abounding in mucous râles; radial pulse merely perceptible; eyes partly open, fixed, and insensible to touch; pu-

pils moderately dilated and not reacting to light; conjunctivæ congested. There was marked lividity about the face and extremities. The patient was cold and moribund.

Seeing that the ventilation of the room and the vigorous atmosphere of a November morning had had no effect in restoring the girl, Dr. Draper administered stimulants hypodermically and Dr. E. C. Brush was called in consultation. After the arrival of Dr. Brush, treatment by stimulants, hypodermically administered, was continued until 9 a. m. without the least improvement in the condition of the patient. At this hour I was called in consultation, and, being informed as to the nature of the case, I took with me a galvano-faradaic battery and a drachm phial of a one-per-cent. solution of nitroglycerin prepared by Parke, Davis, & Co.

Fifteen minims of the nitroglycerin solution were injected in the epigastrium. The good effects of this on the heart action were perceived in about five minutes. It was soon evident to us, however, that several hours would elapse before the system could throw off the poison sufficiently for the patient to regain consciousness. We soon learned, by observing the effects of our remedies, that nitroglycerin was the remedy *par excellence*, and we made it our anchor remedy throughout the treatment. No exact record of the treatment having been kept, I shall have to generalize somewhat. The treatment by hypodermic injections, chiefly of nitroglycerin, was continued at intervals varying from thirty minutes to two hours, according to the indications. At 3 p. m. the vital powers were almost collapsed, and death seemed imminent. Twenty minims of the nitroglycerin solution were injected over the epigastrium, and the poles of the battery applied to the regions along the track of the pneumogastric nerve. Artificial respiration was practiced. In an hour the condition of the patient was as good as it had been at any time since 9 a. m.

This line of treatment was kept up till 2 a. m., when, by the use of a strong current from the battery and slapping the face with a wet towel, the patient seemed to notice those in the room. At 3 a. m. she had so far recovered from the effects of the poison as to mutter "Don't" in protest against the use of the battery and slapping the face with a wet towel. At 4 a. m. she could answer questions, and expressed a desire to defecate. Fearing evil results from allowing her to remain up long enough to defecate, we furnished her with a bed-pan, which she insisted she could not use.

We allowed her to get up, but she could not have a stool. She was no sooner in bed than she desired to get up, and several times she was placed on the chair without an action of the bowels. Thinking this desire to defecate only rectal tenesmus, I administered an injection of morphine in the perineum, and the desire to defecate ceased. From this time the patient went on to a rapid recovery. She was not, however, able to leave her room for two days, and left the hotel on the third day.

---

**Nitrogenous Contents of Sputum.**—"Dr. M. Panoff has examined the sputum of patients suffering from various forms of lung disease with the view of ascertaining the amount of nitrogen expectorated. The details of his results are given in No. 2 of the St. Petersburg Dissertations for the session of 1888-'89. The estimations, which, of course, included both the liquid and precipitated portions of the sputum, were made by means of the Kjeldahl-Borodin process, the general result being that the greatest daily expectoration of nitrogen was 1·14 grammie, and that the sputum which contained the largest amount of nitrogen, both when reckoned by the total daily expectoration as well as by its percentage composition, was that of phthisical patients, while, on the other hand, that which contained the least nitrogen, both absolute and relative, was that occurring in cases of bronchitis and croupous pneumonia."—*Lancet*.

MEDICAL STATISTICS.

IT is a curious fact that medical men in general, while frequently making use of statistical data, seem to have but little knowledge of their real value. Dr. Billings, in the Cartwright Lectures, sets forth in a most interesting manner a number of facts in regard to the data needed, some of the modes of obtaining them, some common errors and omissions, and some of the ways of judging of the probable accuracy of the figures. If medical men would realize how important these points are, how necessary it is to know what to tabulate and what to omit, how many cases are needed in order to furnish material from which to draw inferences, and how greatly these numbers differ when different problems are to be studied—if they comprehended that, owing to the omission of certain facts, tables, no matter how extensive, may be worse than worthless—it is probable that we should be saved much work and should get more knowledge.

Perhaps the most important thing to learn in dealing with statistics is that the results are true of masses, but not necessarily of individuals. "The results of medical statistics," says Dr. Billings, "will not apply to the treatment of any particular case. They can never prove that bloodletting should be employed in all cases of pneumonia or that it should never be applied in any case of pneumonia." It is too frequently the case that men attempt to make statistics prove that a course of treatment which has seemed beneficial in a large number of cases is, therefore, applicable to each case individually. Now, although a large mass of cases may serve to give the average results of treatment, yet in that mass there are many cases which depart from the average, and it is quite possible that treatment which has given good average results should have been fatal to a certain number of individuals, have injured some, in no way have affected others, have saved the lives of many, and have shortened the course of the disease in the rest. It is well to bear in mind that a number may have been killed or injured, though the average results are better. It is utterly wrong to reason from facts obtained which apply to masses, when the individuals composing the masses are to be considered. Suppose that in a given disease ten per cent. die, as shown by large masses of figures, say 100,000 cases. Does this mean that the chances in any one case can be represented as one in ten that death will result? Not at all. The chances in that case may be enormously in favor of the patient's recovery or of his death. It would be as foolish to assume that the average represented the actual chances as to think that it indicated the death of one tenth of each person, instead of one tenth of the mass.

The numbers needed to establish any facts of value in different cases, the margin of error, the absolute necessity of recording sex and age—these and much else of importance Dr. Billings mentions. His lectures should teach those who use or make medical statistics that it is needful to understand what to record and what can really be deduced from the records.

PROTECTION APPLIED TO THE PRACTICE OF MEDICINE.

THE very large number of Americans who winter in the south of Europe, whether for purposes of recreation or for the recovery of lost health, will hear with astonishment and dismay of the recent action of the French Government concerning English physicians practicing abroad. Formerly a foreign physician wishing to practice in the Riviera could qualify by reporting himself at Marseilles and passing the by no means insignificant examination for the grade of *officier de santé*. This was a considerable obstacle and deterred many from pitching their tents in the French winter resorts. But it seems that even this protection is not sufficient. At Nice, Cannes, and Mentone—places, be it remembered, built up entirely by the recommendations of English physicians—the whole of the English and American practice (and very good practice it is in the season) has been in the hands of the well-established English-speaking physicians settled there. This state of affairs seems to have caused a great deal of jealousy among the native doctors, who, as elsewhere on the continent, regard Anglo-American travel as an institution specially devised by Providence for their maintenance. Pressure has been brought to bear upon the French Government, by the representatives of these persons, of such weight as to force M. Fallières, the Minister of Public Instruction, to inform the English ambassador in Paris, with respect to English medical men who may be seeking authority from the French Government to practice in France, that it will not be possible in future for his Department to give the same favorable consideration to applications of this kind as has hitherto been accorded them, whether received directly by the Minister or through the British Embassy, and that the applications will be refused unless "in instances presenting very exceptional claims."

The meaning of this pronunciamento is plainly to the effect that after date no English doctor is to practice in France. Those who have already gained a high professional position in the cities and towns which Englishmen and Americans most frequent will, it is presumed, not be expelled; but they are not immortal, and a few years will see the race die out, and then the French doctor will have it all his own way; he alone will have the honor and glory of looking at the tongue and feeling the pulse of John Bull and Brother Jonathan.

We regard this as a very serious matter, requiring joint action on the part of our Government and that of Great Britain. When we consider the vast number of our countrymen who spend their time in France, it seems outrageous that they should practically be denied the privilege of obtaining necessary advice, to say nothing of sympathy and consolation, from

one speaking their own tongue. A foreign doctor in no way takes the place of one accustomed to our ways of thought and action, even if he does speak English or even if we do speak his language. The French law, if carried out, will render it a punishable offense for a young American or English doctor to travel with a patient in France, and a New York or London consultant will not find in foreign cities a physician to whom he can transfer a patient whose case requires careful explanation.

If the French Government would but inquire into the causes of the influx of visitors to these winter resorts, it would find that the Anglo-American immigration originated largely in the recommendations of those speaking our language. Smollett, an English doctor, brought Nice to public notice. What would Cannes, with its sixty hotels and its floating population of ten thousand, be to-day were it not for the notice into which it was brought by Lord Brougham, and for the recommendations of such authorities in chest disease as Williams and Walshe? As for Mentone, it was made by Bennett. And now, having enjoyed for so many years the products of the conversion of the English sovereign and the American dollar into the French franc, the Department of Public Instruction of the Republic is about to perform that old operation described in detail by Aesop and known to the public as killing the goose that lays the golden eggs.

### MINOR PARAGRAPHS.

#### DRYNESS OF THE THROAT.

From the "Medical News" we copy a formula used by Dr. Solomon Solis-Cohen for the relief of dryness of the throat and mouth, which characterizes both acute and chronic morbid conditions of the mucous membrane. The following ingredients are compounded in the form of a lozenge, to be dissolved gradually in the mouth:

Fluid extract of pyrethrum.....	2 to 3 minimis;
Pilocarpine hydrochloride.....	$\frac{1}{32}$ grain;
Pure extract of licorice.....	2 grains;
Powdered acacia.....	2 "
Glycerin.....	1 minim;
Sugar, enough to make.....	20 grains.

One of these may be taken every two, three, or four hours, as may be indicated. Speakers and singers have informed the author of the preparation that the taking of some such lozenge just before a lecture or concert has enabled them to perform their part with comfort, which otherwise would have been attended with both pain and fatigue.

#### BAD SPIRIT OF NITRE IN PHILADELPHIA.

Dr. H. A. HARE, in the "University Medical Magazine," reports twenty-five examinations of sweet spirit of nitre bought by him at widely separated apothecaries' shops in Philadelphia. Fewer than half of his samples were found good or very good; eight of them were rated as very poor or absolutely devoid of ethyl nitrite, and five were poor. One sample, utterly worthless, was obtained from a shop which for a generation has borne the reputation of a paragon of correctness. The weak specimens were not, as a rule, sold in the more pretentious shops, although there were three such. This result is startling. We do not suppose that, in this particular, there is any greater security in one city than in another, but no such result should

have been found in any town that makes drugs for the country at large. Again, the discovery is an unpleasant one in view of the increasing tendency to use the nitrites in a wide range of diseased conditions. New nitrites have been introduced of late years, but a good article of the sweet spirit of nitre still has a strong therapeutic standing. The test used by Dr. Hare was a solution of antipyrine, ten to twenty grains in the ounce of water. This reveals the presence of ethyl nitrite by causing a deep green color to appear, the reaction being the formation of isonitrosoantipyrine. Dr. Hare used this test in preference to other older ones recommended by the chemists, as being the more suitable to the purposes of the general practitioner.

#### DITHIOSALICYLATE OF SODIUM.

The "Therapeutic Gazette," quoting from the "Revue générale de clinique et de thérapeutique," states that Dr. H. Linderborn recommends this drug as a substitute for salicylate of sodium. It is formed by the combination of two atoms of sulphur and two molecules of the salicylate of sodium, is a very hygroscopic, grayish-white powder, and is very soluble in water. Various micro-organisms are said to be destroyed in forty-five minutes by the twenty-per-cent. solution. It arrests articular rheumatism and is efficacious in the treatment of gonorrhœal rheumatism. It does not produce gastric trouble, ringing in the ears, or any tendency to collapse.

#### THE IMPORTANCE OF RE-VACCINATION.

The "London Medical Recorder" quotes from a pamphlet by Dr. Gerstacker on the sanitary importance of re-vaccination as exemplified in Germany since 1874. That was the year in which the re-vaccination of school-children was enforced, the result of which, according to Dr. Gerstacker, has been the almost total extinction of small-pox. From that year the German army began promptly and strikingly to feel the effect of the law, although no difference was intended or carried out in the army regulations. Dr. Gerstacker places the average duration of the protection against small-pox at ten years.

#### RICORD'S LIBERAL BEQUESTS.

According to the "Lancet," the will of Dr. Ricord gives to the Paris Academy of Medicine ten thousand francs for the establishment of a biennial prize which shall bear his name. A like sum is left to the General Association of Medical Men in France. Five thousand francs have been bequeathed to the Society of Surgeons to found another biennial prize fund. To the Hôpital du Midi he has left his extensive library, as a memento of his half-century of work and interest, and it is in contemplation to change the name of the hospital so that it shall henceforth bear the name of Ricord.

#### CHINESE MEDICAL DEPARTMENTS.

The Chinese Government proposes to create a new form of surgical administration, in regard to both its army and navy. The bureau, in the case of each of them, will be modeled on Occidental methods. Requests for information have been presented to the Government at Washington as to hospital organization and ambulance work in this country. The surgeon-in-chief will probably be a foreigner, with a considerable staff of native assistants who have been trained in European and American schools. A beginning will be made in northern China, by the establishment of a medical college and of several hospitals and dispensaries at points where there are already military stations.

#### THE CREDIT SYSTEM IN MEDICAL EDUCATION.

In the French medical colleges in Canada a curious system of educating on credit has existed for some years. The poor and proverbially honest country boy who wishes to be a doctor, but who has no money for his fees, can, if properly recommended, be provided with lecture tickets and a degree, for which he gives his promissory note, which we hope is well backed. When the young graduate begins to feel the fees dropping into his pocket he is supposed to repay with grateful interest the advance his Alma Mater has made him. Unhappily, this is not always the case. According to the "Montreal Star," the Montreal School of Medicine and Surgery has just won an action in the Circuit Court against one of its former students, who, it was proved, had given it a note for \$75 to cover his tuition fees for one term, but which he left unpaid. Another case of a similar kind is pending against another physician, who, however, is said to have come to the United States.

#### DR. VON HOFMANN'S DEATH BY GLANDERS.

The death of Dr. von Hofmann, of the University of Vienna, has been the occasion, says the "British Medical Journal," of some erroneous statements, among which was one to the effect that he had become inoculated with a hypodermic syringe which had been in use in bacteriological work. The "Journal" holds that the extensive intrathoracic disease, as shown by autopsy in this case, indicates beyond question an infection through the respiratory tract. The exact source of the infection will never be known.

#### THE STILLÉ LIBRARY.

The Medical Library of the University of Pennsylvania contains over 3,500 volumes, the gift of Dr. Alfred Stillé. Other contributions at various times by Dr. Joseph Leidy, Dr. William Elmer, Dr. Joseph Carson, Dr. W. H. Taggart, and Dr. H. C. Wood, bring the total to about 6,000 bound volumes and 5,000 pamphlets. To these there has been added, quite recently, a contribution of special value from Dr. William Pepper, including a large share of his own medical library and many books that formerly belonged to his father.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending December 10, 1889:

DISEASES.	Week ending Dec. 3.		Week ending Dec. 10.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	24	10	17	5
Scarlet fever.....	40	2	71	6
Cerebro-spinal meningitis....	0	0	2	2
Measles.....	30	5	46	5
Diphtheria.....	73	17	94	26
Varicella.....	5	0	5	0

**Wards for Convalescents.**—It is announced that there are two convalescent wards at the Isabella Heimath, each containing fourteen beds. They are intended for convalescents who have no home in which they can find rest and care. The trustees are ready to admit, for a term not exceeding four weeks, convalescents of either sex needing care and rest after acute internal diseases or surgical operations; and no distinction will be made on account of creed or nationality. Applications, bearing the indorsement or recommendation of the attending

physicians or surgeons, should be addressed to the consulting physicians, Dr. August Caillé, 185 Second Avenue; Dr. A. G. Gerster, 56 East Twenty-fifth Street; Dr. A. Jacobi, 110 West Thirty-fourth Street; and Dr. H. G. Klotz, 222 East Nineteenth Street.

**The Orthopædic Dispensary and Hospital.**—At the anniversary meeting of the directors of the Orthopædic Hospital, the report of the work for the past year showed not far from 2,000 patients treated. On the part of the medical profession, Dr. Newton M. Shaffer and Dr. John T. Metcalfe made addresses, and emphasized the fact of the constantly increasing demands upon the medical staff, and of the almost immediate necessity for adding to the accommodations of the building at present occupied.

**The Babies' Wards at the Post-graduate Hospital.**—A reception to the profession and public will be held in the new building devoted to the babies' wards, at No. 222 East Twentieth Street, on Wednesday, the 18th inst., from 2 to 4 p. m. The steady growth of this important work of the hospital during the past five years has finally called for a separate building given up entirely to sick infants. The wards are under the medical care of Dr. Henry D. Chapin, with Dr. J. H. Ripley as consulting physician. The fifth annual report of this hospital announces that the last has been the busiest year of any in the history of the hospital. This institution was the first to secure special care for babies, and, thus far, has been the only place where such work has been carried on continuously. During the eighteen months since the last report was issued, 486 house patients—153 babies and 333 adults—have been treated; 8,086 new patients have been treated in the dispensary, where 32,194 visits have been made. The district physician of the dispensary, Dr. F. C. Carpenter, has treated 263 patients in their homes. An orthopædic ward for children has lately been added to the hospital, and whenever the funds are at the disposal of the directors, a lying-in ward will also be added. This is a much-needed charity—one that appeals at once to all who desire earnestly to relieve and prevent suffering. Contributions to the Post-graduate Hospital may be sent to the treasurer, Dr. L. Bolton Bangs, 226 East Twentieth Street, New York.

**The Northwestern Medical and Surgical Society** gave a social entertainment at Dr. Thomas H. Burchard's house, on the occasion of its twentieth anniversary, November 27th, including an excellent musical performance by members of the society and others.

**The Society of the Alumni of Charity Hospital.**—At a meeting held on Tuesday evening, the 10th inst., Dr. Joseph O'Dwyer showed some new instruments, and Dr. A. T. Muzzy read a paper on "The Prevention of Ophthalmia Neonatorum." Officers for the ensuing year were chosen as follows: President, Dr. D. Bryson Delavan; vice-president, Dr. Ramon Guitérás; secretary, Dr. W. L. Baner; treasurer, Dr. A. T. Muzzy.

**A Medical Official Exonerated.**—Dr. Remsen Taylor, the health officer of Long Island City, has been under investigation for extortion, by the Grand Jury of Queens County, and has received an official vindication.

**The Hypnotic Society of London.**—The "Lancet" states that a number of London medical men have united to form a Hypnotic Society, the purpose of which will be to prevent by law public exhibitions of mesmerism and hypnotism. Another object will be to study privately and in a scientific manner the phenomena of those morbid states.

**The Kings County Medical Society.**—At the December meeting, on the 16th inst., the Committee on Obstetrics is to

make its report, inclusive of papers by Dr. Charles Jewett, Dr. R. L. Dickinson, and Dr. George McNaughton. Their subjects will be, in part, puerperal wound-infection, immediate repair of the uterine cervix after labor, and a case of separation of the pubic symphysis.

**Dartmouth Medical College.**—On November 26th the medical department held its commencement. The graduating class numbered twenty-one.

#### Society Meetings for the Coming Week:

**MONDAY, December 16th:** New York Academy of Medicine (Section in Ophthalmology and Otology); New York County Medical Association; Hartford, Conn., City Medical Association; Chicago Medical Society.

**TUESDAY, December 17th:** New York Academy of Medicine (Section in Theory and Practice of Medicine); New York Obstetrical Society (private); Medical Society of the County of Kings; Ogdensburg Medical Association; Medical Societies of the Counties of St. Lawrence (semi-annual) and Westchester (White Plains), N. Y.; Hunterdon, N. J., County Medical Society (Flemington); Baltimore Academy of Medicine.

**WEDNESDAY, December 18th:** Northwestern Medical and Surgical Society of New York (private); Harlem Medical Association of the City of New York; Medical Societies of the Counties of Allegany (quarterly) and Tompkins (semi-annual—Ithaca), N. Y.; Strafford, N. H., District Medical Society (annual—Dover); New Jersey Academy of Medicine (Newark).

**THURSDAY, December 19th:** New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Mass., Society for Medical Improvement; Addison, Vt., County Medical Society (annual).

**FRIDAY, December 20th:** New York Academy of Medicine (Section in Orthopaedic Surgery); Chicago Gynæcological Society (annual); Baltimore Clinical Society.

**SATURDAY, December 21st:** Clinical Society of the New York Post-graduate Medical School and Hospital.

### Proceedings of Societies.

#### SOUTHERN SURGICAL AND GYNÆCOLOGICAL ASSOCIATION.

*Second Annual Meeting, held in Nashville, Tenn., November 12, 13, and 14, 1889.*

The President, Dr. HUNTER MC GUIRE, of Richmond, Va., in the Chair.

**Report of Gynæcological Work, with special Reference to Methods.**—Dr. R. B. MAURY, of Memphis, Tenn., contributed a very interesting paper with this title. The paper presented a brief summary of the more important portion of his operative work during the past year. With four exceptions, all of the operations reported were done in a private hospital, built especially for the purpose, and under his own control. The summary embraced twenty-one laparotomies for the removal of ovarian tumors, or of the uterine appendages, or for the relief of obscure disease within the abdomen; two laparotomies for ectopic gestation; twenty-eight operations for laceration of the cervix; fourteen perineal and vaginal prolapse operations; five proctoplasties; and four anterior colporrhaphies. The speaker summarized the methods as follows: 1. An antiseptic field of

operation and an aseptic surgeon. 2. A small incision—in the case of inflammatory disease in the pelvis—just large enough to introduce and work with two fingers. 3. Aseptic silk ligatures, as fine as may be consistent with safety in tying. 4. Enucleation of diseased structures, in spite of firm adhesions and even profuse hemorrhage. 5. Irrigation by means of the siphon-trocar as a substitute in most cases for sponging, using simple hot water for this purpose and excluding all antiseptics. 6. Drainage often, and whenever one is in doubt as to its necessity. 7. Careful replacement by spreading out of the omentum before proceeding to close the wound. 8. Inclusion of all the structures in passing the abdominal-wall sutures, and replacing the deep sutures half an inch apart. 9. The use of means for moving the bowels on the second or third day after removing the appendages; and the avoidance, if possible, of opium.

**Direct Kelotomy.**—Dr. W. O. ROBERTS, of Louisville, Ky., read a paper on this subject, in which he reported ten cases and eleven operations. Seven cases had occurred in females, three in males. There had been three cases of umbilical hernia, three of femoral, three of inguinal, and one of ventral. Six of the operations had been done during strangulation, while five had been performed for troublesome irreducible hernias. In the six cases of strangulated hernia the sexes had been equally represented. There had been three inguinal, two femoral, and one umbilical. In five of them the operation for radical cure had been done. The remaining case had been one of strangulated hernia, where stercoraceous vomiting had existed for eight hours before it was seen. General peritonitis had been evident at the time of the operation. Considerable reddish material had escaped when the contents of the sac were returned. Death had followed in thirty-six hours. He had since thought that if, after returning the contents of the sac, he had done a low median laparotomy and washed out the peritoneal cavity, the result might have been different.

The four cases of irreducible hernia had been all in females. Two had been umbilical, one femoral, and one ventral. In one of the former a second operation had been made necessary by the hernia recurring at the end of six months. The tumor also had reformed at the end of ninety days in the case of femoral hernia. The remaining eight patients continued well to the present time.

In all the cases the sac had been first cleanly dissected out and not opened until all hemorrhage had been entirely checked. In both the ventral and umbilical hernias the integument and fascia had been divided by an elliptical incision. After opening the sac, all adherent omentum had been tied with catgut and excised. The remaining contents had then been returned into the cavity. In one case of umbilical hernia the neck of the sac had been tied close to the margins of the opening and cut away immediately in front of the ligature. The stump had then been fastened tightly in the opening with silk-worm gut sutures, and the wound finally closed by interrupted sutures of the same material. In this case no suppuration had occurred, but the hernia had recurred at the end of six months. In both the other umbilical and in the ventral hernias the neck of the sac had been excised on a level with the abdominal opening and sutured with catgut. The opening itself, after its edges had been freshened, had been closed with the continued suture of chromaticized catgut in the ventral hernia, and aseptic corded silk in the umbilical cases. The superficies had been brought together by silk sutures, which had been continued down to the aponeurosis.

In the femoral hernias he had adopted the practice of Mitchell Banks. In the cases of direct inguinal hernia, after tying the neck of the sac just within the ring, and removing all in front of the ligature, the ring was closed with catgut sutures.

In the cases of oblique inguinal hernia he had done Mr. Ball's operation, which consisted in freeing the neck of the sac up to the internal opening, ligating it, cutting away all in front of the ligature, then twisting the neck upon itself to effect closure of the peritoneal orifice, and finally stitching the stump to the pillars of the ring to guard the neck against untwisting itself.

#### The Abortive Treatment of Acute Pelvic Inflammation.

—Dr. VIRGIL O. HARDON, of Atlanta, Ga., read a paper on this subject, in which he said that the views held by gynaecologists in regard to acute pelvic inflammation in the female had within the past few years undergone a radical change. The inflammatory processes formerly regarded as idiopathic, or at least as primary affections, were now almost universally recognized as dependent upon antecedent disease in the ovaries or Fallopian tubes, especially the latter. This change of opinion had to a large extent been due to the result of advances in surgery which had enabled the conditions of the pelvic organs to be studied in the living subject by immediate inspection and palpation instead of through the medium of the vaginal tissues; consequently it was often that a change of opinion on this subject had been most marked among those men who had had large experience in abdominal work. The diagnostic value of abdominal section under such circumstances was almost as great as that of post-mortem examination, and hence the opinion of the laparotomist was entitled to very great weight. As a result of this mode of observation, the conclusion could not be avoided that acute pelvic inflammation was, at least in the majority of cases, associated with septic, gonorrhœal, tubercular, or some other form of inflammation of the tubes. There were two forms of inflammation which were recognized as occurring within the pelvis as a result of tubal disease—pelvic cellulitis and pelvic peritonitis. In many cases both forms of inflammation were simultaneously present in the same subject, and it was not improbable that in all cases when either was present, the other also existed in a greater or less degree.

The treatment consisted in the withdrawal of the effusions from the cellular tissue by means of the aspirator, etc. Where pus tubes were present he would advocate their removal.

Dr. JOSEPH PRICE, of Philadelphia, said that his experience was a little different from that of the essayist. Relief from salines and the aspirator in the cases reported might have been justifiable, but tubes containing pus in every instance called for abdominal section. Dr. Price then exhibited some such tubes, one of which was seven inches in length, and called attention to their frequency in cases of pelvic inflammation.

Dr. GEORGE J. ENGELMANN, of St. Louis, Mo., said that there was a fascination in the results achieved by Dr. Price and other operators in these cases, but he thought the pendulum was swinging too far in that direction. He could indorse the surgical treatment advocated by Dr. Price in dealing with pelvic inflammation which resulted from salpingitis, or where there was pus in the tubes. Many of the cases which were formerly called pelvic cellulitis were the sequelæ of salpingitis or pus in the tubes, but he was satisfied that there were cases which existed without salpingitis.

Dr. W. G. EWING, of Nashville, said that when he began to practice medicine he was on the conservative side, but was now satisfied that many of the cases which came under his observation could have been dealt with surgically and successfully. He favored early operative interference, and said the surgeon should not delay in such cases, for, by so doing, additional adhesions were apt to form with extension of the inflammatory process.

Dr. HARDON said he feared he had been misunderstood, but would now say that tubes distended with pus admitted of but one rational treatment, and that was their removal. He invari-

ably recommended that this be done; but what should the surgeon do with those patients who would not permit an operation? As regarded pelvic cellulitis without disease of the tubes, he could corroborate the statements of Dr. Engelmann, and called attention to two cases which he had reported last year to the association which verified this fact. In these cases he had aspirated and withdrawn several drachms of serum from the cellular tissue. Subsequent examination had revealed absolutely no disease of the tubes. He had examined these patients from time to time, but not the slightest evidence of tubal disease could be found, and there had been no recurrence of the pelvic inflammation.

(To be concluded.)

#### NEW YORK ACADEMY OF MEDICINE.

*Meeting of November 21, 1889.*

The President, Dr. A. L. LOOMIS, in the Chair.

**The Annual Address.**—The PRESIDENT spoke briefly on the subject of the new Academy building. He said that his predecessor, Dr. Jacobi, had expressed a hope that the work would be carried to completion in the near future. These hopes were to-day almost realized. Thus far the building had been paid for, and the lots upon which it was being erected were also paid for. There was sufficient money in hand to carry on the work for some time as it was now progressing, but, in order to insure funds for its completion, it was necessary to effect a sale of the old building. This, it had been hoped, would bring in about \$70,000. If they could sell for this sum and each fellow of the Academy would contribute his share of the sum of \$20,000 more, then by the first of next October they would enter one of the finest buildings in the country free of debt. It devolved upon the members of the Academy to take a more earnest part in this matter. Some had worked well while others had done nothing. The subscription so far had amounted to \$50,000, which had been raised among one hundred and fifty of the fellows. There were six hundred fellows in all, and it seemed that there should really be no difficulty in raising the \$20,000.

#### The Relation of Medicine to the Problem of Socialism.

—Dr. W. M. POLK delivered an address thus entitled. The speaker had stated that he would consider the relation of the medical profession to some of the questions of the day. He would modify the statement and say "the question of the day." No less an authority than Professor Seelye had recently said: "There is one question of our time toward which all other questions, whether of nature, of man, or of God, steadily tend. No one will be likely to dispute the affirmation that the social question is, and is to be, the question of our time." The speaker thought that the profession would be encouraged to inquire into this question by reason of the widespread interest which socialism was evoking. One of the surest evidences of the truth of this assertion was to be found in the frequent and able discussions and dissertations upon it in the current literature of the day. Politicians were making of it a factor in government, and the Church, conscious of the moral aspects of the question, was fast awakening to the necessity of an active censorial position on its part. The social question might be defined as an inquiry into the status of the order of civilized people, and their relations one to the other in the economic arrangements of the social system. The recent growth of the inquiry was due to the conviction that these relations were becoming dangerously abnormal through the action of preventable causes. The causes were being gradually defined and remedies were being sought for by many of the best minds of the day. As was to be expected in such a question, there existed wide differences of opinion. But

upon one point all were agreed—namely, that discontent was widespread, and that this discontent was assuming the nature and proportion of a defined class question upon which the two great orders of present society were arraying themselves, the one in opposition to the other. The question assumed phases which differed somewhat in different countries according to the kind of government which prevailed. As enunciated by the class in whose interest it was first begun, this movement was called socialism. It was the belief of many, and history seemed to confirm it, that in socialism we but witnessed a continuance of that process by which man as a whole was being lifted upward. Examples of the process stood out in every epoch. To go back no further than nineteen hundred years, we found a movement beginning in an obscure village of Palestine which, extending itself among the lower classes, dominated the Roman Empire, and subdued every conqueror who successively overran the realm. The underlying principle was betterment of the lower orders, and in that far-reaching agitation it was not difficult to discover the greatest step in social evolution recorded in history. It was seen again in the Reformation, and its latest imprint stood before us in the tragedy of the French Revolution. Socialism, however, had scarcely been a formulated creed until about the beginning of this century. The stimulus derived from the French Revolution initiated it, and this, together with the growth of the democratic ideas of government, as witnessed in this country, might be said to have developed it. Realizing that little could be accomplished save through political power, its first aim had been toward securing the ballot. Its history so far had been largely made up of successful efforts to that end, so that to-day, in most civilized countries, political power, to a greater or less extent, was practically conceded to it. In this country there was to be seen the highest development of its political effort, and there could be no question that, conscious of its power, it was making ready to advance toward the end and aim of its existence. To-day it practically stood organized for self-protection; its next step would be one of aggression. "Socialism," then, was the expression of the lower orders to show their discontent with the conditions of their lives, and was at the formulation of any ideas and purposes as to the remedy. It drew the line with sufficient clearness between itself and its opponents, so that no one need be ignorant of its purposes. The question at issue was being gradually narrowed to that of property rights, the term property being made to cover everything out of which man met his daily wants, whether it was his money accumulations, his hands, or his brains. It was interesting to note that, while the successful working of republican government in our country had stimulated to a tremendous degree the growth of socialism in Europe, yet socialism had never until the present day been able to assume a definite shape in America. Our peculiar position had undoubtedly been responsible for this immunity. The first aim of socialism, political power, was conceded by us at the outset; and as for the question of "property rights," it could have no bearing. In fact, in this, a new country, all the conditions securing content so far outstripped those of an opposite tendency that anything like general dissatisfaction in any one class of the population was an impossibility. A most curious condition of affairs had been evolved, however, from what was apparently the most fortuitous combination of human circumstances. The fundamental principle of our system was declared to be the freedom and equality of man in the pursuit of any of the just purposes of life. Our domain being large and the population relatively sparse, immigration was successfully encouraged. Ignorance being recognized as a threat to the state, education had been amply provided for and carefully fostered. The pace at which we had moved had been indeed tremendous, but, while demon-

strating some of the advantages of freedom, it had also developed a well-recognized law of nature, the survival of the fittest. It began to show that to the strong literally belonged the victory. Already combinations for the purpose of destroying freedom in competition were assuming shape. It was only necessary to point to the restrictions upon imported contract labor and those upon apprenticeship sought for in one class, and the combination to check production and expenditure in the other. It would appear then that the doctrine of human equality was being worked out among us to a point which would demonstrate that it had inevitable restrictions. The suddenness with which this apparent failure of the practical application of the doctrine had come upon us was mainly due to the abnormally rapid increase in our population through immigration, for this increase had been mainly in the order which had the least in the shape of worldly possessions, and therefore felt most the pressure incident to its acquirement. Instead, therefore, of a limited discontent which could safely be put down to laziness and viciousness, we found ourselves confronted by a rapidly spreading dissatisfaction with the present state of our economic conditions which could be traced to the strain put upon man's resources by the free and active competition for what there was to be had of profit and prosperity in a rapidly increasing population. But this was not all. When educating a man we encouraged him to institute comparisons; he instituted them, and, when applied to himself, content was not always the result. Here in America there was a fear that education might not enable men to reconcile the incongruities which their observation told them existed between the facts of their daily life and the assertion upon the equality of man contained in that corner-stone of Government, the Declaration of Independence. Such men were apt to see in the doctrine of equality of man a panacea for economic inequalities which they saw about them. And if they were touched sorely a selfish interest would lend zest to the desire to apply it to their betterment. That this great question of socialism was primarily one of statecraft there was no doubt. But so were Christianity and Mohammedanism, and there were excellent proofs of the influence of medicine in propagating the one and in civilizing the other. John Watson, in his sketch of the history of medicine, delivered before the Academy some years before, had spoken of the attitude of medicine in the past ages—how, in the person of the Parabolani, it worked as an engine of Christian propagation, and how, in the person of its temples of learning, it stood upon the side of the pagan; how, in the contest that finally witnessed the triumph of Christianity, we were rent in twain, our culture deposed, and our ignorance installed as the directing influence in our affairs. For us then there were both warning and encouragement. The state must rest upon the intelligence of its people for the wise solutions of the questions which vexed it, and especially upon the intelligence of the leading orders of its society. Were not the members of the medical profession of this number, and did they not stand out more prominently than ever before as a recognized force in the social system of the day? And as they had borne no small share in the great questions of the past, it was well that they be not blind to their mission of to-day. The content of a people was dependent upon their physical well-being. The conditions necessary to insure this were at the command of the one order, so that they had but themselves to blame if it was not allowed. But how was it with that other which was forcing the social question to the front? Was there another element in any civilized land, which was better placed than in this, to properly answer this question? And this community—what was it? Was it not the exponent? Did we not find in it the very essence of that question of socialism which was beginning to press so hard upon us? In

its seething mass of humanity, with its pleasures on the one hand, its sufferings on the other, its aspirations here, its lost hopes there, we had the very epitome of the whole human race. And as we passed from home to home, from tenement to tenement, did we find the conditions of healthful life present, or even possible, with the majority of our population? It had been said that the medical profession was the buffer between the colliding forces of society. It seemed to the speaker that there was a woful ignorance, or perhaps woful blindness, on the part of the mass of the higher orders to the physical condition of the lower. How many people in New York really knew what the conditions of healthful life were? They had a general idea, but general ideas were not working formulæ. The speaker believed that the public, of both orders, should be taught that the essence of the discontent was in the absence of the conditions of healthful life. To get the public to heed, exclusiveness must be dropped. For plain people to understand, plain terms should be used to point out the practical application of facts, not theories. Facts were plentiful enough, as was well known. As practitioner, as minister to his ailments, man had always accepted the physician, but as teacher he had been less receptive. Man had always exacted of the profession more than could be given—namely, "eternal life." And failing to get this, he easily became skeptical as to whether we could tell him anything about life at all. Having but a surface knowledge of nature, supernaturalism had become his mainstay, and remained his prop until within the days of present knowledge. And yet, while he had asked for the elixir of eternal life, he had failed to furnish the educational conditions essential to a knowledge of the laws which governed even the short life assigned him. This, perhaps, was natural, recognizing as he did that he was to be the material out of which medical men were to carve their science. If ever there was an age in which knowledge of the laws of life, of health, and of death were more universally sought than in this, history had failed to record it. Education and competitive life had brought the civilized world to our door, so that it might truthfully be said that we stood upon the threshold of the golden age of medicine. It was indeed our opportunity, and if we failed to grasp the occasion it would be the fault of just such representative bodies as the speaker had the honor to address. A broader view of their mission than was involved in the process of self instruction had best be taken. Let them shake off the exclusiveness of their teachings, and take the public more into their confidence and speak directly to it of those laws of life and health which were each day becoming so necessary to it in its present emergency. Say those things which they would be glad to receive from physicians as recognized expounders. Drive home to him whose property right was represented by his brain, or by his muscle, that his body was his capital out of which his profit must come. Show him, in the economics of his life, how important it was that he should keep his body in the best working order. He had heard of chance, of luck; bring it home to him that the luck he lost was lost because of physical defects engendered by heredity or in the hygienic defects of his daily habits. And put it forcibly before him that in the failure of to-day he but saw the paralyzing influence of some infraction of the laws of health yesterday, and that in the conduct of his life to meet his daily wants in health, as in morals, he must accept this doctrine. Let the profession lay before the community the inevitable reaction of such a status of human existence, and in doing it let them do it wisely and do it well, so that it might be said at the end that they had met to the fullest the duty which, in the processes of social evolution, had been laid upon their shoulders, and that, in answer to the mandate of that first law of Nature, they had taught "self-preservation."

## SOCIETY OF THE ALUMNI OF BELLEVUE HOSPITAL.

*Meeting of October 2, 1889.*

The President, Dr. RICHARD KALISH, in the Chair.

**The President's Address.**—On assuming the chair, Dr. KALISH said: "Allow me to give you my sincere thanks for the honor you have done me in electing me to preside over this prosperous society. I am deeply sensible of this honor, and trust, by devotion to the interests and the work of the society, to demonstrate how great is my appreciation.

"A review of the work already accomplished by the society requires but a momentary consideration of the papers read and discussed during the past year to prove how varied and extensive a range of subjects was brought to your notice. A partial list will include 'Demonstration of the Treatment of Lateral Spinal Curvature'; 'Report of a Case of Perforation of the Vermiform Appendix, with Laparotomy'; 'Yellow Fever and the Jacksouville Epidemic'; 'Report of Four Cases of Classified Insanity'; 'Presentation of a Case of Misplaced Heart from Fibroid Phthisis'; 'Trephining, with Replacement of the Button of Bone'; 'The Radical Cure of Hernia'; 'Drainage of the Peritonæum in Acute and Subacute Peritonitis'; and the list might be greatly extended, but this is sufficient to show how wide a field was covered in eight meetings of the society.

"The signal success which has followed the scope planned by the organizers of this society renders me loath to make any suggestions leading to a change in the rules or guidance of the proceedings. Some years ago a determined effort was made to establish a society similar to this and upon plans which then seemed feasible, but the society failed to materialize, if my memory serves me, not even a single meeting being held. Under other plans this society was inaugurated, and in a little over two years from this inauguration its register held eighty-seven names. Another year has passed, and to-day its membership is one hundred and fifty-two, an increase of sixty-five, the roster including members of the profession eminent at home and abroad, whose opinions bear weight and whose knowledge and proficiency have added honor, dignity, and a new luster to the medical profession. As an example of the widespread interest the proceedings of this society is awakening in the profession, it is only necessary to instance the large attendance of rapt listeners at the delivery of the annual oration by Professor William Osler, when the seating capacity of the Academy of Medicine was more than overtaxed by the great number of physicians who not only crowded the large lecture hall, but uncomfortably filled the parlors as well.

"The Committee on Science is endeavoring to secure contributed papers of a greatly varied character, so that subjects relating to all the departments of medicine and surgery may in turn be brought before you. Circulars giving full particulars and asking for contributions, also blanks to be filled in with the titles of proposed papers, have been sent to all the members, and an early response will greatly facilitate the completion of the arrangements for future meetings. As soon as this schedule is completed a printed copy, containing a list of the papers to be read as well as the dates on which they will come before you, will be sent to each member, in order that those interested in a special subject may have timely notice and be prepared for a full discussion.

"There are certain matters to which your notice is particularly directed, and first the necessity of a full and regular attendance at all the meetings. No one wishes to read a carefully prepared paper before an array of empty seats, with few or none present to discuss the views and opinions set forth. With the assurance, however, of a large and critical audience,

the author is spurred on to taking greater care in preparing his paper and to making a greater effort in elaborating his ideas and deductions, and, with the knowledge that these ideas and views will be fully discussed, the paper acquires a depth and breadth it would not otherwise have attained. The meetings heretofore have been well attended, but I would request a larger attendance, even if only for a part of the session.

"Another matter is the completion of the 'Catalogue of Bellevue Hospital,' which to the society is more than a necessity. It will put in an enduring form much valuable data now scattered through various channels and likely to be lost. It is proper that the compilation should be done under the auspices of this society, which is eminently fitted to undertake the work, as it is particularly interested in all that pertains to Bellevue Hospital. The Committee on Catalogue, appointed over a year ago, has made considerable progress, but much still remains to be done. In the compilation of this work the following table of contents was decided upon: An Alphabetical List, a Geographical List, a List of each Staff since 1817, a List of the Visiting Staff, a History of the Hospital, and a History of the Epidemics which have prevailed in the Hospital. The alphabetical and geographical lists, as well as the list of each staff, are nearly completed, but upon the other divisions very little has been done. A catalogue of this nature is usually issued decennially, and the spring of 1890 would seem to be an appropriate time for publication.

"Another matter which should enlist your earnest attention is the proposed publication of the 'Reports of Bellevue Hospital.' An immense amount of clinical material, involving all the practical work done in Bellevue Hospital almost from its inception, is contained in the history-books of that institution. Very little of this has been published, and little benefit indeed has the profession been able to obtain from the valuable experience gained in the hospital, and recorded as it occurred. I have been able to find but three reports of Bellevue Hospital, and these are for the years 1848, 1856, and 1870.

"The report for 1848 is made by the house physician to the Medical Board, and consists of statistical tables of admissions, discharges, and deaths, also the diseases under each of these headings, a table of the diseases of those remaining in the hospital, an obstetrical table for 1848, and a table of the number of admissions, discharges, and deaths for the period extending from 1827 to 1847. For 1856 the report is not unlike that of 1848, but is issued by the Medical Board. It gives these tabular reports, refers to the improvements made in the buildings and grounds, and gives a complete history of Bellevue Hospital from its inception, compiled by Dr. B. W. McCready. For 1870 the report includes Charity Hospital, and gives a description of unusual cases and the statistics derived from new methods of treatment as observed in these two hospitals. Among the contributors are Dr. I. E. Taylor, Dr. A. Flint, Sr., Dr. L. A. Sayre, Dr. F. H. Hamilton, Dr. W. A. Hammond, Dr. F. Delafield, Dr. E. G. Janeway, Dr. T. G. Thomas, and others.

"Many of the European hospitals, notably those of Great Britain, publish annual reports, giving full histories of peculiar cases and a comparison of various methods of treatment as well as a full description of new apparatus and forms of application. There has been considerable discussion of this subject among the members in an informal manner, and it has been suggested that the society, with the advice and co-operation of the Medical Board of Bellevue Hospital, should assume the compilation of these reports.

"If we should decide to undertake this important work it is well to understand before entering upon it that it is a labor involving a great amount of research and entailing quite a large expense. The editing of so extensive a series of books is an

item which must be taken into consideration and thorough and complete arrangements made therefor. I have no plan of operative procedure to suggest, and present this matter that a full and free discussion may take place."

**A Case of Multiple Joint Lesions** was presented by Dr. R. J. CARLISLE. The patient, an Italian boy seven years old, belonged to a family whose history did not point definitely to either tuberculosis or syphilis, and the patient himself had passed easily and promptly through the first dentition, and had been apparently in good health up to two years ago. At this time, without any known traumatism, his present disease had begun. When first seen by the speaker, about one month ago, the first and second phalanges of the fifth finger of the right hand had become diseased, and, the boy being far too timid to admit of a thorough examination, a provisional diagnosis of syphilitic dactylitis was made. At the next examination the whole of the right metatarsus and a part of the left had become acutely involved. The axillary temperature was 99.2° F., and the lungs were not diseased.

When first seen he had been ordered fifteen grains of potassium iodide daily, and at the end of two weeks, as no symptoms of iodism had appeared, the daily quantity was increased to thirty grains; and this quantity had been taken for the last twelve days. To-day for the first time there was some coryza. The smaller joints had become worse during this treatment.

Dr. L. W. HUBBARD said that it was not very common to see so many of the smaller joints involved, and the diagnosis lay between syphilis and tuberculosis. The appearance presented by the fingers strongly suggested syphilis, while the sinuses about the foot were very similar to those usually seen in tubercular joint disease. From the history of the case, in the absence of more definite information, he would consider it a case of tubercular joint disease. As regarded treatment, he would advise disinfection and cleanliness, rest of the diseased parts, and attempts to improve the general nutrition by securing him good food and air, and by the administration of cod-liver oil and the hypophosphites.

Dr. R. H. SAYRE considered the case tubercular, and was strongly in favor of efforts directed toward improving the general nutrition; but, in addition to this, he would advise local treatment with iodoform, preferably by means of injections of an ethereal solution of iodoform.

Dr. FRANK HARTLEY concurred with the previous speakers in the diagnosis of tubercular joint disease, and would also advise against too active local treatment, as, in a similar case which he had observed, each time the diseased parts were subjected to scraping they became reinfected, and the patient grew steadily worse.

**Actinomycosis of the Pleura in the Human Being.**—Dr. T. M. BYRON reported the history of a case of this disease. (To be published.)

Dr. PARKER SYMS asked what the usual duration of this disease in the lungs was.

Dr. BYRON replied that this was only the second time that he had seen a case of peripleuritis; but those who had had a more extended experience with the disease stated that it was of long duration; and in a case of prevertebral abscess due to actinomycosis the patient was treated for several years for Pott's disease.

Dr. E. LE FEVRE wished to know whether the disease was apt to extend to the lungs, and how the actinomycetes gained entrance to the lungs.

Dr. BYRON said that their mode of entrance was probably the same as for the tubercle bacilli; but just what this was had not yet been determined. At the present time an investigation on this subject was being carried on at the Loonis Laboratory,

and it had been found there that on inoculating rabbits with emulsions made from the glands of men who were known to be free from pulmonary tuberculosis, about eighty-five per cent. of these animals became tuberculous, showing that the tubercle bacilli gained entrance into the lymphatics; and it was probable that the same took place with the actinomycetes. The subject had not been thoroughly studied, and it was on this account—the importance of the subject, and the fact that the disease, although not new, was almost unknown—that he had been led to read this paper. He believed that only about twenty-eight cases of actinomycosis had been reported.

Dr. HARTLEY spoke briefly of three cases which he had seen in the Roosevelt Dispensary. The first was in a girl of thirteen years, who had presented herself with an enlargement of the lower jaw which resembled a tuberculous process both in its size and in the scrapings from it; but the appearance of the pus led to a correct diagnosis. The second case was that of a man about twenty-two years old who had had an ulcer on the inside of the cheek for some time, when suddenly it had begun to enlarge rapidly, and he presented himself with a rather diffuse inflammation of the skin, which was quite soft in the center. The discharge from it was examined by Dr. Prudden and found to contain the actinomycetes. In the third case a little girl also had an ulcer on the inside of the mouth, from which the same peculiar material was discharged. Nothing was known concerning the sources of infection in these three cases; two came from different parts of the city, and the other came from the country. He had seen a fourth case, which had been presented by Dr. Lange at a medical society meeting. It was a case of actinomycosis of the liver, which at first had been mistaken for an abscess of the liver.

Dr. BYRON said that the report of these additional cases only served to emphasize his statement that the disease was not so rare as is commonly supposed. A positive diagnosis of the disease could not be made without the microscope; and, in the search for tubercle bacilli by the now classical Ehrlich-Koch method of staining, the actinomycetes were not stained, and were therefore invisible; hence the necessity of physicians giving more attention to the study of this dark part of pathology.

**A Case of Cerebro-spinal Meningitis, with a Remarkable Diminution in the Number of Respirations.**—Dr. J. F. ERDMAN read the report of a case. (To be published.)

Dr. LE FEVRE spoke of a case where rigidity of the muscles of the neck and back, together with Cheyne-Stokes respiration, had continued for eight days. He had made a diagnosis of meningitis, but, after having watched the case for five days, he had called in Dr. Loomis, who thought it questionable about its being a case of meningitis. The patient was given large doses of quinine and recovered. Another member of the family was soon after taken down in the same way, and then it was found that the main sewer pipe was open, and the case, instead of being meningitis, was an aggravated form of sewer-gas poisoning. The temperature had remained at 107° F. for seven days. He would like to know whether, in Dr. Erdman's case, chills had preceded the attack.

Dr. ERDMAN said that there had been none, and the highest temperature recorded had been 99° F. on the day of the eruption.

**A Case of Pyonephrosis.**—Dr. PARKER SYMS read the report and presented a specimen.

The patient was a man under fifty years of age, although possibly appearing to be ten years older. He had been intemperate in his youth, but for some years past had not drunk to excess, and had been in good health. During the two years prior to his coming under the speaker's observation he had had increasing trouble with urination, and he gave a pretty distinct history of

the passage of gravel. When first seen by the speaker, micturition was frequent, and the urine was loaded with pus. He had consulted several physicians, but, so far as could be ascertained, no diagnosis of renal trouble had been made. On examination, a non-fluctuating tumor was found in the region of the left kidney, and this, together with the very large quantities of pus voided, without bladder symptoms, seemed to point pretty clearly to a suppurating kidney. Three days later—May 31, 1889—the operation was performed. At this time he had a septic temperature of 102° F., but his pulse was 100 and fairly strong, and his general condition seemed pretty good. An incision was made along the lower border of the twelfth rib to the anterior superior spine of the ilium and curved forward. This was subsequently enlarged in a forward direction. The kidney was found very firmly adherent, and, during its liberation from its attachments, there was a rapid venous hemorrhage which was controlled by double clamps on the pedicle, so that the patient did not lose more than about three ounces of blood. The kidney was rapidly removed, but no bleeding point was found, and it was probable that it came from a rent in some vein, which was kept open by the presence of the tumor. The operation lasted an hour, including the time taken in examining the patient under ether. The man died unexpectedly from shock about twelve hours after the operation, and his death was probably due to the hemorrhage, which, although not large, was a good deal for a man in his condition.

It might be interesting to discuss the advantages and disadvantages of the operation in the loin as compared with abdominal section. It had seemed to the speaker that in the majority of cases it would be difficult, if not impossible, to remove such a kidney by abdominal section without rupturing it; and the pouring of pus into the peritoneal cavity was certainly a serious matter. By the curved posterior incision one got nearly as much room as by the anterior incision, and it would seem that the advantages of the extra-peritoneal operation were very great.

In answer to a question from Dr. R. H. Sayre as to the time when shock had supervened, the speaker said that the patient went into shock about half an hour after the stopping of the ether, and that he remained in that condition until he died. There was no hemorrhage in the wound, and no opening into the peritoneal cavity. As no autopsy was permitted, he could not say whether the other kidney was diseased, or even whether there was another kidney.

Dr. R. H. SAYRE had asked the question because he had in mind a case in which, after an operation on a patient known to have kidney disease, the patient had gone into a dangerous collapse and remained in that condition for several hours, and had been with great difficulty resuscitated. The collapse had seemed to be due to suppression of urine.

Dr. HARTLEY thought that the curved posterior incision gave all the room that was needed, and as much as was obtained by the anterior incision.

Dr. CARLISLE remarked that he had been under the impression that the danger in giving ether to patients with kidney disease was not from shock, but from suppression of urine.

*Meeting of November 6, 1889.*

The President, Dr. RICHARD KALISH, in the Chair.

**Syndactylism.**—Dr. J. McG. WOODBURY presented a case which involved both feet and hands; there was also a talipes equino-varus of the right foot. One thumb had been freed considerably, and there was a prospect of ultimately getting a good result also with the other hand. The talipes had been treated by a method which had worked admirably in upward

of nineteen cases. It consisted in applying Sayre's sandal, and by means of it bringing the foot in good position, and then righting it by confining the whole apparatus in plaster of Paris.

**Multiple Joint Lesions.**—Dr. FRANK HARTLEY presented a case, which was the one he had alluded to when discussing this subject at the last meeting. The boy was admitted to the Roosevelt Hospital three years ago with an injury to the external condyle of the right humerus. A tuberculous abscess had formed and communicated directly with the elbow joint, which had been accordingly excised by Dr. Sands. Following this operation there had been a succession of recurrences—first, nearer the shoulder and in the external angular process of the frontal bone on the affected side, and subsequently on the opposite side. Subsequently skin gummata had appeared over the shaft of the ulna, then over its olecranon process, and, later still, over both tibiae. So far five or six operations had been performed on this patient, but each operation had been followed by a recurrence of the growth, so that it had become necessary to abandon operative procedures and trust mainly to measures directed toward improving his general nutrition. There had never been any "bone cries," because the process had been mostly superficial and the bone had not been involved. Moreover, before the primary operation there had been no other foci except the one at the elbow. The speaker had watched the case for three years, and he felt pretty sure of the diagnosis. The case which had been presented at the previous meeting would, in all probability, pursue a similar course.

**Ankylosis of the Lower Jaw.**—Dr. L. W. HUBBARD presented a case with the following history: Walter S., aged three years and ten months, in January, 1888, had had an attack of what was called malarial fever, which had lasted about three weeks; and, after an interval of about one week, during which the boy had been apparently well, there had been a return of the fever, and this time it had been accompanied by profound drowsiness. In the following February abscesses formed on the leg, arm, and over the left ramus of the jaw. This latter abscess was incised and drained on March 12, 1888, but continued to discharge until the following June. During this time the jaw had been bandaged to retain the dressing, and apparently no attempt had been made to move the jaw. In June it was noticed that there was very little motion in the jaw, and in September an attempt was made to force open the jaw by means of instruments, but this had resulted in temporarily loosening the lower incisor teeth, so this procedure had been abandoned. Subsequently another attempt was made under chloroform, but the child behaved so badly under the anesthetic that nothing was accomplished. There had been no further treatment until the case came to the speaker in the middle of last July. Although the patient had been kept necessarily on fluid diet, he was well nourished at this time. The jaws could be separated scarcely an eighth of an inch, and there seemed to be no muscular control of the lower jaw. The parents objected very decidedly to the use of an anesthetic, so a method of gradual stretching was adopted and carried out by means of an instrument which the speaker had devised. This instrument consisted of two steel plates, fastened together at one end by a separable hinge, and capable of being separated at the other end by turning a screw. It differed from the usual wedge-shaped instrument in having a separable hinge, and in being made considerably thinner at this end, which in this case was absolutely necessary in order to permit the introduction of the instrument into the mouth. The original intention in having the hinge separable was to facilitate the cleaning of the instrument; but it was subsequently found that there was an additional advantage—*i. e.*, having partly separated the jaws of the instrument, a cork could be inserted between the plates near the hinge and the action of the screw reversed, by which the

instrument was made to exert considerable pressure on the molar teeth.

Owing to long disuse, the muscles of the jaw were very weak, particularly the depressors, so that electricity was employed as an adjuvant, and with benefit. At the present time the instrument could be inserted as far back as the molar teeth; but it was observable that when the child was excited he had less control over the muscles of the jaw, which did not open as much as at other times.

(The instrument was exhibited, and its use demonstrated.)

Dr. J. W. S. GOULEY said that he had treated about half a dozen such cases, all in children. The closure of the jaw had been due sometimes to an osteitis from decayed teeth, and sometimes to cicatrices following stomatitis; but in all the cases there was a permanent and unilateral contracture of the masseteric muscles. He had employed various instruments, beginning with one devised by Dr. Valentine Mott. This instrument effected the desired object, but in several instances broke the teeth. In some cases he had separated the jaws quite rapidly under an anesthetic, while in others the gradual method had been adopted. In the latter method, after opening the jaw a little, a small wedge of cherry wood (which was found to be better than cork) was inserted and kept in the mouth; and this treatment was continued, not merely for weeks or months, but for years. In one case, that of a girl of twelve years, these wedges had been worn daily for ten years, but at the end of this long period she could only separate her teeth half an inch. At this time she demanded an operation, and he exercised a portion of the maxillary bone according to the method of Esmarch, with the result of enabling her to open her mouth and chew her food; but the operation had caused an ugly deformity. The other cases had not been followed for so long a time; but in none of them had the original method employed been successful, as there was a recontraction. Dr. Valentine Mott had told the speaker that he had tried both this method and the slow one, and had even divided the masseteric muscle on the affected side, but had never been completely successful. The case presented to-night was worthy of careful treatment, as the child was young, and the chance of ultimate success was better, for the contracture was not so marked as it had been in the cases which he had narrated. He approved of the instrument, as, on account of its broad bearing, it was less likely to injure the teeth.

Dr. HUBBARD said that he had based his hopes of success in the case on the yielding nature of the contracture, as at no time, so far, had it been necessary to employ a force sufficient to cause much pain or make the teeth sore.

**The Radical Cure of Varicose Veins by Multiple Ligation.**—Dr. CHARLES PHELPS read a paper thus entitled. (To be published.)

Dr. J. D. BRYANT said that it had been his good fortune to witness some of these operations, and also the results. One of the dangers incident to the existence of varicose veins had not been touched upon in the paper, but had been illustrated in a case in his own practice. The case had been one of phlebitis associated with a well-marked varicose condition along the inner side of the knee joint, and the patient had died from pyæmia.

That varicose veins were amenable to treatment had been known since the time of Celsus, and from very early times the application of ligatures to varicose veins had been more or less generally recommended. The principal operative methods were: 1. Direct ligation of the veins, with the removal of a portion. 2. The application of ligatures at isolated points, or multiple ligation. 3. The use of caustics. Those familiar with the teachings of Dr. Gross knew that he preferred the use of caustics to multiple ligation; but the speaker's own preference

was for multiple ligation, or for ligation and excision. This question had recently been thoroughly discussed abroad by the German surgeons, who were about equally divided in favor of these two operations. Which method offered the best chances for the patient? There were three objections to passing any form of needle subcutaneously around a vein: 1. The danger of including a nerve, thereby modifying function or sensation. 2. The danger of wounding the vein, which would be very serious if the needle were not thoroughly aseptic. 3. A likelihood of including in the ligature the tissues surrounding the vein, which, although perhaps not dangerous, was certainly not requisite.

If the vein was exposed by an incision, the ligature could be passed around it without exposing the patient to any of these dangers, and with the additional advantage that collateral branches could be avoided. Although his experience with multiple ligation had not been so extensive as that of Dr. Phelps, he had done it many times, and had never observed suppuration; and, in a somewhat more limited experience with removal of portions of veins, suppuration had occurred in only one case. In simple cases he thought multiple ligation the better method, but where there were many and large veins to deal with, a free incision, with the removal of two inches or more of the vein, was the safer procedure.

As regarded the results of operation, there was no question that the veins were occluded and ulcers healed; but one could hardly say that there had been any permanent cure. The length of time which varicose veins took to develop was greater than the time the cases reported to-night had been under observation; and, besides this, the same causative conditions existed in the patients after as before operation. There was also no doubt that the *venae comites* might themselves become varicose, for in many instances, while ligating the posterior tibial behind the internal malleolus, very tortuous varicosities had been found, both with and without more superficial varices. The subcutaneous and the open methods of ligating veins were the best operations we had at present for the treatment of these infirmities.

Dr. GOULEY said that he would have very little hesitation in choosing between these two operations; for, both theoretically and practically, the subcutaneous method was the safer one, as there was always greater risk of complications from an open wound than from small punctures as made by Dr. Phelps. The reader of the paper had given the indications for ligation of varices, and had by implication furnished also some general indications; but there were special indications which should be mentioned. As an illustration he cited the case of a medical man who had come under his observation some twenty years ago suffering with large varices of the leg and thigh where the saphenous vein had been about half an inch in diameter. At its point of communication with the femoral vein there had been an ampulla two inches and a half in diameter, which had extended like a huge aneurysmal sac up the thigh to Poupart's ligament, beyond which it could not be traced. In such cases no method of operation would have been safe. The previous speaker had spoken of the operation of excision; but there had been another craze in this country—*i.e.*, the injection of varices with perchloride or persulphate of iron. He had once been tempted into doing this, and had come very near regretting it, although the patient had lived in spite of the damage done. The method consisted in injecting into the vein a few drops of the perchloride of iron with a Pravaz syringe, while pressure was made above. There was no certainty that a serious thrombosis would not result. The operation had been done frequently by one of his hospital colleagues, but the results had been very unsatisfactory.

In connection with the subject of contra-indications, he related the history of the case of one of his patients who had had a thrombosis of the iliac vein following some operation. This had resulted in a swelling of the leg like a classical "milk leg" in a puerperal patient, and subsequently in the formation of a large abscess in the upper part of the thigh. Eight or nine months after his recovery from this the speaker had noticed superficial varices of the leg and thigh, and in the course of a year there had been a great bunch of varicose veins in the hypogastric region. The greater part of the blood from the leg had been found to traverse the hypogastric region to open by one of the large venous trunks into the right femoral; and, when this was compressed, the enlarged hypogastric veins had become much swollen, some of them being three quarters of an inch in diameter. A surgeon had proposed an operation for the purpose of closing these veins; but, had this been done, the consequences could be easily imagined. (Photographs of this patient were shown.) The man lived twelve years, and at the autopsy the left iliac vein had been found to be completely closed. The question of cure of varicose veins was by no means settled, and a period of four or five years would scarcely be a sufficient test of the permanency of the cure.

Dr. J. R. CONWAY said that his experience with the method of multiple ligation was limited to three cases, but the results so far went to corroborate the statements made by Dr. Phelps in his paper. In one case, that of a woman, the veins had been much dilated from the lower third of the thigh nearly to the ankle. Near the knee the veins had formed a large thin-walled tumor, and in the lower third of the leg had been an extremely deep ulcer of five years' standing, which had resisted all attempts to cure it. Nine ligatures had been applied to the veins at intervals of an inch and a half to two inches, and she recovered very rapidly. The two other cases had not been so severe. In one of them nine ligatures had been applied to a varicosity which had had a diameter about equal to that of the thumb. The result had been complete obliteration of the veins. In the third case only three ligatures had been employed, and the veins, although much diminished, had not been entirely occluded, owing to the re-establishment of the circulation through anastomosing branches. An interval of two inches between the ligatures seemed to be about the proper distance to secure obliteration of the vein. In none of these cases had there been inflammation, suppuration, or pain; and the patients had recovered rapidly. The operation was a simple procedure, and there did not seem to be much danger of including in the ligatures nerves or other important structures.

Dr. HARTLEY had never seen any particular trouble from infection of the wound, whether the case was treated by subcutaneous ligation or whether the vein was excised. In some cases, especially where there were ulcers, it would seem to be very difficult to prevent infection; but, even in these cases, if the ulcer were disinfected and kept dry, there would be no interference with the process of healing. He had been accustomed, where the veins were large, to tie the vein above and below and excise, and also to tie the neighboring branches. Where varicosities were very extensive, a continuation of this process would make the operation unnecessarily lengthy, so he had been in the habit of employing, under such circumstances, the multiple ligatures.

Dr. PHELPS said that he did not maintain that the cure at the present time was radical, and he considered the method by excision about as good, except that it was very tedious. He wished especially to insist upon the necessity of the multiple occlusion of the vein, either by ligature or otherwise, in order to secure obliteration of the vein.

## Book Notices.

*Lectures on Bright's Disease.* By ROBERT SAUNDBY, M. D. Edin., Fellow of the Royal College of Physicians, London, etc. With Fifty Illustrations. New York: E. B. Treat, 1889. Pp. vi-290. [Price, \$2.75.]

THE author gives one of the best summaries which have come under our notice of the various views held in regard to the vexed questions of albuminuria, dropsy, and the urinary and vascular changes found in renal disease. He writes also a most excellent chapter upon the clinical examination of the urine, both microscopical and chemical. We can hardly, however, accept all his statements regarding the clinical significance of tube-casts. When we come to his classification of Bright's disease we can not help feeling that he should either have kept to one of the older ones or given some comprehensible reason for adopting the one he has selected. He speaks of "febrile nephritis," "toxæmic nephritis," and "obstructive nephritis." Now, we suffer enough from bad classifications, and we should not have one thrust upon us which is incomprehensible in its very meaning. Who would imagine that "obstructive nephritis" meant what is often called "surgical kidney" or "suppurative nephritis"? Except for this classification, the book is very good, and the remarks upon treatment especially deserve praise.

*Electricity and the Methods of its Employment in removing Superfluous Hair and other Facial Blemishes.* By PLYM. S. HAYES, A. M., M. D., etc. Chicago: W. T. Keener, 1889. Pp. vi-128.

THIS treatise contains the usual statements upon the subject, and is a contribution to book-making rather than to medical literature. The busy practitioner has no time for it, and it seems powerless to enlighten the laity except to the most limited extent.

### BOOKS AND PAMPHLETS RECEIVED.

A Text-book of Practical Medicine, designed for the Use of Students and Practitioners of Medicine. By Alfred L. Loomis, M. D., LL. D., Professor of Pathology and Practical Medicine in the Medical Department of the University of the City of New York, etc. Eighth Edition, revised and enlarged. With Two Hundred and Fifteen Illustrations. New York: William Wood and Company, 1889. Pp. xvii-1147.

Chemistry: General, Medical, and Pharmaceutical, including the Chemistry of the U. S. Pharmacopœia. A Manual on the General Principles of the Science, and their Applications in Medicine and Pharmacy. By John Attfield, F. R. S., M. A., and Ph. D., of the University of Tübingen, etc. Twelfth Edition. Philadelphia: Lea Brothers and Co., 1889. Pp. xvi-13 to 770. [Price, \$2.75.]

Notes on a Case of Macula Cæruleæ. By Fred J. Leviseur, M. D. [Reprinted from the "Journal of Cutaneous and Genito-urinary Diseases."]

The Cure of Hernia by the Use of the Buried Antiseptic Animal Suture. By Henry O. Marey, M. D., LL. D. [Reprinted from the "Journal of the American Medical Association."]

Chronic Inversion of the Uterus. By Henry O. Marey, M. D., LL. D. [Reprinted from the "Journal of the American Medical Association."]

The Bible Doctrine of Immortality. Shown by Numerous Texts. Compiled and edited by Joseph Wheeler, of St. Louis, Mich.

Medical Communications of the Massachusetts Medical Society. Vol. XIV, No. 111. 1889.

Jahresbericht über die Fortschritte auf dem Gebiete der Geburts-hilfe und Gynäkologie. Herausgegeben von Prof. Dr. Richard Frommel in Erlangen. II. Jahrgang, Bericht über das Jahr 1888. Wiesbaden: J. F. Bergmann, 1889. Pp. viii-651.

## New Inventions, etc.

### A GRAVITY DOUCHE.

By S. E. COOK, M. D.,  
HOLDREGE, NEB.

My object has been to produce a physician's gravity douche that would supply an even flow throughout, so long as the relations between nozzle, reservoir, and cut-off were not disturbed, that would give a regularly intermittent flow when desirable, and of any desired strength of each pulsation, in which the temperature of the fluid in the reservoir could be gradually raised, and as it passes from the reservoir strained of sediment, and that would not inject air.

From experience I know that my instrument possesses these qualities, and I think is not unduly complicated. Figs. 1, 2, and 3 show the different steps I have followed in perfecting my design, Fig. 3 being the perfect apparatus.

The design, Fig. 1, is a simple closed can, A, with an outlet nipple, E, for attachment of the rubber tube, a screw cap, G, with washer, covering the opening for filling, and a straight tube, C, open at both ends (externally above and internally below near the bottom of can), to supply air to the interior of the reservoir and produce an even flow. This reservoir will produce an unvarying current until the fluid falls below the level of the lower end of the tube, C, when the reservoir is practically empty.

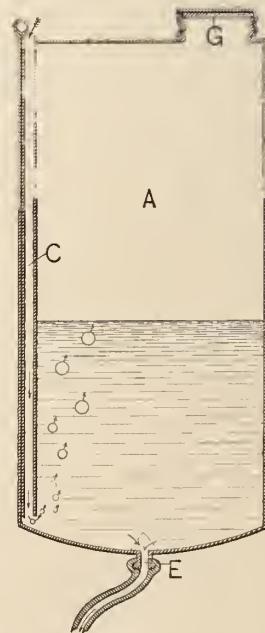

FIG. 1.

The drawing, Fig. 2, shows an open reservoir, A, provided with a small outlet nipple, E, beneath which is a smaller closed reservoir, B, supplied with an air-tube, D, long enough to reach above the level of the fluid in A. Within this smaller reservoir is a cylindrical float, K, slightly smaller in every direction than B, so as to be quite free to move in a vertical direction a quarter of an inch. This float is centrally perforated by a light rod provided at its lower extremity by a conical valve. This valve rests upon a valve-seat in the center of the bottom of B, which is continued into an outlet nipple, F, for the attachment of the rubber hose.

The reservoir, A, being filled, if the discharge nipple, F, carries the fluid from B faster than it can enter through E, a series of regular pulsations occurs, continuing so long as the fluid lasts in A. The *modus operandi* is as follows: The air being expelled, the valve and float resting on the valve-seat are kept in that position by their own weight, pushing downward, and the weight of the column of fluid in the rubber hose pulling downward. Against these two forces is the buoyancy of the float, which increases as the fluid in B rises. This upward force finally becomes the greater and the float with valve suddenly rises. The opening of the valve transfers the weight of the fluid in the discharge pipe from the valve to the fluid in B, which is pulled downward with a rush. When the fluid in B is low enough the float lowers and the valve suddenly closes. This action repeats itself so long as the supply of fluid lasts. There being always a bed of fluid in B, the injection of air is impossible. The action represents very accurately that of the hand compression syringe.

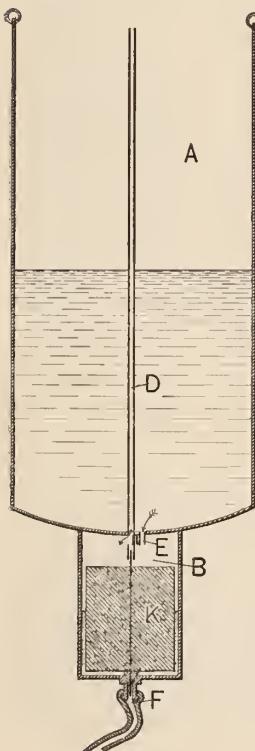

FIG. 2.

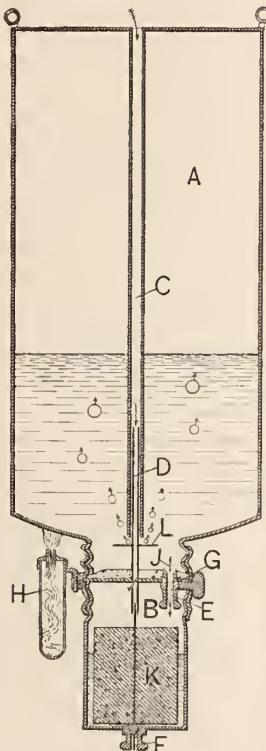

FIG. 3.

In order to combine these two ideas in one instrument, I have devised that shown in Fig. 3—the reservoir in Fig. 1, A, with the air-tube, C, centrally located, and the opening for filling changed to the bottom. The screw cap or stopper, G, is provided with a screw flange on each side, serving to connect the large reservoir with the small one. The nipple, E, is provided with a stop-cock to regulate the supply of fluid from A to B. The stopper, G, is also perforated centrally for, and provided with, an air-tube, D, the upper end of which enters C, extending some distance above the level of fluid in C. This tube, D, supplies B with air, maintaining a proper equilibrium. I further provide G with a small loop to hold the hook or arm of a small alcohol lamp, II, when necessary, to increase the temperature of the fluid in A. In order

to further guard against the escape of air bubbles through the nipple, E, a circular disc, L, somewhat larger in diameter than C, and perforated for D, guards the lower extremity of C. A strainer, J, also overlaps the outlet vent.

To fill the reservoir, unscrew and remove G and invert the reservoir. If a continuous current is desired, unscrew and remove the small reservoir, B, with float, and attach the hose to E. If an intermittent current is desired, attach the hose to F, leaving B in place.

Revert the reservoir and hang it high enough to get the desired strength. In using the intermittent current, the stop-cock, E, determines the number and length of the pulsations in a given time, while the height of B above the nozzle determines the force of each beat. By using the stop-cock, from one or two to twenty beats in a minute may be secured with a force determined by a head of from one to five feet.

If the temperature of the fluid is desired to be gradually elevated light and place in position the small alcohol lamp. The sensations of the patient will decide the limit of heat, when the lamp can be removed.

Of course, ordinarily the continuous current will be desirable, as in intra-uterine medication, where a very gentle even flow is desired, while for vaginal use alone, as in Emmet's method, many cases would be benefited by a pulsating current.

I have corresponded extensively with our leading gynaecologists, and, with but few exceptions, they approve of my idea. Some favor the continuous current for all purposes, while others have informed me that to gain the full therapeutic effect of hot water they prefer the interrupted current of the "hand-bulb" syringe, and have on that account partially or wholly discarded the use of the "fountain" syringe.

My syringe corrects these defects and, though doubtless still capable of improvement, is reliable and convenient. The reservoir I intend shall hold at least a gallon, which I believe to be the most useful size. It can be made quite cheaply, being entirely of tin, and needs no engineer to run it.

## Miscellany.

**Buffalo Lithia Water in the Treatment of Stone in the Bladder, etc.**—In the "Virginia Medical Monthly" Dr. John Herbert Claiborne, of Petersburg, Va., writes as follows: "I have for many years been prescribing the use of the Buffalo lithia water in cases of lithiasis, uremia, Bright's disease, cystitis, and allied affections, and with the same marked results which have followed its exhibition in like conditions by a number of other physicians. The most striking instance, however, in which I have seen the solvent properties of the waters manifested has been in the case of Mr. M., of this city. Mr. M. had been subject to attacks of lithiasis for several years, but in August last, after one of the most violent attacks of nephritic colic, passed gravel from the kidney into the bladder, where it remained for a week or more, setting up a severe inflammation of that viscus, with all its painful and distressing symptoms. Finally, however, the gravel re-commenced its journey, and became lodged in the prostatic portion of the urethra, cutting off the flow of urine and causing retention. Being compelled to use a catheter for the relief of this symptom, I pushed the calculus back into the bladder, as there was too much inflammation to resort to either the crushing of the stone or to its removal by lithotomy. I put the patient to bed, restricted him to a milk diet, administered opium suppositories in sufficient doses to relieve vesical tenesmus and pain, and directed him to drink the Buffalo lithia water in the largest quantities which he could bear. He succeeded in drinking from half a gallon to a gallon every twenty-four hours, and, at the end of about ten days, commenced to pass the detritus of the gravel, as I suppose, in quantities which seemed incredible. At all events, after passing his water upon a clean board, and allowing as much of it to flow off as would, you could then scrape up with a knife a teaspoonful or two (after every passage of urine) of phosphates, urates, etc., closely resembling whitewash which had been applied to the board, and which had there dried. This continued for a week. I then washed out the bladder several times with a warm solu-

tion of boric acid, and Mr. M. was soon on his feet again. At this writing he says that he is perfectly well, and feels, for the first time in many years, entirely free from all kidney or bladder trouble."

**Dr. Hammond's Sanitarium**, in Washington, is said to contain a greater number of patients now than at any time since it was opened, about a year ago. We learn that Dr. Hammond is making a number of experiments in the treatment of epilepsy by trephining over the site of the suspected brain lesion and paring the convolutions.

**American Pharmaceutical Products at the Paris Exposition.**—Messrs. W. R. Warner & Co., of Philadelphia, have been awarded a silver medal in recognition of the excellence of their pills and effervescent salts.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the abstract of sanitary reports received by him during the week ending December 6th:

CITIES.	Week ending—	Estimated population,	Total deaths from all causes,	DEATHS FROM—

**Oysters.**—Oysters are so nutritious and of so much value in many forms of convalescence, as well as so largely employed as a luxury, that it is to be regretted they should have fallen under the ban of a scare. It is so easy, when the public mind is disquieted and alarmed by the prevalence of an epidemic, to fix the blame upon one special article of diet, and to be lulled into a false sense of peace provided that this substance is avoided; but, on the other hand, the connection between the disease and the supposed peccant substance is very frequently imaginary. The relief obtained by branding some possibly innocent substance may occasionally serve to divert attention from some radical sanitary defect, while it also causes an irrational distaste for some article of diet which requires much time and experience to eradicate. Contamination with sewage is justly regarded as a danger, and one of the latest suggestions is that some epidemics of typhoid fever

are to be traced to the use of oysters thus poisoned. It is an undoubted fact that sometimes attacks of diarrhoea follow the ingestion of oysters, but the comparative rarity of this leads many to brave this danger with an easy mind. The proof of the connection between typhoid and oysters can only be established by careful inquiry. So many sanitary defects exist in Dublin that we should be sorry to find the stigma cast upon foreign oysters regarded as a satisfactory solution of the problem, still less as a reason for taking no measures to relieve that city from the frequent and powerful odors which at present pervade it. While it is possible that oysters may cause disease, it is certain that the other question urgently calls for attention and improvement.—*Lancet*.

#### ANSWERS TO CORRESPONDENTS.

**No. 302.**—We know of no competent observer of the present day who looks upon the lenticular spots as absolutely essential to the diagnosis of typhoid fever, but most authors agree that their absence or the fact that they are not observed renders the diagnosis doubtful for a time.

**No. 303.**—They are identical.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

## Lectures and Addresses.

### SOME POINTS IN THE PROGNOSIS OF VALVULAR HEART DISEASE:

AN ADDRESS DELIVERED BEFORE  
THE MEDICAL SOCIETY OF THE PHILADELPHIA HOSPITAL.

BY FREDERICK P. HENRY, M. D.,  
PHYSICIAN TO THE PHILADELPHIA AND TO THE JEFFERSON  
MEDICAL COLLEGE HOSPITALS.

YOUR flattering invitation to address you found me unusually busy, and my first impulse was, naturally, to decline it. I did not at first see how, in the pressure of other work, I could make ready, in the short interval allowed me, to address you on any subject in a manner satisfactory either to myself or to you. On second thought, however, it occurred to me that I might have something to say on the important and highly practical matter of prognosis.

Much has been said, and with great force, in favor of the view that prognosis is the most important of the various subdivisions of medical science. I do not know that I am prepared to accept this statement as applicable to all diseases, but I am firmly convinced of its truth with reference to those of the heart, and I am sure that a moment's reflection will serve to convince you of it. Imagine yourself in the place of a man hitherto strong, active, and hard working, with children dependent upon him not only for support, but for protection and counsel in the daily emergencies of life. He becomes conscious of a gradual failure of vital power, and is compelled to admit that the source of this trouble is the heart. He feels the deadly arrow in his side. "*Hæret lateri letalis arundo.*" Finally he consults a physician and finds his fears confirmed. Is it not a foregone conclusion that the first question of this man, to carry out our figure, will be, Can the arrow be extracted, or, if not, how long will it rankle there? I am sure I need not say another word to convince you of the paramount importance of prognosis in heart disease.

The idea of sudden death is invariably associated with that of heart disease, and yet, in the majority of cases, we can positively assure our patients that no such event is to be apprehended. It is only of two forms of cardiac disease that sudden death can be said to be the frequent termination, and these are aortic insufficiency and angina pectoris—the true angina pectoris of Heberden. In cases of mitral insufficiency sudden death is a rare event, occurring, according to Leyden,\* in about two per cent. of the cases—that is to say, not much more frequently than in individuals with no heart disease whatever. In such cases, therefore, we are quite justified in trying to free the minds of our patients of all dread of an event of such rare occurrence.

In the prognosis of heart disease the age, sex, and mode of life of the patient should be taken into careful consideration. In quite young children the prognosis is most unfavorable, the course of the disease being, as a rule, rap-

idly progressive. I recall the case of a boy of six who was attacked with acute articular rheumatism and mitral disease causing insufficiency, and who died in six months with great ascites and general anasarca.

In youth and early manhood, on the other hand, the prognosis is comparatively favorable, owing to the kind of valvular affections that are most prevalent at this time of life.

In advanced age, according to Leyden, the prognosis is decidedly unfavorable, and this is because the commonest cause of these affections at this time of life is arterio-sclerosis, which is generally a steadily progressive disease. Compensation for valvular defects, however, occurs quite as readily in advanced life as in youth, the heart being probably the only organ of the body of which the relative size increases with age.\*

The second part to be considered in the prognosis of heart disease is *sex*, and it may be laid down as a general rule that the prognosis is more favorable in females than in males. This difference in favor of females is not so marked in hospital as in private practice, because the life led by females of the lower classes is not materially different from that of males. They undergo the same privations, and many of them are engaged in severe manual work. Still there is a decided difference, and this is due chiefly to the facts that arterio-sclerosis, a common cause of heart disease, is comparatively rare in the female sex, and that in females those forms of disease are most prevalent which warrant a favorable prognosis.

*The mode of life* is doubtless the point of greatest importance in the prognosis of heart disease. Manual labor in heart diseases is like the fuel which feeds the fire, or, rather, like the bellows which fans it. For this reason the well-to-do classes are able to resist the progress of heart disease much better than those who depend for subsistence on their own bodily exertions.

*The disposition* is of almost equal importance, for outbreaks of temper and violent emotions generally act in the same way as severe bodily exertion. In this connection the most interesting case on record to us medical men is that of John Hunter, who had long suffered from angina pectoris and died from the immediate effects of violent excitement. The following extract from the Hunterian oration for 1855, by Joseph Ridge, M. D., will, I am sure, be heard with interest:

"Arrived at the hospital, he found the board already assembled, and, entering the room, presented the memorial of the young men and urged the propriety of their being admitted. In the course of his remarks he made some observation which one of his colleagues thought it necessary instantly and flatly to contradict. Hunter immediately ceased speaking, retired from the table, and, struggling to suppress the tumult of his passion, hurried into the adjoining room, which he had scarcely reached when, with a deep groan, he fell lifeless into the arms of Dr. Robertson, one of the physicians of the hospital who chanced to be present."

\* Leyden, "Ueber die Prognose der Herzkrankheiten," "Deutsche medicinische Woehenschrift," Nos. 15, 20, 21, 22, 1889.

\* Leyden, *loc. cit.*

Hunter, from all accounts, was a man of ungovernable temper and quite conscious of his infirmity, for before the meeting referred to he had "expressed his apprehension lest some unpleasant dispute might occur, and his conviction that if it did, it would certainly prove fatal to him."

The manner in which the patient responds to treatment is another point of importance in forming our prognosis. There are great differences in this respect. In some cases the usual effect of digitalis, for example, is not easily obtained; in others the effect of this remedy is promptly manifested but speedily exhausted. This drug, and others of the same kind, should be employed with great economy. When the desired effect has been obtained through their use—in other words, when cardiac irritability has subsided and the pulse, from being rapid, irregular, and perhaps intermittent, has become of normal frequency, regular, and free from intermission—the drug should be withheld and an attempt made to maintain the circulatory equilibrium by means of nutritious, easily digestible food, tonics, especially the vegetable bitters, and an occasional saline laxative. The latter is of great service in preventing venous stasis, for it unloads the vessels of any excess of fluid and places them in the most favorable condition for the absorption of proper nutriment.

With reference to prognosis, cardiac affections may be divided into the three customary classes: 1. Non-organic diseases. 2. Diseases of the valves. 3. Diseases of the muscular structure. It is of the utmost importance, from a prognostic point of view, to be able to separate the non-organic from the organic disorders, and yet in certain cases it is extremely difficult to make the distinction. As a rule, the diagnosis of non-organic disease is justified when the most careful physical examination fails to detect anything abnormal either in the size of the heart or in the sounds to which its action gives rise. This diagnosis will receive support if the patient is young, of a neurotic diathesis, and especially if of the female sex. It must not be forgotten, however, that an anaemic murmur may be present, and when this occurs in connection with the manifold subjective and objective symptoms of functional heart disease the diagnosis must often be held in reserve by the greatest expert in cardiac diseases. A few words here with reference to inorganic heart murmurs. There is, I believe, little or no difference of opinion with reference to the fact that they are all systolic. In the majority of cases they are heard only at the base of the heart, though occasionally at the apex. The former murmurs have been called haemic; the latter, dynamic; but the term inorganic covers them all, for it implies the fundamental fact that, in case of death, no lesion of the valves can be found to account for their existence. We are not entirely ignorant, however, with reference to the mode of their production. Experiments have shown that a murmur is not produced by the quiet flow of fluid through a tube of uniform caliber. If, however, the fluid be forced rapidly through the tube, a murmur is produced, and the ease with which this is done is in inverse ratio to the density of the fluid. Dr. B. W. Richardson, of London, says that "if our blood were reduced to the con-

dition of distilled water, and we could live and hear, as we do now, we should probably always be conscious, not only of the heart sounds, but of a soft, internal, musical murmur, produced in our own vessels."

An inorganic murmur, in short, is produced by blood of low specific gravity flowing through the vessels under high tension. It has long been supposed that the arterial tension in chlorosis, in which these murmurs are most often heard, is low; but this is not the case, as may be proved, not only by means of the sphygmograph, but by the facts that the heart is often found hypertrophied and its second sound accentuated. A loud second sound, of course, implies high tension in either aorta or pulmonary artery. Again, an inorganic murmur does not immediately follow a copious bleeding, as it would if due to low arterial tension, but makes its appearance when the volume of the blood has been restored by the absorption of water. When an inorganic murmur is heard with greatest intensity at the apex, it has been called, as already stated, dynamic, and is caused by mitral regurgitation due to imperfect contraction of the left auriculo-ventricular orifice. During systole, as has been proved by Ludwig and others, the size of the auriculo-ventricular orifice is reduced one half. If, however, the cardiac muscle is weak, as in anaemia, and especially if the blood tension is also high, the closure will be imperfect and regurgitation will result. "This regurgitation is not due to a dilatation of the orifice beyond its normal limits, but to an incompetent contraction during systole, and thus at post-mortem the orifice and valves appear perfect."\*

The practical bearing of these remarks is that an examination of the blood may be of decided value in determining whether or not a cardiac murmur is organic. It does not necessarily follow, however, that a cardiac murmur in an anaemic individual is inorganic. In fact, according to Dr. Goodhart,† of London, anaemia long continued may give rise to valvular disease. The doubts concerning the nature of a murmur may sometimes be removed by the effects of treatment. If the murmur persists after the blood has been restored, by proper treatment, to its normal composition, it is organic. If the anaemia persists in spite of treatment and the case steadily progresses to a fatal termination, the doubts concerning the murmur may not be removed until the heart is inspected on the post-mortem table.

Having decided the murmur to be organic—*i. e.*, dependent on some valvular imperfection—the questions which at once arise are: 1. Does the character of the murmur—that is, its seat, intensity, tone, etc.—influence the prognosis? 2. Is there any prospect of a cure?

The best prognosis, other things being equal, is afforded by cases of mitral insufficiency, by which I mean that in this form of valvular lesion compensation is more readily made and maintained than in any other. The worst form of valvular defect is aortic insufficiency, and it is in this variety of cardiac disease that sudden death is most apt to occur. Between these two extremes lies mitral stenosis. Of course

\* Garland, "Boston Med. and Surg. Journal," 1883, vol. cix. In this article, and in one in the same journal by F. C. Shattuck, will be found a thorough consideration of inorganic heart murmurs.

† "Lancet," vol. i, 1880.

there are numerous exceptions to the rule just laid down. For example, cases of aortic insufficiency of ten, fifteen, or twenty years' duration are not infrequently observed, but, on the whole, the facts will be found to be such as I have stated.

In estimating the gravity of a valvular lesion it is important to observe whether, besides the murmur, the valvular sound can also be heard. When the normal valvular sound is entirely replaced by a murmur, the lesion is more extensive and the prognosis, of course, more grave than when both murmur and sound can be detected. It is a common mistake to suppose that the gravity of the lesion is in direct ratio to the intensity, the loudness, of the murmur, whereas the fact is that loud murmurs are generally more favorable from a prognostic point of view than faint ones. The loudest valvular murmur I ever heard was in a boy, still living, and now about twelve years of age, and was undoubtedly due to a congenital stenosis at or near the orifice of the pulmonary artery. The most singular fact concerning this murmur is that it was detected by the boy's mother. The lad was supposed to have swallowed a cent, and his mother, thinking the coin might be lodged in his throat, put her ear to his chest and heard the murmur. Not understanding its nature, she brought the boy to me. I may say that the congenital defect has never caused the boy any inconvenience, or in any way interfered with his physical development. With reference to loudness of murmurs it is well known that in mitral stenosis the murmur is louder in an earlier than in a later stage of the affection. In other words, the narrower the button-hole contraction of this form of valve lesion, the fainter is the sound to which it gives rise. The specimen I now show you is an extreme example of mitral stenosis. The left auriculo-ventricular orifice has been, as you perceive, converted into a mere slit, and this condition has doubtless been of long duration. Nevertheless, at no time during the two years in which the man was in the hospital was the valvular murmur a loud one. The consequence was that there was much difference of opinion concerning the precise nature of this case. For my part I never felt any doubt about it, because five years before his admission to the Philadelphia Hospital he had been under my care at the Episcopal Hospital, so that I had the great advantage of being able to recall to mind his case in its comparatively early stages.

I have used the word "cure" in connection with valvular heart disease. I propounded the question whether there was any prospect of a cure of this much-dreaded malady. It is easily answered. A number of undoubted cures have been reported by the most competent observers, but the prospect of cure, in the sense in which I am using the word, is infinitesimal. By cure I mean the disappearance not only of all the symptoms, but also of all the signs of heart disease. Such cases are on record, and a number of them have been collected by Professor Leyden, of Berlin, in his valuable paper to which I have alluded.

The question of the disappearance of a cardiac murmur is a delicate one, its presence or absence being, as a matter of course, largely dependent on the existing degree of blood pressure. It is a matter of almost daily observation that

the intensity of a murmur may vary within wide limits, so that these instances of reported cures will always be open to criticism. The fact, however, remains that notwithstanding the presence of a well-marked murmur indicative of serious functional impairment of a valve, an individual may enjoy a very fair degree of health. I recall the case of a physician, about sixty years of age, who, a few years ago, was a prominent member of the Philadelphia County Medical Society. I met him one day at a committee meeting, and in order, I suppose, to pass the time while waiting for the indispensable quorum, he asked me to examine his heart. I did so and was amazed at hearing a loud, rasping, mitral regurgitant murmur. I could not dissemble my surprise, and, fortunately, there was no occasion for me to do so, for my patient, if I may so call him, knew all about it. "Why, doctor," said he, "I have had that murmur for ten years." He was actually proud of it. He died about two years after the time I speak of, but whether or not from failing cardiac action I am unable to state.

As long as there is perfect compensation for the lesion, the patient with valvular heart disease is conscious of no bodily imperfection. It is a great mistake, however, to encourage such a person in any attempt to compete, whether in the way of business or amusement, with individuals in perfect condition—*i.e.*, if such attempts are attended with physical exertion. The inevitable medical tendency to pass from one extreme to another is nowhere more marked than in the prognosis of heart disease. It is not long since the belief was prevalent that valvular heart disease doomed the patient to a speedy death, in spite of the fact that the individual in whom the diagnosis was made, perhaps by mere accident, was conscious of no cardiac trouble. Such views were definitely disproved by Sir Andrew Clark, who reported six hundred and eighty-four cases of valvular disease which had been in existence for at least five years without leading to any serious impairment of health. A complete reaction from the old pessimistic views at once set in, and, instead of immuring such patients in their homes and condemning them to a life of inactivity, they are now often encouraged to exert themselves to the utmost of their limited capacities. In my opinion, the present tendency is to encourage patients with heart disease to over-exertion. They are not sound, vigorous individuals, and, although they should, as far as possible, keep themselves from brooding over their ailment, they should also never completely forget its existence. The only exercise in which they should indulge to any great extent is walking. Any exertion which involves much use of the arms, such as rowing, is injurious, and tennis, base-ball, or swimming is suicidal. The latter is true of cold bathing, and probably the most injurious combination of exercise possible is swimming in cold water.

In the foregoing remarks I have given you nothing more than the barest outline of the subject chosen for this evening's discussion, and here and there have wandered from it to throw out a therapeutic hint. I trust I have at least succeeded in impressing on your minds the practical importance of the study of prognosis in valvular heart disease.

## Original Communications.

### EXPERIENCE WITH EARLY OPERATIVE INTERFERENCE IN CASES OF DISEASE OF THE VERMIFORM APPENDIX.\*

BY CHARLES McBURNEY, M. D.,  
VISITING SURGEON TO THE ROOSEVELT HOSPITAL.

I VENTURE to introduce once more a subject that has been so ably treated by numerous writers, because I have for some time been devoting my attention in suitable cases to a particular line of treatment, and because I have been fortunate enough to have had recently a considerable number of cases of disease of the appendix under my care. Nearly two years ago the account of a case of successful laparotomy for perforation of the vermiform appendix was read before this society by our much-lamented colleague, Dr. Henry B. Sands. The case was a most brilliant one throughout, and illustrated particularly well the cleverness of diagnosis and the rapidity of successful action which we all remember as so characteristic of the reader of that paper. It should not be forgotten that at that time such action was a very bold step into ground that was almost unknown. We did not all agree with Dr. Sands in the views which he expressed in regard to the pathology of perityphlitis, but these views did not prevent him, when the proper case occurred, from making, in regard to treatment, a brilliant stride in advance of others. This case gave an impulse to the study of inflammatory affections of the vermiform appendix from which we shall not recover for a long time. During the following months Dr. Sands devoted much attention to this study, and it was my privilege to assist him in a number of successful operations for the removal of the appendix at an early stage of disease. It seemed to me that each one of these operations shed a flood of light upon the pathology of the so-called pericæcal inflammations, and during the summer following, while discussing this subject, he expressed to me views which were far in advance of most surgeons and very different from those which he entertained at the time when he wrote his last paper. If he were here to-night he would, by the results of his own last year's original work, enlighten us upon many points respecting the pathology of perityphlitis. I feel it a pleasure and a duty to thus refer to Dr. Sands, because, unfortunately, no special record has been kept of his last year's brilliant work, and his sudden death prevented him from telling us himself what would have been so valuable. Certainly no other surgeon ever did so much to improve the treatment of a very fatal disease. Beginning with the first suggestions of Dr. Willard Parker, which taught surgeons how to save many lives, although by a slow and often unsatisfactory process, Dr. Sands ended his work in this direction by showing us how we might cut short at its very inception a disease that is even to-day responsible for many deaths.

It is not my intention in this paper to attempt to pre-

sent the subject of pericæcal inflammations in a systematic manner. That has already been done, and very recently, by a large number of writers. I have chosen rather to dwell upon some points in the pathology and treatment of these inflammations, which are beginning to be better understood and which especially interest us all. The fact that inflammatory affections of the vermiform appendix give rise to a considerable number of the so-called pericæcal inflammations is now accepted in every part of the medical and surgical world, although one still reads of perityphlitis and paratyphlitis, and of intraperitoneal and extraperitoneal abscesses. Certainly all of these terms are misleading, inasmuch as each of them, when used without explanation, implies that the particular disease to which it refers is a disease by itself, and fundamentally different from the others. The usual term perityphlitis means, strictly speaking, nothing more than an inflammation of the peritonæum surrounding the cæcum, but it is understood by many to mean often a localized and harmless peritonitis arising from impaction of faeces, by others a fatal septic disease originating in perforation of the appendix. Now it is unquestionably true that every case of inflammation of the appendix is sooner or later accompanied by inflammation of the neighboring peritonæum, either on the cæcum or mesentery or ileum, etc., but if from the whole list of acute inflammatory affections occurring in the right iliac fossa we set aside those originating in the appendix, how many shall we have left? Very rarely will occur a perforation of the cæcum by ulcer or foreign body, giving rise to a local peritonitis at this point, and traumas from without may accomplish the same result. For all of such causes as compared with inflammations of the appendix, let me hazard the proportion one in one hundred.

How many cases of localized peritonitis or periphritis arise from impaction of faeces in the cæcum? Some writers would lead us to believe that this is a frequent cause, and not long ago it was looked upon as the *most* frequent cause. Is there a *single* observation brought from the dead-house or from the operating-table to support this idea? I have never heard or read of such observation, and I do not believe that any such case ever occurred. Clinically we meet with cases of pain in the right iliac fossa, accompanied by some rise of temperature, and not infrequently in these cases we may detect masses of faeces in the cæcum, but no peritonitis exists, and it is no more likely to arise from this cause than from ordinary constipation, which often causes pain and rise of temperature. Correctly speaking, then, peritonitis localized in the immediate neighborhood of the cæcum and characterized by the well-known symptoms may, with the rare exceptions referred to, be attributed to an inflammation of the vermiform appendix in some one of its numerous stages. This inflammation may be a comparatively mild catarrhal one, affecting little more than the mucous membrane, or it may have rapidly passed through various stages to complete gangrene of the organ. I must therefore prefer to use the term inflammation of the appendix, or appendicitis, and give up, once and for all, the terms perityphlitis, paratyphlitis, extraperitoneal abscess, etc., as misleading and not valuable except in explanation of sec-

\* Read before the New York Surgical Society, November 13, 1889.

ondary pathological processes. In regard to the so-called extraperitoneal abscess as a result of inflammation of the appendix, there remains nothing to be said to any one who has read Dr. Weir's admirable paper in the "Medical News" for April 27th of this year. The statements and observations which Dr. Weir there makes are perfectly convincing, and I have often confirmed many of them during an operation. As a late result of a much-neglected case, pus may force its way through the lateral or posterior peritoneal lining of the abdomen, but even in very old cases this must be a rare condition, and I have myself never met with such a one. All of these abscesses originating in inflammation of the appendix are intraperitoneal. Inflammatory adhesions, which glue together the adjacent coils of intestine, prevent the contents of the abscess from flowing into the pelvis or among the intestinal folds. At every point the pus is bounded by peritonæum. All of the operations done by the Willard Parker method require section of the peritonæum which forms the anterior wall of the abscess. I have dwelt upon this point because it is a very important one, and one's views in regard to it will determine his operative methods. In this connection I must refer to two other terms—extraperitoneal abscess and extraperitoneal incision for the opening of such abscesses. These again are very misleading, and imply that uninflamed peritonæum can be pushed away from the iliac fossa, the connective tissue broken through, and the abscess evacuated. If these abscesses are, as I have stated, *all* (with possibly a very rare exception) intraperitoneal, then, of course, these terms are false and misleading. The peritonæum may be pushed back and the abscess incised deep in the iliac fossa by a roundabout and unsurgical method, but when incised the peritonæum will be cut. In the present state of surgical opinion, it remains with those who claim that they meet with extraperitoneal abscesses and make extraperitoneal explorations to prove their point. In not a single one of the early operations for appendicitis which I have done and seen done has there been the slightest doubt as to the fact that the incipient abscess was entirely within the peritoneal cavity. I mean that this fact has always been demonstrable to the satisfaction of every one present. This one must consider as a valuable piece of evidence, for the observations were made at a period in the disease when there could be no obscurity as to the actual condition present. Weir has clearly shown also, in the paper already referred to, by carefully analyzing the reports of one hundred autopsies, that in no one of them did the abscess originate in the extraperitoneal tissue, and that in only four was pus found there at all. Weir also states, when referring to the difficulty of demonstrating the intraperitoneal origin of these abscesses after a considerable abscess has formed, that in only eight out of twenty-six abscesses opened by him could he "recognize that the inner wall of the abscess was made up of loops of intestine bound together by adhesions." But, as I have already said, *no difficulty* is found in making this demonstration when an operation is done at an early stage of the disease.

In these early operations I have found a very varied condition of the appendix and its surroundings, from a mild

catarrhal condition of the mucous membrane accompanied by some infiltration and thickening of the submucous and other tissues, to the state of complete gangrene of the whole organ, with more or less extensive peritonitis.

In one instance I removed the appendix from a young lady who in the course of little over a year had had no less than twelve attacks of so-called perityphlitis. These attacks had been severe, giving rise to great pain with rise of temperature, and causing alarm not only to the members of her family, but to her medical attendants, two of these at least being as careful observers as exist in New York. The operation was done during a period of complete health and after careful consultation, to prevent recurrence. The appendix was found rigid and swollen, the mucous membrane mildly inflamed, the other tissues of its walls greatly thickened. Not the slightest evidence of peritoneal inflammation or adhesion existed. The appendix was readily removed and the patient made a rapid recovery. The operation was done nine months ago. Since that time the patient has enjoyed unbroken health, has resumed active exercise, and has gained twenty pounds in weight. In another case, also a young lady, attacks of abdominal pain, accompanied by vomiting, exquisite tenderness in the right iliac fossa, and considerable elevations of temperature, had occurred on four different occasions. This patient had also been taken care of by the most competent men. Curiously enough, just at the time of this patient's last attack her sister died without operation from a violent purulent peritonitis caused by perforation of the appendix. Subsequently to this last attack and during a period of complete health I removed the appendix after careful consultation with her physician, Dr. J. W. McLane, to prevent recurrence. A condition of disease somewhat in advance of the case already narrated existed. The appendix was quite firmly bound by old adhesions to the under surface of the intestinal mesentery and to the cæcum. The mesentery of the appendix had been nearly obliterated; the organ itself was dark-colored, considerably swollen, but soft. The mucous membrane was very dark-colored and swollen, and inclosed some fine faecal grains. Two partial strictures of caliber existed which produced retention of a dirty brown fluid. The evidences of former limited peritonitis existed on the neighboring portion of the cæcum. This patient also made a rapid recovery, being out of bed at the end of two weeks, with a wound completely healed. The operation was done over four months ago, and the patient has remained in perfect health, having gained largely in weight and having resumed active exercise from which she had been entirely debarred. These two cases are quoted at this point to show that comparatively slight conditions of inflammatory disease in the appendix may give rise to threatening illness, which by some would be described as resolving perityphlitis without further explanation. There can be little doubt that both of these cases were preparing for abscess or general peritonitis.

In other cases—all in an acute stage of inflammation—and which will be quoted later, the conditions found have been these: In one the appendix formed a considerable cyst containing nearly an ounce of dark-brown pus. No communication with the cæcum existed.

In several the appendix was swollen, discolored, diseased throughout, but gangrenous only at one or two points where perforation had occurred, and in these cases one or more faecal concretions existed, either within or just outside of the appendix.

In several the appendix was in general only moderately diseased, but perforation had occurred, and quite firm recent adhesions had tied the appendix to some adjacent part, doubling it upon itself and so inclosing a small collection of pus with or without concretion.

In two cases the appendix was thick, but flattened so as to be with difficulty recognized, and very firmly bound to the under side of the cæcum, and in two cases the appendix was completely gangrenous. In all of these acute cases peritonitis existed—usually a plastic peritonitis of greater or less extent—always involving the cæcum and generally the adjacent intestinal coils and abdominal walls. In one case the omentum was quite extensively involved, partly enveloping the appendix. In no case was the appendix more than lightly attached by adhesion to the peritoneum covering the iliac muscles, and in none was *extraperitoneal* inflammation observed, excepting sometimes in the anterior abdominal wall. In most cases some pus was found more or less confined by adhesions within a limited area, and in one absolutely no adhesion of any kind existed, though the appendix was perforated by concretion, and very foul pus filled the pelvis and ran freely upward beside the colon.

The pathological conditions of the appendix, as compared with the symptoms in my own cases, most positively show that one can not with accuracy determine from the symptoms the extent and severity of the disease. I therefore doubt the safety of the advice given by several recent writers, to watch the symptoms and to be guided by their violence in determining the method of treatment. This will appear more clearly in the histories of the cases. I should like now to refer to some of the special symptoms *the weight and value of which have been subsequently determined by an immediate operation*, for it is in this manner that we shall mostly advance our knowledge of the pathology of appendicitis. By autopsy we can not learn very much more in this direction, if one may judge by the length of time it required to learn the important single fact that abscesses originating in the appendix are almost invariably intraperitoneal. Pain to a greater or less extent is present in all cases of appendicitis, but many a mistake has been made and a golden opportunity lost by looking for pain in the iliac fossa and an *absence* of pain in other parts of the abdomen. General abdominal pain is often all that the patient will complain of during the first few hours of his attack, and in many cases it requires a careful and pointed examination to determine that the cause of the pain is situated in the iliac fossa. But after the first few hours it becomes more and more evident that the chief seat of pain is at that point, and the general pain then usually subsides. The epigastric region is frequently the point first complained of. One patient, who died on the third day from violent septic peritonitis from perforation, complained of comparatively little pain even when the iliac fossa was firmly com-

pressed. The *exact* locality of the greatest sensitiveness to pressure has seemed to me to be usually one of importance. Whatever may be the position of the healthy appendix as found in the dead-house—and I am well aware that its position when uninflamed varies greatly—I have found in all of my operations that it lay, either thickened, shortened, or adherent, very close to its point of attachment to the cæcum. This, of course, must, in early stages of the disease, determine the seat of greatest pain *on pressure*. And I believe that in every case the seat of greatest pain, *determined by the pressure of one finger*, has been very exactly between an inch and a half and two inches from the anterior spinous process of the ilium on a straight line drawn from that process to the umbilicus. This may appear to be an affectation of accuracy, but, so far as my experience goes, the observation is correct.\* //

Chill and vomiting are frequent, but so often absent as to be in no sense of much diagnostic value. Fever to some extent is present in all cases, but very different in degree, some severe cases having a temperature on the first day of less than 100·5°, others rapidly reaching a temperature of 103·5°. But, as nearly excluding non-inflammatory pains, the presence of this symptom is certainly of importance. Rigidity in the abdominal muscles, generally much more marked on the affected side than on the other, I have found very constant, and I believe it to be a sign of value.

Abdominal distension by tympanites varies greatly, and its degree by no means measures the severity of the diseased process. It may be very decided during the very first hours of a mild case, and also entirely absent in the worst form of sudden perforation. It must, of course, be influenced greatly by the condition of the patient's bowels, the ease with which the intestine in each individual is brought to a state of paresis, and by many other causes. But when the gut has been found during the operation to be overdistended, the portion of gut so affected has always been the large intestine. Probably paresis from the local peritonitis is here a large factor.

Tumor of greater or less size I have usually been able to detect at a very early stage, but the composition of this tumor, as shown during operation, has varied greatly. In one case the tumor consisted of the distended unruptured appendix, which was partly wrapped in an inflamed and thickened omentum. In another it was formed of a mass of intestinal coils swollen and glued together by recent plastic exudation. This tumor was large, quite firm, and gave one the impression that a large quantity of pus was present; but only a very minute abscess was found, and that was situated quite beneath the cæcum. But under other some tumor can invariably be detected; and this agent will, I think, be found to be a valuable help to diagnosis in some doubtful cases. The tumor may be dull on percussion, as when pus has formed and lies against the anterior abdominal wall; but I have more than once found a small deep tumor containing pus, which was so com-

\* Since reading this paper I have carefully observed three other cases. In two the point of pain shown by pressure with one finger was two inches, and in the other an inch and seven eighths from the anterior spine.

pletely covered in front by intestines that the percussion note, before ether was given, was purely tympanitic. The pulse during the onset of appendicitis is usually rapid and irritable. The patient prefers to have the right thigh elevated, and objects to its overextension. Rectal examination at the onset I have not found of any value.

The combination of symptoms present will usually render a correct diagnosis as to the seat of the disease quite easy, but in reference to the stage which the disease has reached—that is, whether pus has formed or not, whether the appendix is already perforated or not, even sometimes whether already general septic peritonitis exists or not—the diagnosis is often very doubtful. I remember one case where Dr. Sands performed a beautiful operation and saved the patient's life. At the consultation held before operation four gentlemen were present. Three of them had certainly seen many cases of appendicitis. Three quite different opinions were expressed. Dr. Sands thought that the appendix was perforated, and that pus had formed. One of the others thought there was probably appendicitis, but advised an extraperitoneal incision. Another thought the case so mild that it should be treated without operation. Dr. Sands operated by an incision along the right edge of the rectus muscle, opened an intraperitoneal abscess just in the middle of his incision, and removed a perforated and sloughing appendix. The patient rapidly recovered. This case occurred very shortly after Dr. Sands read his last paper before this society. I mention it simply to show that the diagnosis of the exact condition in such cases is not easy. A means of diagnosis lauded by some, permitted by others, and totally condemned by a few, is the exploring needle. I believe that the use of this instrument will become less and less frequent as we know more of the disease. While perhaps occasionally permissible at a late stage of the disease, it is certainly totally to be condemned at its beginning. The discovery of pus with the syringe is, to be sure, gratifying to a hesitating operator, but the withdrawal of an injected needle through several layers of peritoneum, which it may have passed during its introduction, can totally nullify a good subsequent operation. And, if the needle does *not* discover pus, which has often happened even when that fluid has been present in considerable quantity, then the man who pinned his faith on a needle is induced to underestimate the importance of the case and its mode of treatment.

Some years ago I went a long distance into the country prepared to operate upon a nine-days-old abscess, the result of appendicitis. There existed a large fluctuating tumor, and the case was plain and needed just one cut. But the family physician was very conservative, and said the time had not come, and that there was no pus. I was in despair, for the journey took many hours. Fortunately, I had a good hypodermic syringe with me. The doctor said rather superciliously that that thing was harmless anywhere. So he permitted its introduction; and when the barrel filled with pus he yielded to an operation, and treated me afterward with great respect. But to search for pus with a needle, first in one direction and then in another, at the risk of doing harm, and with no certainty of acquiring

any real information, is a practice as unsurgical as it is unnecessary.

I think that there is still much misapprehension in the minds of many practitioners as to the symptoms produced by perforation of the appendix. Many associate with this condition, and with no other, a very violent onset of the disease with quite well-marked symptoms, as compared with the less severe commencement of a slowly forming abscess. The truth is that, in the early stage, no accurate diagnosis can be made as to whether the appendix is perforated or not, excepting in those cases where comparatively mild symptoms *suddenly* become much aggravated, when perforation or the rupture of an abscess may be inferred. Perforation often occurs with but few symptoms at the very beginning of the disease, but, being preceded by the formation of more or less plastic adhesion of the appendix, no sudden increase in the severity of the disease occurs at all. An abscess slowly forms, which may increase to a considerable size without being discovered, and then force its way, or proceed by infection, in the most dangerous directions. The comment might fairly be made upon this description of the early symptoms of appendicitis that the diagnosis of the disease is very obscure and uncertain. To the careful observer it is not difficult, however, to determine as to the existence of the disease. The only real difficulty lies in determining within the first few hours what the future progress of the disease is to be in deciding whether firm adhesions are forming, which will effectually exclude pus from the general peritoneal cavity, and so provide for subsequent safe evacuation of abscess, or whether no such protecting wall exists, and an overdistended appendix threatens to instantly set up a fatal peritonitis. If this difficulty could be set aside by a more careful study of symptoms, and without losing valuable time, our course would be clear, and we should no longer helplessly hesitate as to when to operate and when to stand aside. There is no reason to think, however, that diagnosis from symptoms alone will ever reach that perfection. We need some further aid to diagnosis; some positive and rapid means of determining what method of treatment we are to adopt. We have reached a point where we can never be satisfied with the mortality that attends an expectant treatment. What we wish to accomplish in the treatment of appendicitis is, not to save half of our cases, nor four cases out of five, but *all of them*; and how is this end to be attained except by improved methods of diagnosis at the very earliest stage of the disease? I hope that I may never again go every day to visit a threatening case, waiting bashfully for the authority of a clearly defined general peritonitis before I dare take action. I do not mean to deny that many very ugly-looking cases of appendicitis go on to the formation of abscess which may be safely opened and end in complete recovery; we have all of us seen many such. I am well aware that numerous cases have presented all the symptoms of the disease, have become very ill, and have finally recovered without any operation. Within two years I have seen two cases, in one of which the patient was so ill that I refused to operate, and in the other case I strongly urged operation and was refused permission. Both of these patients recovered after long illness without

operation of any kind. Probably the abscesses emptied themselves at some point into the intestine. But such unexpected recoveries, and the frequent formation of abscesses which can be opened safely at a later stage, even the many cases which quite rapidly terminate, at least temporarily, without suppuration, do not console us for the heavy mortality caused by appendicitis. What this mortality has been we shall of course never know. We do know that the cases which are recognized and which die are numerous, and it is safe to assert that a very large number of fatal cases of peritonitis commence with an unrecognized inflammation of the vermiform appendix. No one will dispute that if we could so improve our methods of diagnosis that we could recognize within the first few hours the serious nature of many cases, we would operate in these cases at once, willingly preferring to incur the risks of an operation rather than face the certainty of death that septic peritonitis implies. How may we improve our methods of diagnosis? At present I see no clearer road than the exploratory incision permitting a direct inspection of the parts and a complete study of the disease. If it can be shown by future experience with improved methods of operation, and with more perfect anti-septic precautions, that the exploratory incision for inspection of the diseased appendix is much more free from danger than the expectant treatment, then there could be but one answer to the question, What is the best treatment? The firm conviction that very early operation for the cure of appendicitis can, with proper care, be done with very slight risk, has induced me to subject a considerable number of these cases to the earliest operation possible, and my chief purpose to-night is to present to you the results of my work in this direction. It is proper to state that no case of appendicitis has been refused operation, and that all the cases operated upon in the early stage of the disease are here reported:

CASE I.—E. M. P., a young gentleman nineteen years of age, complained of general abdominal pain at 11 A. M. on May 21, 1888. The pain was regarded as due to indigestion, and was treated with family remedies. In the afternoon the patient fainted, and by four o'clock his pain had greatly increased in severity. He received a little morphine and hot applications were applied. At 5 P. M. his mouth temperature was 98·4°, his pulse 100. During the night and the following day the patient complained sometimes of severe pain, and occasionally felt much better; he took a considerable quantity of milk, and at 8 P. M. his temperature was only 100°. During the second night he suffered much pain, and at 5 A. M. on the 23d it was noted that his pain was chiefly in the right iliac fossa. At 5.30 he had a severe chill and his temperature rose to 103°, his pulse to 120. At this time he was visited by his physicians, Dr. Fessenden N. Otis and Dr. William K. Otis, who diagnosticated at once acute appendicitis, and requested me to see the patient. This I did at about 8.30. I found the pulse and temperature as stated, and the following condition: Great rigidity of right abdominal muscles; exquisite tenderness on pressure at a point just two inches internal to the anterior spine of the ilium, in the direction of the umbilicus. Beneath the finger at this point could be felt a small resisting mass, less than one inch in diameter. No dullness on percussion anywhere. General appearance excellent. The diagnosis of appendicitis already made by Dr. Otis was confirmed by myself, and an hour later by Dr. Sands. Immediate operation advised and accepted.

General appearance of patient excellent. It should be noted that at 11.30 the temperature had fallen to 101°.

Operation at 12 o'clock, just forty-nine hours from the first pain. Present, Dr. F. N. Otis, Dr. William K. Otis, Dr. L. R. Morris, and Dr. Tuttle.

Ether anaesthesia. A slightly oblique incision four inches and a half long, the center of this incision being two inches from the anterior iliac spine toward the umbilicus. Tissues of abdominal wall quite markedly oedematous, particularly near the peritoneum. On opening the peritoneum freely, the appendix came at once into view. It was larger than a man's thumb, dark-brown in color, tense, evidently full of fluid, and at no point gangrenous, but its wall evidently nearly as thin as paper. A tail of omentum partly enveloped it, and this was much inflamed and freshly adherent. Everywhere else the peritoneum was healthy, and not an indication of the formation of any bounding wall of adhesions existed. Coils of small intestine surrounded this full-to-bursting sac. The omentum was gently separated and the inflamed portion ligated and cut away. The mesentery of the appendix was carefully tied in sections, and the base of the appendix dislodged from an inverted pouch of cæcum, ligated at its base, and cut away. It proved to contain at least half an ounce of very foul brown pus, but no concretion. Its communication with the cæcum was closed by stricture, so that the unbroken, purulent, acutely inflamed cyst was removed entire. The stump was disinfected with 1-to-1,000 bichloride solution. Two silver-wire sutures passing through the whole thickness of the abdominal walls closed the upper part of the wound, and one similar suture the lower part. The central portion was loosely packed with iodoform gauze down to the ligated stump. Dressing of iodoform and bichloride gauze over all.

At 6.40 P. M., less than six hours after the operation, patient's temperature was 99·8° and pulse 80. A small quantity of morphine was given for wound pain. The dressings were changed on the third day, and a perfectly aseptic condition of wound found. This patient made a rapid and absolutely unbroken recovery, and is to-day perfectly well.

This is, I believe, the first recorded case where an acutely inflamed unruptured appendix has been removed full of pus. Who can doubt what the result would have been in this particular case had the cyst ruptured, and the operation been delayed a few hours? Would not the opportunity for recovery have been lost had the advice so often and so recently given been followed—to delay operation until symptoms of spreading peritonitis appeared?

CASE II.—John S., ten years of age, was admitted to my care at the Roosevelt Hospital on August 19, 1889. He gave no history of previous attacks. A week ago he became ill, and complained of general abdominal pain. He went to bed, and says that since that time he has been feverish and has not been free from pain. Four days ago the chief seat of pain is said to have been in the right side and low down. On admission his pulse was 110, his temperature 103·4°, and he was nauseated. Between the umbilicus and the right iliac spine was noted a considerable tumor, which was markedly tender on pressure. The percussion note over the tumor was dull. No tympanites existed. The general appearance of the patient was that of severe illness. I operated on the same day. The usual incision was made, and the tissues found in a normal condition down to the peritoneum. The anterior peritoneum itself was perfectly uninflamed, and uninflamed small intestine covered the anterior face of the tumor. When these were drawn toward the median

line, a mass of adherent intestines was disclosed, which inclosed a small indurated tumor.

The intestinal coils were gently separated on the anterior face of the tumor, and several drachms of faecal pus at once escaped, emptying a cavity somewhat tubular in shape and large enough to admit the finger. The appendix lay in this cavity, congested, much swollen, and infiltrated with pus. No perforation existed, and no concretions were found. The appendix was tied off with silk and removed. A rubber drain was introduced, the cavity packed with iodoform gauze beside the drain, and a full antiseptic dressing applied.

On the following day, August 20th, the boy's temperature was  $99^{\circ}6$  as against  $103^{\circ}4$  of the day before, a reduction in less than twenty-four hours of nearly four degrees. This patient recovered rapidly and completely, and on September 25th his wound was entirely healed.

CASE III.—W. K., a male, sixteen years of age, was admitted to my care at the Roosevelt Hospital on July 26, 1889. Previous history negative. Forty-eight hours before admission first felt pain in the right iliac fossa. On the next day diarrhoea set in; abdominal pain was quite general, though more distinctly localized in the right iliac fossa than elsewhere, and this increased up to the time of admission to the hospital. The patient's temperature was then  $102^{\circ}$ , his pulse 110. The abdomen was slightly distended and tympanitic. In the right iliac fossa was found a small, very tender non-fluctuating tumor, which lay just inside of the anterior iliac spine. Diagnosis, acute appendicitis.

Operation at 3.30, July 26th. The usual incision was made. Beneath the incision were found normal non-inflamed intestines. These were drawn toward the median line, when the appendix was found projecting stiffly forward and slightly upward by the inner side of the caput coli.

It curled around the end of the cæcum and then turned upward and forward. Slight recent adhesions tied the appendix at its base only to the cæcum. At other points it floated freely among non-inflamed intestines. The adhesions were broken down and the appendix ligated at its base and removed. It was six inches and a quarter long, edematous, and much thickened and inflamed throughout. Minute foci of pus were scattered through its substance, but there was no concretion and no perforation. On its removal the seat of operation was left perfectly clean, but, to insure safety, a rubber drain was passed through the loin directly to the base of the stump, and the anterior wound was partly closed and partly packed with iodoform gauze. The next day patient's temperature was  $100^{\circ}$ . His wound was inspected, but not dressed completely until July 30th. No pus was found. This patient made an unbroken recovery without incident, and his wounds were completely healed on August 19th.

CASE IV.—Annie O., eighteen years of age, was admitted to the medical wards of the Roosevelt Hospital on May 29, 1888. Six years ago she had an attack similar to the present one from which she entirely recovered without operation. Two days ago she was seized with severe epigastric pain accompanied by fever and headache, and tenderness on pressure in the right iliac fossa. On admission, the abdomen was tense, tympanitic, tender on pressure at all points, but more especially in the right iliac fossa. Here a small tumor is distinctly felt. I saw this patient for the first time on May 30th, and, having expressed the opinion that she should be operated upon at once, she was transferred to my care. At this time her symptoms had become much more threatening; abdominal distension was extreme. Her temperature was low,  $100^{\circ}4$ , pulse 100, respiration 36. I operated at once, making the usual incision. The tissues of the abdominal wall were oedematous and the deeper ones much fused together. Beneath

the center of the incision the distal end of the appendix was readily found. It was much enlarged and thickened, and greatly discolored. At first no pus was seen, but, on gently separating the end of the appendix from adjacent parts, a small cavity was found beneath it containing less than one ounce of pus. The cavity was cleansed with hot water, and it was then seen that the appendix was perforated at about its middle and lying in the perforation was a large faecal concretion. The whole appendix was then removed after ligating the base, the cavity was swabbed with 1-to-1,000 bichloride solution, two rubber drains introduced, and the cavity packed with iodoform gauze. A complete antiseptic dressing was applied. On June 1st the patient's temperature was  $99^{\circ}$ , pulse 100, respiration 18. Abdomen free from pain or distension.

This patient made an unbroken recovery, being out of bed on June 23d, with a small, superficial, flat ulcer still to heal.

CASE V.—Charles E. A., twenty-five years of age, was admitted to the Roosevelt Hospital on September 1, 1889. Patient gives a history of probable appendicitis occurring five months ago.

Two days ago, after several weeks of abdominal discomfort, the patient was seized with severe abdominal pain, nausea, vomiting, and fever.

On admission, his temperature was  $102^{\circ}$ . Internal to the anterior iliac spine, on the right side, some resistance and tenderness on pressure were noted. Diagnosis, appendicitis.

On September 2d, under ether narcosis, the usual incision was made, the tissues of the abdominal wall being found very edematous. Marked adhesions and thickening of the peritoneum were found over a large area, indicating clearly the existence at some previous time of a quite extensive peritonitis. This probably occurred during the attack referred to above. The appendix was found, after some difficulty, hanging over the edge of the pelvis, greatly thickened and hardened. After being freed from adhesions, it was ligated close to its base and removed. The immediate neighborhood of the stump was cleansed and the space packed with iodoform gauze. The upper portion of the abdominal wound was closed by suture. With the exception that a slight superficial abscess developed beneath the suture line, this patient made an easy recovery, and was discharged, with a wound completely healed, on October 17th. This patient was operated upon by Dr. Frank Hartley, my first assistant at the hospital.

CASE VI.—Miss E. C., twenty-five years of age, a patient of Dr. W. T. Alexander, of this city, had complained of a sense of uneasiness and discomfort in the right abdominal region, low down, for two or three weeks. She had, however, gone about as usual, and walked several miles daily. On June 18, 1889, in the evening, she was seized with severe general abdominal pain, most severe in the epigastrium, and was nauseated. She went to bed, and was then first seen by Dr. Alexander, who diagnosed appendicitis, and ordered hot applications and a little morphine, with complete rest in bed. On the following day Dr. Alexander asked me to visit the patient. This I did in the afternoon. The patient's temperature was then  $101^{\circ}$ , and her pulse 100. She had a very ill look, and complained bitterly of the slightest pressure over the right iliac fossa and of some tenderness all over the abdomen. I advised immediate operation. There were present at the operation Dr. W. T. Alexander, Dr. G. T. Jackson, and Dr. R. P. O'Neill, and these gentlemen assisted me.

I made the usual incision. The tissues of the abdominal wall were normal, and within the peritoneal cavity scarcely the slightest trace of adhesions was found. The appendix, nearly completely gangrenous, as large as one's middle finger, lay just outside of the caput coli, not perforated, but containing two large faecal concretions, just ready to escape through very soft

gangrenous tissue. A little purulent fibrin lay beneath the appendix. No limiting wall of any kind existed, and reddened small intestine lay above and below. The mesentery of the appendix was carefully aud with some difficulty tied off, the appendix ligated at its base and removed. The immediate neighborhood was then thoroughly cleansed with 1-to-1,000 bichloride solution, dusted with iodoform, and packed with gauze. A rubber drainage-tube was introduced beside the gauze down to the stump. The upper part of the incision was closed with two sutures. The patient suffered from nausea and tympanites for two or three days, when her temperature fell to normal and remained so. On the seventh day the wound discharges were decidedly faecal, and continued to have this character for about a week. The wound then became perfectly healthy and rapidly healed. This patient has gained greatly in health and weight, and has been, up to date, perfectly well.

CASE VII.—Edgar C. B., a stalwart young man, twenty-one years old, complained of pain in the lower part of the abdomen during the evening of January 13, 1889. The next morning, when he had gone to work, this pain spread through the whole abdominal cavity and became very severe. He reached home with difficulty and went to bed. During the afternoon of the 14th—that is, at the end of about twenty hours—the pain localized itself chiefly in the right iliac and lumbar regions. At noon on the 15th he had a chill, and, feeling very ill, came to the Roosevelt Hospital in the evening. His temperature was then 101·6°, pulse and respiration about normal. The abdominal muscles on the right abdominal half were rigid, and very acute tenderness was complained of when pressure was made over the right iliac fossa about two inches inside of the anterior iliac spine. No tumor could be felt. The diagnosis of acute appendicitis was made, and I determined on an immediate operation. This was done at 11 P. M., as nearly as possible forty-eight hours after the first symptom. The usual incision was made. The tissues of abdominal wall were found in a normal condition. Beneath the line of incision were coils of non-inflamed small intestine. These were pushed inward, exposing a mass of small intestines matted together by adhesions and quite free from the iliac fascia. After a short search, and after breaking down some of these adhesions, the appendix was found, passing backward and inward from the cæcum, then doubling back upon itself. It was closely tied by adhesion to the cæcum and adjacent mesentery. The adhesions were broken down, the mesentery of the appendix tied off in sections, and the appendix itself ligated at its base with catgut and removed. The appendix was much diseased, thickened, and distorted, but not ruptured. On section I found within it some black, semi-fluid material. The mucous membrane was gangrenous throughout, and the wall of the appendix at one point gangrenous *as far as the peritoneal coat*. The stump was sponged with 1-to-1,000 bichloride solution. The upper part of the wound was closed with silver stitches, a rubber drainage-tube passed down to the stump, and the open wound packed with iodoform gauze. During the next twenty-four hours considerable pain was experienced, and for a few days constipation was obstinate. On the morning of the 17th the temperature became normal and remained so throughout convalescence, which was unbroken and entirely completed by February 11th. A small superficial ulcer was completely healed on February 21st.

CASE VIII.—C. G. McK., a young gentleman twenty-three years old. First attack of pain in right iliac fossa two years ago. Second attack in May last, when he was confined to bed five days with fever and severe pain and tenderness in the same region. On Thursday morning, October 17th, he had a sudden attack of severe pain in region of appendix, went to bed, and his temperature was noted to be 99°. In the evening his tempera-

ture rose to 100°. Pain and tenderness steadily increased. Friday he remained in the same condition, and was seen by me, at the request of Dr. E. E. Swift, later at night. The patient was haggard and looked ill. Tenderness on pressure about two inches inside of the iliac spine was very marked. An ill-defined tumor existed, and decided distension of abdomen. Operation was advised, but the circumstances were such that it was postponed until twelve o'clock on the following day.

Operation October 19, 1889. Ether anæsthesia. The usual incision was made. On opening the peritonæum, an enormously distended *caput coli* filled the wound and rendered the search for the appendix extremely difficult, forcing me to handle the intestines far more than was to be desired. The appendix was at last found, flat, wide, and so firmly adherent to the under surface of the cæcum as to be identified with great difficulty, and numerous firm old adhesions prevented the free movement of intestines and at one point formed a nearly constricting band. An indurated mass beneath the center of the appendix was opened with the finger by separating adhesions which, however, were very strong, and many of them evidently old. From this mass about a drachm of foul faecal pus escaped and was sponged away. The difficulty of dissecting away the appendix was so great that I was finally obliged to desist and to be satisfied with removing only that portion of it which formed the wall of the abscess. The cavity was very thoroughly cleansed, and an attempt made to return the prolapsed large intestine and close the wound. This was found to be exceedingly difficult, owing to the very excessive distention of the gut, and much time was expended and much handling of gut necessitated. Finally the wound was closed as in other cases, the lower part being packed and drained. The patient recovered well from the effects of the operation, but at the end of twenty-four hours his temperature rose to 102°, and the abdominal distension increased. He was bright and looked fairly well, however, and I did not expect serious illness. His temperature, however, continued to rise, symptoms of peritonitis developed, complete paresis of bowel persisted, and the patient died at the end of four days, of peritonitis. No autopsy could be obtained.

Whether the difficult and unusual handling of the intestines was the chief cause of peritonitis, or whether constricting bands, formed by old adhesions, caused actual obstruction, I am unable to say. No movement of the bowels could be obtained and no flatus passed after the operation excepting by the aid of a long rectal tube. Certainly the peritonitis was not septic, and such was the opinion of Dr. Delafield and Dr. Swift, who visited the patient with me. Moreover, when, on the second day, I removed the packing, I found a perfectly healthy wound, without the slightest sign of infection. One thing is clear—that, had the operation been done during the patient's first attack two years ago, none of the great difficulties which I met with would have been encountered.

I stated at the beginning of this paper that I did not here intend to review the treatment of appendicitis in a systematic manner, but I should not do justice to the real subject of this writing were I to drop the matter at this point. I must, in the first place, as accurately as possible, define the class of cases of appendicitis to which I have applied the method of treatment described; and then I wish to devote a few minutes to a description of the technique of the operations. I have presented eight cases of appendicitis operated upon at an early stage of *acute* inflammatory process. These eight cases include all of those

operated upon since May 20, 1888, to date. Previous to May 20, 1888, I had never operated upon a case except by the older methods. During this period of eighteen months I have seen and operated upon a much larger number of cases of appendicitis at late stages in the disease—that is, when extensive abscess has existed, and in some cases of early general septic peritonitis due to appendicitis. Such cases are excluded from the list given, as belonging to an entirely different category. I have measured the stage of the disease, not by the number of hours or even days that it has existed, but by the character and extent of the inflammatory process, all cases being included in the list excepting those where it was clear that large, comparatively safe abscess was forming, or where general septic peritonitis was already established. I should, moreover, state that in every case operation has been done as soon as possible after being seen, excepting that in the fatal case various circumstances, contrary to my wish, necessitated a delay of about twelve hours. In no case has a diagnosis of appendicitis been made which has been subsequently proved by operation to be incorrect. To those who have been in doubt as to whether the operation or the disease carries with it the most danger, I think these cases, although limited in number, must be convincing in favor of the operation. All will acknowledge that every case of appendicitis may, so far as the cleverest observer can tell, have to pass by many very dangerous obstacles before reaching the smooth water of a comfortable abscess. For my part, I would endeavor to insure safety early, before reaching the rapids, rather than trust to finding my way with my eyes blindfolded through a dangerous passage. I am familiar with the good-natured jest that the surgeon is now ready to cut every one who has a stomach-ache. The death-rate from appendicitis within the professional circle of New York alone is a sufficient answer to that criticism.

But I should be much misunderstood if I should give the impression that, while I believe the operation to be less dangerous than the disease, I also believe the operation to be simple and easy of execution. I look upon it as often an exceedingly difficult one, and one which requires as much care and patience and attention to detail as any with which I am familiar. Moreover, I have never seen two cases of appendicitis operated upon in which the pathological conditions, the position of adhesions, the relation of surrounding parts, etc., were very nearly alike. Every case presents some new problem, and in every case there is large opportunity for the exercise of careful judgment as to how best to meet this or that difficulty. Of course there must be pioneers, as Sands was, and such may be the most successful, but my strong feeling is that it is well worth while for any one who may have to do this operation to see it done, at least once, first.

Before describing the steps of the operation, I refer again to the important aid to diagnosis of which I have already spoken—namely, the ascertaining, by the pressure of a single finger-tip, that the point of greatest tenderness is, in the average adult, almost exactly two inches from the anterior iliac spine, on a line drawn from this process through the umbilicus. Much greater tenderness at this

point than at others, taken in connection with the history of the case and the other well-known signs, I look upon as almost pathognomonic of appendicitis. This point indicates the situation of the base of the appendix, where it arises from the cæcum, but does not by any means demonstrate, as one might conclude, that the chief point of disease is there. The abscess, or concretion, or cyst may be at quite a little distance, but the greatest pain, on pressure with one finger, will be felt at the point described.

The incision should be a liberal one, for much room may be required, and a five-inch cut in the adult is not too much. It should follow as nearly as possible the right edge of the rectus muscle, and the center of the incision should lie opposite to or a little below the anterior iliac spine, on a line drawn to the umbilicus. When the external oblique aponeurosis is cut through by this incision, the aponeurotic structure, in which the other abdominal muscles end, comes into view, and is easily divided without cutting muscular fiber. Then the fascia transversalis, the subperitoneal fat, and the peritoneum are cut in succession. If pus has formed close against the anterior abdominal wall, these last-mentioned tissues will be found infiltrated with serum, and even thickened so as to look like cheesy tubercles. Otherwise these parts may appear perfectly normal. On opening the peritoneum the appendix may at once be seen, or adhesions and inflammatory exudations may have so distorted the parts that a careful and difficult search may be required to find the appendix at all. It may be flattened out and glued firmly to the inflamed surface of the cæcum by old and recent adhesions, or it may be coiled upon itself and buried out of view in a mass of lymph. The finger is often quicker than the eye to detect the appendix in these conditions, as it is very certain to be found where the greatest thickening, as felt by the finger, exists. More than once I have had to turn the cæcum out of the wound and examine carefully the usual region of origin of the appendix before I could identify it. Usually then with the finger or a dull-pointed instrument the adhesions can be broken down or tied off, as may seem required by vascularity. If the appendix has been thus separated, I have usually tied it off with silk or catgut close to the cæcum and cut it away, and generally between two ligatures. Careful disinfection of the stump should be made. I have scraped its interior and disinfected with 1-to-1,000 bichloride solution, and then rubbed in iodoform. Once, where it looked dangerous, I tied with silver wire, and then used the fine-pointed cautery to disinfect. If thoroughly cleansed, it seems to be unnecessary to lose time in sewing the peritoneum over the stump, as recommended by Treves. When the appendix has been removed nothing remains to be done but to disinfect the whole neighborhood, insert a drain, and pack the small space with iodoform gauze. The upper half of the wound may perfectly well be tightly closed with stout sutures, which should include the whole thickness of the abdominal wall—peritoneum as well. In some cases I believe it to be good practice to introduce a large drain by a separate opening well above and behind the iliac spine, for in some cases the region of disease may extend especially in that direction.

But the question may fairly arise in any case as to whether it is wise to attempt to dissect out the appendix and remove it. If the difficulties of dissection would evidently be very great, I think it is better to open the abscess if there is one, cleanse the cavity, and, leaving the appendix *in situ*, pack and drain the wound.\* The packing I have usually removed on the third day and replaced it with less, and the cavity has rapidly granulated. If, at the time of operation, one introduces sutures throughout the whole length of the wound, leaving the central and lower ones loose, these can subsequently, after one or two dressings, be tied, and the wound thus rapidly narrowed. Over the whole wound, of course, a complete dressing is applied, and good bandaging is better than any binder, to prevent the possibility of extrusion of gut by either vomiting or intestinal distension. None of my patients have developed a hernia at the site of operation. I have kept them all in bed for four weeks or more. None have had any recurrence of inflammatory action of any kind.

A few more words, Mr. President, and I have finished. Are there any contra-indications to this operation in a clear case of appendicitis? I think there are. Very great abdominal distension, which might in a given case probably be relieved by a few hours' treatment, would lead me to delay the operation, for expulsion of intestine is a very serious obstacle to the proper completion of the operation without risk. Unusual obesity I should regard as a good reason for a more expectant method of treatment. But the most important contra-indication of all is the absence of any one of the necessary safeguards and aids, such as the best assistance, the best light, and the best appliances for performing a perfectly aseptic operation.

**NOTE.**—Since writing the foregoing paper, I have operated in three other cases of acute appendicitis. One of them was that of a lad, fifteen years old, a patient of Dr. G. A. Spalding's. The operation was done at the fortieth hour of the disease, the temperature being high and the symptoms very threatening. The appendix, much diseased and containing two large concretions, was removed. The temperature fell on the following day to 99°, and has been normal ever since that time. The patient is now safely convalescent.

The second case was that of a patient of Dr. Jarecky's, fifteen years old. The operation was done at the beginning of the fifth day. The appendix, gangrenous at two points as far as the peritoneal coat, was still not perforated even at this late date. It was removed, and the patient is now safely convalescent.

The third patient, already referred to in a note, is nearly well. None others have been operated on in an acute stage of inflammation up to date. The number of operations is, therefore, eleven. Of these, one proved fatal, probably from obstruction by a band not discovered.

**The Health of Connecticut.**—According to the State Board of Health's "Monthly Bulletin," the total number of deaths reported from 168 towns during the month of November was 896, including 8 from scarlet fever, 13 from cerebro-spinal meningitis, 77 from diphtheria and croup, 5 from whooping-cough, 1 from erysipelas, 26 from typhoid fever, 7 from malarial fever, and 5 from typho-malarial fever. There were also 121 deaths from consumption, 58 from pneumonia, and 28 from bronchitis.

\* In a case operated upon since writing this paper, it would have been a dangerous proceeding to remove the deeply seated and strongly adherent appendix. I broke its wall at one point, and then drained through the loin and packed in front. The treatment was completely successful, and the patient is safely convalescent.

## PERITYPHLITIS.\*

BY FRANK HARTLEY, M. D.

**MR. PRESIDENT:** The case I present this evening is one of perityphlitis with suppurative peritonitis. Though it does not strictly belong to the class of cases reported by Dr. McBurney, it is nevertheless interesting, as I think it shows us that, no matter what the condition within the peritoneal cavity, we may now and then succeed in giving material benefit.

This patient, Louis E., fifteen years of age, was admitted to the Roosevelt Hospital, June 1, 1889, under my care. His family history was good. He had never been sick but once, and that sickness was probably plenrisy. He had never before his present illness suffered from pain in the right iliac fossa, nor was he subject to constipation or diarrhoea. His present illness began fourteen days before admission, with a sudden and intermittent pain in the abdomen about its midline. This was increased after each meal and upon any exertion. For eight days he had no other symptoms than this pain. At the end of the seventh day his physician administered a rectal enema without effect. On the eighth day the pain was felt in the right iliac fossa for the first time, and at this time it became continuous and of a "dragging" character. Headache and weakness were now present, but no fever. On the eleventh day there were added to the symptoms already present repeated severe chills, increased sleeplessness, cold sweats, and complete anorexia. On the morning of the fourteenth day the pain became more general and more severe, though in the right iliac fossa the tenderness was more marked than elsewhere. He had been treated up to the present time for typhoid fever.

On admission he was of slender build, emaciated, features pinched, and showing a distinct septicæmic cachexia. Heart normal. Lungs, a few friction râles at base. Abdomen moderately distended; tender in every portion. The right iliac fossa presented no distinct tumor, but the examination was unsatisfactory on account of the pain and tympanites. Slight dullness in iliac fossa. Resistance to pressure was more marked here than elsewhere. Rectal examination showed a tender, slightly bulging spot on the right side. Respiration, 26, thoracic; pulse, 120, weak; temperature, 101° F. He was very restless, and lay in bed with his knees drawn up.

Patient was stimulated with whisky and Magendie's solution, five minims, before operation. Disinfection of skin over abdomen. Incision, on outer border of rectus muscle, six inches. Peritonæum was seen to be, before incision, thickened, edematous, and inflamed. When opened, a large amount of fetid gas escaped, and a general suppurative peritonitis was disclosed. This consisted of purulent foci, of fibrino-purulent exudate, and, in places far removed from the iliac fossa—upon the small intestines and the mesentery—of a catarrhal exudate. The greater portion of the intestines were not agglutinated, but where the purulent collections were found they were agglutinated by recent fibrino-purulent exudation. These coils of intestines presenting were quickly turned aside to allow an exposure of the vermiform process; it was found lying in a cavity containing fully half an ounce of foul-smelling and greenish pus and formed by a dome of agglutinated intestines and a floor of what appeared to be peritonæum and iliac fascia, which was very edematous, infiltrated, and gangrenous. The cavity of the abscess was wiped out with sponges soaked in a solution of bichloride of mercury (1 to 1,000), and the peritoneal cavity was

\* Read before the New York Surgical Society, November 13, 1889.

itself protected by sponges from the contents of this abscess. The appendix, two inches and a half in length, lay behind the caput coli and firmly adherent to the iliac fascia. The iliac fascia, at the point of attachment of the vermiciform process, was gangrenous. The vermiciform process was perforated at its point of attachment and upon its median surface. No concretion was found within it, but several loose faecal concretions were found loose within this cavity. The whole appendix was frail and sloughy, its surface being covered by a fibrino-pus. The appendix was removed, its base ligated with silk, and its end cauterized with Paquelin's thermo-cautery. The whole abscess cavity was carefully sponged out with a solution of bichloride of mercury (1 to 2,500), and iodoform powder rubbed into it. The suppurative peritonitis was now traced up, and all the intestines covered with pus and fibrin were in succession brought out of the wound and sponged off with a solution of bichloride of mercury (1 to 2,500). Beyond the immediate neighborhood of the abscess cavity adhesions had not occurred. The intestines were coated with pus and fibrin. This extended along the mesentery to its attachment, and into Douglas's *cul-de-sac* and the small intestines lying upon the opposite side. These were all similarly treated—irrigation, Thiersch's solution. Counter-opening made in the lumbar region, above the crest of the ilium and to the outside and below the kidney leading to the bottom of the abscess. Rubber drainage. Abdominal incision closed above and below with silk sutures, passing through skin and peritoneum. Middle left open. Abscess cavity packed with iodoform gauze. Iodoform gauze packing also carried to the coils of intestines in its immediate neighborhood in small strips, each end coming into the wound, and the rest lying upon and between the infected intestines. Occlusive dressing.

The patient bore the operation fairly well. Abundantly stimulated.

*June 2d.*—The patient weak. Temperature, 100°; pulse, 80. Small voluntary movement.

*3d.*—Temperature, 99°; pulse, 80. Very weak, but seems better. Dressed. Packing soaked with pus. Tube working well. Irrigated with Thiersch's solution. Packing replaced in part where soaked with pus (*i. e.*, in the abscess cavity). Tympanites still present. Five movements to-day.

*5th.*—Second dressing. Gauze filled with pus removed. Irrigated. Packing replaced.

*6th.*—No thorough irrigation can be made. Tube plugged. Gauze removed. Tube washed out. There is now a distinct cavity leading to the former situation of the appendix. Iliac fascia has separated as a slough. Gauze over the intestines beyond the abscess removed in part. Irrigated, and again packed slightly.

*8th.*—Dressed again; looks well; all gauze removed from the abdominal cavity. Abscess cavity lightly packed. General condition good.

From present time on till his dismissal, July 17th, nothing more than several sloughs, coming away through the posterior drainage, was observed. It steadily healed, and now, November 22d, he presents himself with a firm cicatrix and no tendency to hernia.

**Abscess of the Antrum.**—“A new diagnostic sign of abscess of the antrum was brought forward by Dr. T. Heryng, of Warsaw, at the Congress of Otology and Laryngology, held at Paris during September. The patient is placed in a dark room and his mouth lit up with a small electric lamp, placed above the tongue. Two bright-red spots will then appear below the lower eyelids. If the cavities are filled up with pus, or occupied by a tumor, these red spots will not appear, but, as soon as the pus escapes or the cavity is washed out, the spots again become visible.”—*Medical and Surgical Reporter.*

## COMPLICATIONS OCCURRING IN THE CLINICAL HISTORY OF OVARIAN CYSTS.\*

By RICHARD DOUGLAS, M. D.,

NASHVILLE, TENN.,  
FELLOW OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNÆCOLOGISTS; FELLOW OF THE BRITISH GYNAECOLOGICAL AND THE SOUTHERN SURGICAL AND GYNAECOLOGICAL SOCIETIES.

In the natural history and growth of an ovarian cyst there are impending accidents and complications occurring, rendering diagnosis doubtful and operation questionable, permissible, or imperative.

The development of a cyst is in itself so pronounced a pathological process that it is but reasonable to anticipate danger. To distinguish the symptoms so arising from those of other peritoneal diseases, and to relieve the pain and immediate distress, are questions of material concern to the general practitioner. The eminently practical surgeon may rest content with a surgical diagnosis—that is, that an operation is demanded—but the truly scientific will prefer to thoroughly analyze the clinical features of the case, deduce his pathological problem, and, if an operation is undertaken, his chances of “being surprised” or “meeting with unexpected conditions” are reduced to a minimum. Upon the other hand, by prompt action or judicious conservatism we save the life of our patient.

Experience shows that general and subjective symptoms are almost valueless in the diagnosis of ovarian cysts. The entire group of rational and associate symptoms may be negatived by the physical signs. Having determined by physical methods the existence of a cyst, there are events and complications occurring in which, to distinguish the clinical phenomena, we are forced to rely almost entirely upon rational symptoms. In former times, ere yet the eager and expert laparotomist was rife within the land, it was no unusual thing to meet with an ovarian cyst that had seen its days of activity, and for years had remained in a stationary and quiescent state. Such lethargy is unheard of now. Even if Nature were disposed to provide accommodation, the zealous surgeon would break in upon its repose and, like Macbeth, “murder sleep.”

The behavior of an ovarian cyst is not governed by any arbitrary pathological law. From the incipiency of its growth, while yet we may mistake it for hydrops follicularis, to its termination it is liable to certain accidents, attributable to the characteristics of the tumor and the peculiarities of the patient.

We may thus divide the complications into two classes: First, those affecting the tumor itself—viz., adhesions, twisting of the pedicle, inflammation, suppuration, rupture, calcification, and others of minor importance. The second class, complications due to the presence of the tumor, but not affecting materially the growth itself. Under this head we have ascites, albuminuria, marasmus, and intestinal obstructions. Other diseases may be met with, but they are so infrequent that they do not merit consideration. Pregnancy is a decided complication, but neither a disease nor the result of the tumor.

\* Read before the Southern Surgical and Gynaecological Association, November 13, 1889.

*Adhesions.*—With the development of a tumor and its infringement upon the limited space of the peritoneal cavity, as a natural consequence, more or less adhesions are formed. We are told by the most acceptable authorities that there are certain outward signs to which we may attach much reliance in the detection and diagnosis of adhesions. The strongest, broadest, longest adhesion presented to us in any given case of ovarian cystoma is that which binds the tumor to the uterus—that is, the pedicle. We are yet incapable of forming any idea of the length and character of the pedicle. Therefore it is not presumable that we can apply the rules given by Frederick Bird and Spencer Wells for the diagnosis of adhesions. The clinical history is, in some measure, a guide, yet I well recall in my own experience a small cyst in a woman who had passed through three distinct attacks of peritonitis. The operation was undertaken with apprehension of formidable adhesions, yet the entire sac came away without the severance of a single band.

Small dermoid cysts are more liable to inflammation, and therefore readily contract adhesions. After tapping, adhesive bands form at the site of operation.

Strangulation of the pedicle, from torsion or otherwise, causes venous stagnation. Mortification would quickly supervene, were it not that adhesions are promptly formed.

Adhesion to a viscous may be in direct apposition. The "immediate" form of Tait, or quite a lengthy, broad, flat, or round band, the "mediate" variety, may attach the cyst. Omental adhesions are by far the most frequent. I have seen the greater omentum attached to the anterior surface, and spread out and universally attached, like a "monk's cowl," over the entire surface of the tumor. While it is not the purpose of this paper to deal with the technique of ovariotomy, I may be pardoned if I emphasize some well-known facts in the management of adhesions. All omental attachments must be ligatured, grasped with pressure forceps on the distal side, and omentum cut through between, care being taken to suture or tie and divide all holes in the omentum; it is obvious such openings are but snares for intestinal obstruction. The freeing of a fettered cyst from a viscous is often a most difficult procedure. Such attachments are usually soft and highly vascular. In their separation, nothing is better than a sponge (Smith), our aim being to sponge or peal the viscous from the tumor, and not the tumor from the viscous.

The haemorrhage attendant upon the separation of these firm adhesions may be controlled by pressure. If that does not check it, and it is inexpedient to ligate, the salt of iron may be employed. Of course, when practicable, nothing is so secure as a No.  $\frac{1}{2}$  silk ligature. Accessible adhesions, even though very extensive, are not considered as seriously complicating the case. It is very much to the contrary when the adhesions are deep down in the pelvis. In their separation we are in constant danger of injuring bowel, bladder, ureter, or some of the large blood-vessels coursing just beneath the peritoneum.

Another accident that may befall an ovarian cyst is rotation of the tumor or torsion of the pedicle.

The "American Journal of the Medical Sciences," Octo-

ber, 1888, contains a truly classical article on "Rotation of Ovarian Tumors," by Mr. Knowsley Thornton.

From this, and the discussion in the British Gynaecological Society on the report of R. T. Smith's rather celebrated case, and from two cases under my own observation, I chiefly gather my information. This accident is met with in every variety of tumors. The only physical condition necessary is a tumor free of adhesions and a pedicle of sufficient length. Rotation of ovarian tumors is found in patients of all ages, yet far more frequently in young women, and quite sufficiently often at the time of menstruation for us to associate that circulatory phenomenon as an active aetiological factor in its production. Many observers have met with a twisted pedicle during pregnancy. Barnes mentions three cases in which rotation was caused by the gravid uterus, which, growing from below, impinged upon the tumor, exerting leverage upon the side, thus causing it to turn around. This explanation is quite satisfactory for those cases associated with pregnancy. Tait very ingeniously accounts for rotation by the passage of faeces causing each time a slight rotation of the tumor. From an analysis of many reported cases, it appears that rotation occurs just as often on the left side. Mr. Tait's theory will answer only for tumors of the right side.

Doran thus explains the accident in one case: "A little artificial distension of the intestine caused it to press against the tumor so as to push its left side backward, stretching and twisting the pedicle." The same author further says: "Still I believe that, as a rule, the twisting of a pedicle is to be explained by the simpler doctrine. The tumor, comparatively free laterally and anteriorly, rotates on its own axis every time that the patient, after walking or lying upon her back, turns around and rests on her side."

Peristaltic action of the bowels has been suggested as a cause of rotation (Stephens).

When strangulation of the circulation takes place in consequence of the twisting of the pedicle, symptoms of varying severity follow. The intensity of the symptoms is governed to a great extent by the degree of strangulation. When there is complete arrest of circulation the symptoms are those of localized peritoneal irritation, abdominal pain and tenderness, quick pulse, fever, and vomiting, and in all cases of sudden strangulation there are grave local and constitutional symptoms described as abdominal shock. Schnirnoff considers suddenly developing ascites as indicative of torsion of the pedicle. The tumor itself undergoes certain changes. Generally it enlarges, becomes tense, hard, more elastic, and less fluctuating.

An ovarian tumor with twisted pedicle may be confounded with a ruptured ectopic gestation sac. In the one case we have to guide us the usual symptoms and signs of pregnancy; in the other they are wanting. In one there was a well-defined tumor, which, with the onset of the symptoms, became more distinct and even more tense than before. In rupture of the tube from pregnancy the tumor is ill-defined and even less distinct than before rupture. In tubal rupture the collapse is decidedly more marked than we meet with in twisted pedicle. The shock from rupture may pass off, but to recur again with the renewal of the hemorrhage.

If a patient survives the first shock attendant upon rotation of the tumor, the subsequent history is inflammatory. Twisting of the pedicle has been mistaken for intestinal obstruction. The presence of a tumor and symptoms occurring therein, together with the readiness with which the bowels respond to mild laxatives, should eliminate this as a possible error. In consequence of twisting of the pedicle, there is, of course, interference with the circulation, venous stagnation occurs first, arterial pressure continues to force blood into the tumor, rupture of an overcharged vessel follows, and we have hemorrhage into the cyst. In this way we may account for the clinical phenomena of enlargement and tension of the tumor, and no doubt the great shock observed in these cases is largely, if not entirely, due to the hemorrhage which generally follows in consequence of the rotation. This question received liberal notice before the British Gynaecological Society. The theory of hemorrhage as the cause of shock was more acceptable to me than the twisting of a functionless pedicle. With rotation of the cyst and absolute strangulation of the pedicle, as we all have seen, inflammation and gangrene would be looked for as a natural consequence. "It is," says Barnes, "the most common and immediate effect certainly in some cases to lead to gangrene." This is not the opinion of that conscientious observer and eminent ovarian pathologist, Doran, nor does it accord with the experience of operators.

"The steps of the process seem to be gradual rotation without symptoms or serious pathological change, then sudden serious symptoms, with rapid increase in the tumor, then decrease or complete cessation of the growth, followed sooner or later by renewed activity" (Thornton).

The full explanation of all this is, that rotation is a gradual process. When suddenly becoming acute, strangulation with all its clinical phenomena is developed. Now, gangrene does not inevitably occur, as Barnes seems to think, but, as the result of the peritoneal inflammation, adhesions quickly form, and it is now through this adventitious connection that nourishment is to be obtained. The supply of blood being at first only limited in amount, the tumor naturally decreases in size from sheer starvation, and, as we well know from indisputable cases, atrophy and spontaneous cure may in this way take place. Usually, however, adhesions become more numerous, and, later on, the tumor again springs into activity. Under these circumstances the pedicle may atrophy, and even disappear. Such a case would prove highly perplexing to the operator. Bantock, with the voice of an enormous experience, said that a tumor so strangulated would contract adhesions; that he had never seen nor heard of a patient dying from twisted pedicle.

Now, to the practical question, What are we to do when we meet with a twisted pedicle? If we submit our patient to immediate operation, we are compelled to operate with her in the condition of shock, if not collapse. This is a disadvantage no operator cares willingly to take upon himself. Knowing that it is exceptional for the patient to die in the primary stage, is it not prudent to adopt the recommendation of Bantock—that it is unwise to operate during shock? Let us wait for reaction, which we are assured will be established.

In consequence of torsion of the pedicle, we have shown, hemorrhage frequently occurs. This bleeding is within the cavity of the cyst, due to rupture of a vessel on the inner surface; the strong peritoneal covering is more resistant, and does not yield so readily to blood pressure. Hemorrhage into the cyst may be due to other causes than twisting of the pedicle. It is unusual for a patient to die from this cause.

In addition to the hemorrhage and acute symptoms attendant upon strangulation of the pedicle, we may have a condition of equal gravity arising from inflammation and suppuration of the cyst. Peritonitis may assume such an active form that immediate operation would commend itself to us as the only alternative. Suppuration of an ovarian tumor may be due to torsion of the pedicle, to careless and useless tapping, and from traumatisms. In suppuration of ovarian cysts the circumstances are desperate, and fully warrant prompt operative interference.

*Rupture of the Sac.*—This accident sometimes occurs in consequence of over-distension, suppuration, weakening by papillomatous degeneration, or as the result of violence. The symptoms attendant upon this accident depend upon the size, character, and seat of rupture, the nature of the escaping fluid, and the amount of hemorrhage. If the fluid is non-irritating, and the opening permitting slow leakage, little, if any, reaction may follow. Cysts that have undergone colloid degeneration are prone to rupture. Dr. Mann, in his excellent article on this subject, says: "This colloid material is generally very irritating." The only two cases of ruptured cysts I have seen contained colloid material. In neither of these was rupture attended by symptoms sufficient for diagnosis. One of the cases occurred in the service of Mr. Meredith at the Samaritan Hospital, London. The omentum, intestines, liver, and spleen were all completely covered with colloid. The cyst had evidently ruptured some time before, yet there were no symptoms of peritonitis. The case was an exceedingly ugly one to manage. An abundance of the colloid matter was left behind, though thorough irrigation was employed. A drainage-tube was not used. The patient recovered without a symptom.

Papillomatous growths are favorable sites for rupture. The immediate danger in such cases is not great, because the villi prevent free flow of the fluid. The remote danger is in the infection of the peritoneum. For obvious reasons a monocystic tumor is more liable to rupture than the proliferating, glandular, or multilocular variety. Some authorities maintain that an interligamentary cyst is more liable to rupture than one of true ovarian origin. Any degenerative change in the sac may cause rupture. Dr. Anna Broomall reports at some length a case of rupture due to the violent action of a cathartie. Acute pain, evidences of collapse, and marked change in the form of enlargement are the symptoms pointing to rupture. If the patient does not succumb to the shock of the accident, she is in imminent danger of septic peritonitis. Immediate operation with thorough irrigation and drainage are imperatively demanded.

*Calcification.*—Calcification is sometimes met with in operations. It is scarcely probable that the condition could be even supposed in differential diagnosis.

*Ascites.*—At some time in the history of an ovarian cyst it is not unusual to have quite an accumulation of ascitic fluid. It then becomes our duty to "establish direct causal relation between the ascites and the abdominal tumor" (Coe). We must bear in mind that there are other causes of free fluid in the cavity than mere irritation of the peritoneum by malignant growths, or pressure from an abdominal tumor; cardiac, renal, and hepatic diseases all give rise to ascites. We are prone to treat this complication lightly. It is of vital importance and of immense prognostic value that we eliminate every other possible cause of ascites before we attribute it to the pressure of the tumor. Some effort at a differential diagnosis by examination of the fluid has been made. Having excluded the usual causes of ascites, we must bear in mind that it sometimes is an associate symptom of other complications occurring in the cyst. Torsion of the pedicle, as we have shown, setting up peritoneal inflammation, may give rise to a rapid accumulation of ascitic fluid. Rupture of an ovarian cyst would give us a sudden and rapid ascites, in which a diagnosis might prove, under the circumstances, quite bewildering. An exploratory operation would be our only means of definitely determining the origin of the fluid.

Papillary cystomas irritate the peritoneum, consequently their growth is nearly always attended by ascites. Colloid carcinoma and sarcoma, and in fact all forms of malignant ovarian growths, are so generally associated with ascites that it is considered a leading symptom in their diagnosis. A small tumor with ascites appearing early is strongly presumptive of malignancy. If the ascites is from obstructed circulation, the liquid will be a limpid fluid resembling water, perhaps slightly colored, containing a little albumin but no fibrin, and giving no sediment. If the ascites is from peritoneal inflammation, the liquid will be thinner but never transparent, always cloudy, looking like buttermilk, and smelling like decayed cheese. If the effusion is from simple serous irritation, the liquid will be albuminous, rather clear, though sometimes colored like bile. In the sediment will be found elements of great importance. Large irregular cells may be seen, having a central nucleus, surrounded by a quantity of granulations. The presence of these cells is usually taken as a sign of malignant growth ("Medical Times," November, 1885).

Before a body of so distinguished specialists as I have the honor of addressing, it would be a consumption of valuable time to enter into the diagnostic methods for the detection of ascites. Its presence as an accompaniment of a tumor does not interfere with operation, provided we may assure ourselves that it is not due to malignant disease (Mann). It is the observation of Coe that in such cases the patients rapidly decline after operation. If ascites is due to cardiac, hepatic, or renal diseases, drainage will be required, the cause still existing. The tax to the patient's vitality will be very trying.

*Albuminuria.*—Albuminuria is a frequent complication of cystoma. The mere presence of albumin in the urine is no uncommon thing, especially when associated with high specific gravity. In such cases the pressure of the tumor is the cause of the disease, and with its removal the albumin-

nuria also disappears, like, for instance, the albuminuria of pregnancy (Bantoek). Albumin in urine of low specific gravity is presumptive evidence of advanced kidney disease, and such patients do not bear an operation well. The function of the kidneys should always be carefully considered before operation.

## Correspondence.

### LETTER FROM LONDON.

*A Successful Case of Cholecystenterostomy.—Myxedema in a Child.—Electrolysis in Stricture of the Urethra.*

LONDON, December 7, 1889.

At the last meeting of the Medico-chirurgical Society Mr. Mayo Robson brought under the notice of the society a successful case of cholecystenterostomy. His patient was a married woman who, in April, 1887, had one ovary removed for pyosalpinx, and in the following January came under his care with acute peritonitis and a swelling in the region of the gall-bladder. Laparotomy was performed, and about eight ounces of fetid pus were removed from the gall-bladder; no gall-stones could be detected. The gall-bladder was stitched to the abdominal wound and drained, and the patient made a good recovery, with a biliary fistula. Although she retained good health during the fifteen months when the fistula was open and discharging the whole of the bile, her condition was a very miserable one, since no apparatus could be made to catch the overflowing fluid when she was walking about. On March 2, 1889, the abdomen was reopened through the old scar in the linea semilunaris. The viscera in the neighborhood were found to be so matted together that it seemed to be impossible to fix the gall-bladder to the duodenum, and, as the hepatic flexure of the colon was conveniently near, the gall-bladder was fixed to it by a double row of chromicized catgut sutures, a free communication being made between the two viscera; and the outer opening (the old fistula) of the gall-bladder was stitched up. In order to guard against accident, a glass drainage-tube was placed in the right kidney pouch and brought out at the lower end of the wound. The outer surface of the gall-bladder evidently gave way to some extent, for bile appeared through the drainage-tube within a few days of the operation, followed shortly by a faecal discharge. The wound granulated, and after a few weeks completely healed, the motions toward the end becoming more and more bile-stained, until in appearance they became quite normal. This is believed to be the first case in which this operation has been undertaken for the cure of biliary fistula. Curiously enough, the only successful case hitherto recorded was also in a woman. It is too early yet to feel any confidence as to the final result in this case, but one can not help feeling a considerable degree of curiosity as to the ultimate effect of pouring the bile into the large intestine. So far as the processes of assimilation and absorption are concerned, one would think the bile would be of no more use than if it were still draining away through a fistula, and yet the patient has remained in a fairly satisfactory condition for six months from the operation.

At a meeting of the Clinical Society lately held, Dr. Abercrombie showed a case of great interest—viz., that of a little girl of fifteen with myxedema. The case seemed to be just the connecting link between myxedema and sporadic cretinism, a demonstration of which was much needed. The report of the committee of this society some two years ago expressed the

opinion that sporadic cretinism did not differ in any essential feature from myxoedema, and this case seemed to afford just the proof of this that was required. According to the mother's statement—and there seemed no reason for disbelieving her—the child was quite healthy until about eight years of age, and she then had an illness which lasted for three years, for which she kept her bed nearly the whole of that time. What the symptoms were the mother could not say, but the doctor had called it Bright's disease, and it was an interesting point that whenever the child was asked what the matter was she said "dropsy of the face." Nothing referable to the throat was noticed during the illness. Since then, the mother stated, the child had not grown and had deteriorated mentally, and, from being quick at her lessons, could now learn nothing and had a very indifferent memory. The mother was most positive that before this illness the child's intellect had been good, and that she had had pretty features and soft silky hair. The child was very stunted, but thick-set, of about the height of a child of nine. Her face was decidedly puffy, especially under the eyes, and her complexion was quite characteristic of myxoedema. The isthmus of the thyroid could not be felt, but the rings of the trachea were easily palpated. Her hands were square and spade-like, and her skin was rough and her hair coarse. The case was generally accepted by those who examined her at the meeting as an undoubted instance of myxoedema, and it is to be presumed that the primary illness was really some inflammatory condition of the thyroid gland leading to its atrophy.

Electrolysis as a mode of treating disease does not make rapid progress in public favor over here, but Dr. Steavenson, of St. Bartholomew's Hospital, is one of the few exceptions to the general rule, and has given it an extended trial in cases of stricture of the urethra with Mr. Bruce Clarke. The latter has lately placed on record the results, as far as they are known, in fifty cases; of these, twenty-three patients were known to be well at periods after the operation varying from a year and a half to three years, in two cases no relapse had taken place at the end of four years, while only nine had required subsequent treatment. These results must be considered excellent, but the difficulty is that all persons are not equally competent to undertake the treatment, a fact which probably accounts for the failures of many operators and the consequent disfavor with which this treatment is mostly regarded.

**Jaborandi and the Hair.**—"Some discussion has taken place as to the use of jaborandi in connection with the hair. The senior surgeon to the London Skin Hospital states that it is a valuable drug in the treatment of diseases of the hair; promotes the growth in certain cases and influences the color in others. He deprecates its use, however, except under medical advice. The President of the British Trichological Association declares that jaborandi, when used with care and discretion externally for certain hair diseases, is undoubtedly a very useful drug, and, in cases which have not submitted to other treatment, must prove beneficial in every respect. Dr. Gurney, of the Hair and Skin Hospital, speaks highly of the drug both as an external and an internal remedy."

*British and Colonial Druggist.*

**The Native Egyptian as a Subject for Surgical Operation.**—"The native Egyptian is an extremely good subject for surgical operation. Clot Bey, the founder of modern medicine in Egypt, has it that 'it requires as much surgery to kill one Egyptian as seven Europeans. In the native hospitals, the man whose thigh has been amputated at two o'clock is sitting up and lively at six.' Shock is almost entirely unknown, and dread of an impending operation quite an exception. In explanation may be noted the resignation inculcated by their religion; the very small proportion of meat in, and the total absence of alcohol from, their diet; and in general their regular, abstemious, out-of-door life."—*Medical and Surgical Reporter.*

FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, DECEMBER 21, 1889.

THE EPIDEMIC OF INFLUENZA.

A FORTNIGHT ago it was reported that an epidemic of influenza was prevailing in St. Petersburg and causing great inconvenience to business, especially in factories and other places where manual labor was carried on. On the 12th of December the cable announced that the disease, after having attacked Berlin, had made its appearance in Paris, and that over six hundred of the shopmen in the Magasin du Louvre were suffering from it. London will next be heard from, and then doubtless we shall have it ourselves. It is well to know what to expect.

Epidemic catarrhal fever made its last appearance in England in the winter of 1847-'48, a fact now entirely forgotten, and any correct information as to its characters and the course it took would be most difficult to obtain were it not for the history of the epidemic carefully recorded by the late Dr. Peacock, of St. Thomas's Hospital, London, whose clinical studies in connection with disease of the heart have given him a place among the first of English physicians.\*

In the introductory chapters Dr. Peacock informs his readers that there are records from the thirteenth century of the visitations of influenza as an epidemic about ten times in a century. In large towns about half the inhabitants escape the attack, and in London during the last epidemic the mortality was increased by 5,000 deaths in six weeks. Various names have been given to the disease. The name influenza was given to it in Venice and Milan in 1741. In France it is called *grippe*. Old English writers call it *pose*, which signifies a running from the nose, and the word is used in that sense by Chaucer.

The meteorological conditions preceding epidemic visitations are mentioned in vague terms, but sudden and great alternations of temperature have generally been recorded. The disease is described as consisting of three varieties, viz.: Simple catarrhal fever, catarrhal fever with pulmonary complications, and catarrhal fever with abdominal complications. Passing over the simple catarrhal form, we come to Dr. Peacock's severer cases, twenty-eight of which fell under his observation. In eleven cases there was acute or subacute capillary bronchitis, in four bronchitis supervened on tuberculous disease of the lungs, in six there was bronchitis complicated by disease of the heart or aorta, and in seven attacks of pneumonia occurred. Of these, the most serious complication was the capillary bronchitis, which in some of his patients proved fatal. The mortality, placing together all the forms of pulmonary complication,

\* "On the Influenza or Epidemic Catarrhal Fever of 1847-'48," by Thomas Bevill Peacock, M. D., Physician to the Royal Free Hospital and to the City of London Hospital for Diseases of the Chest. London: Churchill, 1848, pp. 182.

came to nine deaths in forty-eight cases. These were all hospital cases and necessarily of a severe character, the patients having, before admission, been in a low state of health. Dr. Peacock considered that the mortality of the epidemic did not exceed three or four per cent. of the whole number of persons attacked, a very serious mortality, if he is correct in his estimate.

Abdominal complications were present in thirty-one cases out of the seventy-nine. These may be divided into, first, cases characterized by disorder of the gastro-enteric mucous membrane; secondly, those in which the enteric affection was combined with hepatic derangement and a tendency to relapse or to assume a remittent character; and, thirdly, those complicated with rheumatic symptoms. There were only five deaths in the thirty-one abdominal cases.

Dr. Peacock lived long enough to present in a condensed form the result of his observations made forty years ago, in the shape of the article "Influenza" in Quain's "Dictionary of Medicine," which under the present circumstances will be read with great interest.

### MINOR PARAGRAPHS.

#### THE RIVAL FRENCH CANADIAN UNIVERSITIES.

FOR many years the Victoria College has been the principal center for medical education among the French inhabitants of Lower Canada. It has had an honorable career of some forty years and has turned out many graduates. Unfortunately, however, for its religious tone, in the Province of Quebec, where religion and medicine are closely mixed, its degrees have been presented by a university of Protestant tendencies, that of Victoria in Cobourg. To counteract this noxious influence and to enable the faithful to be certain that their doctors prescribed medicines of the proper ecclesiastical flavor, a rival school was established which granted degrees from the fine old Catholic University of Laval in Quebec. A bitter struggle ensued and many were dragged into the strife without any knowledge of the questions at issue. Politics has crept in; one school is tainted with liberalism, the other leans toward the old Tory party. The unprejudiced looker-on would find it hard to say what it was all about. A few months ago an amalgamation was arranged and conflicting interests were duly regarded. But the feelings of the students had not been considered. Since the session opened a continuous state of war has existed, and, according to a daily paper, one of the professors recently felt called upon to illustrate his lecture with a loaded revolver. Among the teachers there is no better feeling than among the students. After bitter fighting among themselves an appeal to Rome has been decided upon, and all parties have agreed to abide by the arbitration of His Holiness. In the mean time the students, who have paid their fees, complain with some justice that while all the squabbling is going on there is no teaching done. A number of them, at a meeting recently held, have decided upon asking the law courts to issue a mandamus to compel the faculty to give the instruction set forth in the annual announcement.

#### HOW "FAITH-CURE" MAY SPREAD DISEASE.

CERTAIN ignorant Scandinavians in Brooklyn and vicinity have adopted, in a very fatalistic way, a doctrine of healing by faith and prayer. They do not believe in medicine or physicians, and they will not call in the aid of the latter, except in

cases where death is impending. One of them said recently: "I want a physician to come and see my child in order to comply with the law, which says that a physician should see the case within twenty-four hours before death; the law gives me a certificate of death if I do this." The women who have adopted this strange fanaticism have united themselves into an order which they call the "Lodge of Faith," which nurses the sick free of charge and abjures the employment of any medicines. It is believed that these nursing sisters have been the means of spreading scarlet fever and diphtheria, going as they do, with a perfect abandon and disregard of earthly consequences, from one house to another.

#### CYANIDE OF ZINC AND MERCURY AS AN ANTISEPTIC DRESSING.

In the "Lancet" for November 9th Sir Joseph Lister publishes a paper describing his efforts to obtain a more suitable antiseptic application than bichloride of mercury. He first employed a gauze charged with a solution of corrosive sublimate in blood-serum; but serum was not always obtainable, and the gauze was harsh and not very absorbent. Next, sal alembroth (chloride of ammonium and bichloride of mercury) dissolved in serum was employed; this seemed more efficient as an antiseptic than the bichloride of mercury alone, and was less irritating; but the salt was so soluble that the serous discharge from the wound would wash it out, concentrating it near the edge of the dressing and irritating the skin by the presence of the large amount of the salt. Cyanide of mercury was next employed, at the suggestion of Mr. Martindale. Mr. Cheyne found that while its germicidal effect was small, its inhibitory power was about 1 in 10,000. This salt was very irritating, however, so the less soluble cyanide of mercury and zinc was tried; in the proportion of 1 to 800 it prevented putrefaction, but it seemed to be an irritating application, and was used with the cyanide of mercury. Biniodide of mercury was an efficient antiseptic, especially if associated with starch; but, like the sal alembroth, it was too irritating. The cyanide of zinc and mercury was again tried, this time unmixed with the cyanide of mercury, the gauze being moistened with a corrosive-sublimate solution of 1 to 4,000, and with starch as a medium for incorporating the salt with gauze, a small quantity of sulphate of potassium being employed to prevent pastiness of the mixture. An antiseptic dressing was thus obtained that has proved very effective in the surgical wards of King's College Hospital. Before using gauze prepared in this way it should be moistened with a 1-to-4,000 bichloride-of-mercury solution.

#### THE "NEW EVANGELISTS."

THE faith-healing believers who style themselves the "New Evangelists," and profess to be willing to let their children, sick with scarlet fever or other contagious diseases, go without medical attendance, and to avoid all sanitary precautions, are found to be amenable to law. Three different acts appear to meet the case of this kind of cruelty; first, there are the special enactments for the protection of minors; secondly, the Penal Code has an "omnibus section" which makes it a misdemeanor to fail to provide food and medicine for a sick dependent person; and, thirdly, a sanitary ordinance, also of an "omnibus" character, against those who through negligence contribute to the spread of communicable disease. The second of these legal provisions, that of the Penal Code, is that which the prosecuting officers will prefer to try under in most cases. These facts were brought out by Dr. J. C. Bierwirth, physician to the Brooklyn Society for the Prevention of Cruelty to Chil-

dren, in a paper read before the Kings County Medical Association on December 13th. The "New Evangelists" seem to be ignorant and misguided rather than lawless, and as soon as they have been convinced that the law requires that their children shall have medical attendance and that seclusion must be observed in scarlet fever and the like, they will cease to be troublesome.

#### THE CHARITY HOSPITAL ALUMNI SOCIETY.

At the meeting of the Medical Society of the Alumni of Charity Hospital, held on the evening of December 10th, Dr. A. T. Muzzy read a very interesting paper on "The Prevention of Ophthalmia Neonatorum." Dr. Joseph O'Dwyer presented some new laryngeal tubes, which are shorter than his former models and of much larger caliber—in fact, giving a passage very little smaller than the trachea itself, thus facilitating the removal of membrane, mucus, etc. Another modification consists in having the collar at the top of the tube hinged to the shaft in front, so that removal is easily performed with the finger. The collar, which is held in place by springs, may be lifted readily, forming a ring into which the tip of the finger is inserted and the tube readily withdrawn without the use of instruments.

#### PRIVATE LUNATIC ASYLUMS.

THE New York State Commission in Lunacy has taken a very commendable step in the adoption of the following: "*Resolved*, That hereafter no license for the establishment and keeping of an asylum or institution for the care, treatment, or custody of the insane or persons of unsound mind, for compensation or hire, shall be granted except to a duly qualified medical practitioner of recognized professional skill and standing, who is a graduate of a legally incorporated medical college and has had actual experience in the care and treatment of the insane."

#### ONE OF THE DANGERS OF THE NURSING-BOTTLE.

AN infant, four months old, was lately reported to have been choked to death by swallowing the rubber nipple of a nursing-bottle. The insecure way in which nipples are often attached to the bottle, as well as the custom of leaving the infant alone with a bottle to quiet it, gives grounds for expecting the greater frequency of such accidents.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending December 17, 1889:

DISEASES.	Week ending Dec. 10.		Week ending Dec. 1.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	17	5	21	5
Scarlet fever.....	71	6	71	5
Cerebro-spinal meningitis.....	2	2	1	1
Measles.....	46	5	70	2
Diphtheria.....	94	26	109	30
Varicella.....	5	0	1	0

**A New Hospital for Pittsburgh.**—By the will of the recently deceased John A. Shoenberger, an iron-master of Pittsburgh, a bequest of \$800,000 is made for a Shoenberger Memorial Hospital, that will occupy a site of eight acres of land next to the Alleghany Cemetery.

**An Epidemic of Scarlet Fever in an Orphan Asylum.**—The secretary of the Ohio State Board of Health has just in-

vestigated an epidemic of scarlet fever in the Soldiers' and Sailors' Orphans Home at Xenia, and he reports that the hospital is unfit for use, its wards are crowded, and diphtheria and scarlet-fever patients are kept in rooms adjacent to wards occupied by persons with minor ailments. His report was condemnatory of the management.

**The Hoagland Laboratory.**—In the winter course at this laboratory, beginning on December 20th, the three departments of bacteriology, physiology, and histology will be in operation. A fee of \$15.00 will be charged in each of the two former and \$20.00 in the last. The charge for animals is not included in the fee. The library will receive over thirty standard foreign journals.

**Virchow's "Cellular Pathology."**—The "British Medical Journal" states that Professor Virchow continues to work diligently upon the new edition of his "Cellular Pathology," and that he expects to have it completed by the time that the International Congress meets at Berlin.

**Change of Address.**—Dr. O. J. D. Hughes (Meriden, Conn.), to No. 88 East Main Street.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 1 to December 14, 1889.*

**WOLVERTON, WILLIAM D.**, Major and Surgeon, Fort Douglas, Utah. Leave of absence for one month, to take effect on or about December 18, 1889, is hereby granted, with permission to apply at Headquarters, Division of the Missouri, for an extension of seven days. Par. 2, S. O. 114, Department of the Platte, November 30, 1889.

**GARDINER, JOHN DE B. W.**, Captain and Assistant Surgeon, will, by direction of the Secretary of War, be relieved from duty at Fort Reno, Indian Territory, upon the arrival at that post of James C. Merrill, Captain and Assistant Surgeon, and will report in person to the commanding officer, Fort Supply, Indian Territory, for duty at that post. Par. 8, S. O. 279, A. G. O., November 30, 1889.

**McCAW, WALTER D.**, Captain and Assistant Surgeon, Fort McPherson, Georgia. Leave of absence for fifteen days is hereby granted. Par. 3, S. O. 276, Division of the Atlantic, December 3, 1889.

**HALL, JOHN D.**, Major and Surgeon. Leave of absence for ten days, to take effect upon being relieved from duty at Fort Niagara, N. Y., is granted. Par. 11, S. O. 285, A. G. O., Washington, December 7, 1889.

**CARTER, EDWARD C.**, Captain and Assistant Surgeon, will, by direction of the Secretary of War, be relieved from duty at Willett's Point, N. Y., upon the arrival at that station of **EWEN, CLARENCE**, Major and Surgeon, and will then proceed to Fort Walla Walla, Washington, and report in person to the commanding officer of that post for duty, reporting also by letter to the commanding general, Department of the Columbia.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the two weeks ending December 14, 1889:*

**NEILSON, J. L.**, Surgeon. Detached from the U. S. Steamer New Hampshire and ordered to the U. S. Steamer Portsmouth.

**BEYER, H. G.**, Passed Assistant Surgeon. Detached from the U. S. Steamer Portsmouth and placed on waiting orders.

**SIEGFRIED, C. A.**, Surgeon. Detached from the Naval Station, New London, Conn., and ordered to the New Hampshire.

**HALL, JOHN H.**, Passed Assistant Surgeon. Ordered to the Naval Station, New London, Conn.

KITE, I. W., Assistant Surgeon. Detached from the Naval Hospital, Philadelphia, Pa., and ordered to the Naval Hospital, Pensacola, Fla.

Ross, J. W., Surgeon. Detached from the Naval Hospital, Pensacola, Fla., and placed on waiting orders.

Ross, J. W., Surgeon. Detached from the Navy Yard, Pensacola, Fla., and placed on waiting orders.

KITE, I. W., Assistant Surgeon. Detached from Naval Hospital, Philadelphia, Pa., and ordered to the Navy Yard, Pensacola, Fla.

ROGERS, B. F., Surgeon. Ordered to special duty at Norfolk, Va.

LEACH, PHILIP, Passed Assistant Surgeon. Ordered to duty at the Naval Academy, Annapolis, Md.

#### Society Meetings for the Coming Week:

**MONDAY, December 23d:** Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

**TUESDAY, December 24th:** New York Academy of Medicine (Section in Laryngology and Rhinology); New York Dermatological Society (private); Buffalo Obstetrical Society (private); Medical Society of the County of Lewis (quarterly), N. Y.

**WEDNESDAY, December 25th:** New York Surgical Society; New York Pathological Society; American Microscopical Society of the City of New York; Medical Society of the County of Albany; Philadelphia County Medical Society.

**THURSDAY, December 26th:** New York Academy of Medicine (Section in Obstetrics and Diseases of Women and Children); New York Orthopaedic Society; Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private).

**FRIDAY, December 27th:** Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

**SATURDAY, December 28th:** New York Medical and Surgical Society (private).

#### Obituaries.

**Charles Henry Nichols, M. D., LL. D.**—On Monday, December 16th, Dr. Nichols, the superintendent of the Bloomingdale Asylum, died at his post in that institution, in the sixtieth year of his age. His malady was malignant disease of the liver, with secondary involvement of the peritoneum.

Dr. Nichols was a native of Maine, and received his medical education in New York and Philadelphia, taking his degree from the University of Pennsylvania in 1843. He began his asylum service in 1847, at Utica, N. Y., and was appointed physician to the Bloomingdale Asylum in 1849, but resigned the office in 1852. Under appointment by President Fillmore he superintended the construction of the Government Hospital for the Insane, at Washington, and took charge of the institution when it was ready for the reception of patients. After many years of devotion to the Washington asylum he was recalled to Bloomingdale as medical superintendent. In both asylums, and in all the affairs of his life, his course was marked by intelligent and zealous devotion to the progress of his art and to the most judicious conduct of the work committed to him. Personally, Dr. Nichols

was plain and ardent of speech, but gentle and genial to a degree that impressed everybody with the purity and loyalty of his character.

**Thomas B. Harvey, M. D., LL. D.**, of Indianapolis, dean of the faculty of the Indiana Medical College, died on Thursday, the 5th inst., within a few hours after an attack of apoplexy that overwhelmed him while he was delivering a lecture to the class. The deceased, who was in his sixty-third year, was a native of Ohio and a graduate of the Medical College of Ohio. Most of his professional life was spent in Indiana, and a great part of it in Indianapolis, where he acquired a wide reputation as a physician and as a teacher of medicine.

#### Letters to the Editor.

##### DANGER IN THE RHEOSTAT.

1706 WALNUT STREET, PHILADELPHIA, December 12, 1889.

To the Editor of the *New York Medical Journal*:

SIR: Dr. Tod Gilliam's letter in the last number of the Journal contains a most timely warning, now that the use of relatively heavy currents in medical work is so common, but the terrifying and mortifying accident of unwillingly shocking a patient with three hundred and fifty milliampères when but seventy were desired should not condemn the *form* of this controller. I do not know who made the "hydro-aluminium" rheostat used by him, but whoever was responsible for it made a grave error. It is essential that a water-current controller should have plates that are non-corrodible under the continuous use of heavy currents, as electrolysis always occurs in it, and the small space between the upper portions of the plates is an invitation to such accidents. To select aluminium as possessing such properties is sheer nonsense. A single use of the contrivance with two hundred milliampères would coat the positive plate with oxide to be added to by each subsequent use. The carbon controller possesses no such disadvantage, and, if the upper portions of the plates are made impervious to water by boiling in paraffin, their action is perfect and constant. Some complaints of a slight shock of five or ten milliampères at the start, after repeated use, are doubtless due to upward creeping of the water in the absence of this coating.

My own controller, constructed of graphite on a porcelain disc, needs only slow movement to insure against any kind of shock. It has been given to the profession without restriction or patents, and I still warmly recommend its use in preference to cell-selectors.

G. BETTON MASSEY, M. D.

144 MAIN STREET, WEST, JACKSON, MICH., December 14, 1889.

To the Editor of the *New York Medical Journal*:

SIR: The "Danger in the Rheostat," as reported by Dr. Gilliam, in your issue of December 7th, is undoubtedly of more frequent occurrence than is reported in the journals. It is true that the accidents that occur are not always quite so bad as the one that happened in Dr. Gilliam's experience, but, nevertheless, the numerous unpleasant shocks that patients are continually receiving because we can not always control the current of electricity makes this one therapeutic agent less frequently used than it would be otherwise. The "collector" is denounced for its want of a nicely of gradation of current. The hydro-aluminium rheostat supplies the gradation of current, but, on account of the electrolytic action on the plates, this style of graduate is not safe to use for fear of an experience more or less like that referred to.

But, in this connection, I am glad of the opportunity to call attention to a little device which gives me *absolute* and *perfect* control of the current at all times and under all circumstances. This device can be used either with a battery or on any incandescent-light circuit with perfect safety. You are *never* in the direct circuit; but it is so arranged that you can shunt any fractional part or number of milliampères without shock to your patient. From the same device you can operate your cauteries and have the faradaic current. The "Gish ideal rheostat," to which I refer, is a handsome little box, about eight inches square, and contains but one continuous bare wire, so arranged that it gives us absolute control of the current. The rheostat must be seen to be appreciated.

F. W. MAIN, M. D.

## Proceedings of Societies.

### NEW YORK SURGICAL SOCIETY.

*Meeting of November 13, 1889.*

The President, Dr. LEWIS A. STIMSON, in the Chair.

**Fracture of the Skull.**—Dr. B. FARQUHAR CURTIS presented a boy, nine years of age, upon whom he had operated for very extensive fracture of the skull. The patient, while leaning over a railing, had lost his balance and had plunged head foremost down two flights of stairs, a distance of twenty-five or thirty feet. The fall had been unbroken until near the floor, when the patient's head had struck the back of a bench, splitting off the woodwork. The accident occurred on September 10, 1889, at 10.30 A. M. The boy was picked up unconscious and carried to the hospital. There was profound shock, the pupils were dilated, the surface was cold, the pulse feeble and very variable in rapidity, averaging about 120, respirations 33, temperature 98.4° F. in the rectum; there was also a "cephalic cry" at frequent intervals. Stimulants were administered subcutaneously and by enemata. It was deemed advisable to wait for reaction before operating. About 1.15 P. M. the patient began to show signs of reaction, but at 8 P. M. he was still in a condition of coma. Examination of the head when the boy was received at the hospital showed an area, extending from the right side of the occipital protuberance to within an inch of the left eyebrow and about three fourths of an inch in width, in which the soft tissues seemed to have lost their support, and there was a decided depression at each end of this area. Bony crepitus was obtained in several places throughout this area. On September 11th, at 9 A. M., the patient's general condition was good, but he was still entirely unconscious. The pupils were contracted, but disturbing the patient dilated them. Every few minutes there came short periods of restlessness and the cephalic cry. Muscular movements were less active on the left side than on the right, but there was disease of the left hip joint. It was decided to operate first on the posterior depression on the right side of the head. The scalp having been shaved and carefully cleansed, the patient was anesthetized with chloroform. A curved incision was made from a point two inches above the root of the right ear and carried with the convexity upward to about an inch and a quarter from the sagittal suture, then downward two inches and a half to the right of the occipital protuberance. The tissues were divided down to the bone, the flap being reflected downward. As the dissection had only disclosed the lower part of the depressed fragment, a second incision was made running from the highest point of the former in-

cision transversely toward the left parietal eminence for a distance of two inches.

It was evident that there were two main fissures, one running transversely across the vertex from ear to ear, the other obliquely from the right parietal eminence to the left frontal eminence, both gaping about an eighth of an inch. There were numerous shorter fissures, so that every portion of the bone of the vertex was easily movable. Under the flap there was an oval piece of bone, two inches by three, lying behind the transverse fissure just mentioned and a little to the left of the median line. The anterior edge of this fragment was driven under the bone just in front. A groove was made along the border of overlapping bone with a Hey's saw and the bone removed with a rongeur up to this groove. The depressed bone was then pried up and removed. The dura pulsated so feebly that a clot was suspected and an exploratory incision was made, but no clot was found, and the incision was closed with a single suture. Two small pieces of bone were replaced on the dura, and the scalp flap was then brought into position and sutured, a small drainage-tube being used. On account of the magnitude of the operation already performed and the condition of the patient, it was decided to defer exploration of the anterior depression. The periods of restlessness occurred at longer intervals, and the cephalic cry disappeared after the operation. Muscular co-ordination was perfectly re-established. On the third day the patient had become quiet and tried to talk, but was unable to articulate. On the fifth day there were three very severe syncope attacks, probably from over-stimulation. On the ninth day after the operation the patient was very much improved and was able to play with toys. He still had periods of restlessness and was unable to articulate distinctly. The wound had healed by first intention except at the point of junction of the transverse with the curved incision, where it had a sloughy appearance, with some sero-purulent discharge. On the eleventh day a second operation was done. The patient was etherized, and Broca's center was located as follows: A line was indicated from the tip of the mastoid process of the left temporal bone to the alveolar process of the superior maxillary. Parallel to this another line was indicated from the external angle of the orbit to a point 5 cm. posteriorly. The greater depression lay just above this point, and around this as a center a horse-shoe-shaped incision was made with its convexity upward, one end of the incision being behind and above the external angle of the orbit, the other end two inches and a half posterior to this. The incision was carried down to the bone and the flap dissected downward. A fissure was found corresponding nearly to the coronal suture and gaping an eighth of an inch. The entire frontal bone was found depressed, so that it lay below the level of the parietal bone. The depressed edge was removed with the rongeur, increasing the space between the bones to a third of an inch for two inches. This was done because the frontal bone could not be elevated, for it returned to its former position immediately. In this area a clot was found of about the size of a 25-cent piece lying over Broca's center, which was cleaned away, and the dura was found slightly pulsating. The dura was not opened. The wound was closed and an antiseptic dressing applied. Improvement in speech was noted on the day after the operation, and the patient's condition had since been one of continued improvement. At the present time the wound presented four narrow granulating surfaces of varying sizes; in the posterior one there was a sinus leading down to dead bone—the last fragment of the grafts, which did not take. The patient talked fairly well, his intelligence was fair, and co-ordination was perfect.

**The Surgical Treatment of Appendicitis.**—Dr. CHARLES McBURNEY read a paper on this subject (see page 676). He also

presented four patients from whom he had removed the vermiciform appendix.

Dr. A. G. GERSTER said that he had listened with a great deal of pleasure to Dr. McBurney's extremely interesting report of the excellent work which he had done in a heretofore dark region of surgery. Just such observations and results were necessary to demonstrate uncontestedly those views which had been contested by the speaker and others for a long time. He had, however, been thoroughly converted to the views expressed in the paper. He believed that a great deal of light had been shed on the subject which was extremely valuable and stimulating to further efforts in this special field. The thanks of the profession and of humanity were due to the men who achieved such results in spite of professional opinion in opposition to the feasibility of the procedure.

Dr. ROBERT ABBE said that, in reference to the case cited in which there had been a fall of temperature while the inflammatory process was progressing, it had occurred to him, and he presumed to others, that there was often a lull in the severity of the symptoms on the second or third day which was rapidly succeeded by progressive peritonitis, and that these were almost uniformly fatal cases. This lull was often misleading as to the real condition of the patient and the progress of the attack, and was, in his opinion, the opportunity for safe surgical interference.

Dr. GERSTER said that there was a symptom observed in other cases where pus or septic material was causing high tension. High fever existed, and when rupture occurred there was a simultaneous lull in the symptoms. In osteomyelitis, where the periosteum was subject to great tension, high temperature and serious symptoms existed while this tension lasted. When perforation of the periosteum took place there was a lull, the symptoms reappearing when an extra-osseous abscess formed.

The PRESIDENT showed an appendix removed in a case of recurrent appendicitis which had come under his notice some two weeks before. The patient was a sailor, twenty-six years of age, who had been admitted to the Chambers Street Hospital on the 25th of October. He had had at that time a great deal of pain in the right iliac fossa and had required morphine. The speaker saw him the day after, when his temperature was 100·5°; there was some rigidity of the abdominal muscles of the right side with tympanitic resonance, but no tumor could be felt. There was marked tenderness on pressure midway between the umbilicus and the right superior spine of the ilium. There had been a previous attack fourteen months before, and another at some period about two years before that. The man at first declined operative interference, but the next day consented to it, although his symptoms then seemed less marked. The speaker was assisted at the operation by Dr. McBurney. After the incision was made the intestine was drawn aside and the *caput coli* raised, but there was no sign of the appendix. On handling the lower end of the ileum and its mesentery, close to its attachment, some thickening was found. On tearing apart some tissues of new formation on the lower side of the mesentery, the appendix was exposed. The appendix, which was closely adherent to the mesentery, was then detached and tied off at its base with a catgut ligature and removed. The microscopical examination had shown the tissues of the organ to be studded with small round cells, the structure proper of the mucous membrane being entirely lost. Within the organ there were only two or three small concretions. No pus was found and the adhesions which bound the appendix down were evidently such as had resulted from previous attacks.

Dr. R. F. WEN thought that Dr. McBurney had confirmed a statement that had been made previously—namely, that the dan-

ger of the disease was greater in many instances than the danger from the operation. Among the eleven cases in which he had operated during the past year he had encountered three in which the abscess was deeply situated in the abdomen, and in which the parietal peritoneum was not involved—in other words, where the general peritoneal cavity had to be opened before the pent-up pus could be liberated. All the others had been met with later in the course of the disease, with the general abdominal cavity shut off by more or less parietal adhesion. After touching briefly on the history of several of these latter cases of appendicitis, the speaker narrated the details of the case of a young medical man who had been seized on a Saturday evening with pain in the iliac fossa and sent for him on the next morning. He found tenderness in the right iliac region which was severe enough to prevent manipulation and examination. Opiates were administered. The temperature, which had been 102°, began to fall, and by the evening of the second day it was only a little above 100°. This led to the hope that delay might be safe, but during the night the patient suffered excessive pain with elevation of temperature, although the next morning the temperature had fallen again. The patient was now considered to be in a critical condition, and an operation was performed fifty-two hours after the beginning of the pain. It was difficult to keep the bowels within the cavity during the operation. When the omentum was raised and the appendix exposed, three or four ounces of pus escaped. The organ was found to be perforated and to contain one solid faecal concretion. The peritoneal cavity, which had become somewhat smeared with the pus of the abscess, was washed out with a salicylic-acid solution and everything possible was done, but the end was a fatal one.

Two other cases were described, in one of which laparotomy with ablation of the appendix had been performed with success within fifteen hours of the inception of the disease. The third patient, operated on at the end of fifty hours, was relieved, but succumbed on the fifth day, from uræmic convulsions. Another case, which had made a profound impression upon him at a time when he had formulated the opinion that it was well to operate early in this disease, was that of a nervous and impulsive young woman who was suffering from pain in the right iliac fossa. He had made, under ether, prior to an intended operation, a thorough examination, and, although the belly was unusually lax, had found nothing but some thickening of the right broad ligament. The patient had then, on the speaker's withdrawal from the case, passed into the hands of a gynaecologist, who diagnosticated an inflammatory process in the right broad ligament. Under treatment this young woman had recovered. He had also seen three cases in which the origin of the tumor might have led to its being considered perityphilitic, although it was from a lesion of the gall-bladder. In two of them the disease had been proved to exist, and in the third it could fairly be assumed to have existed. In the first instance the incision, just above the ilium, had given vent to a quantity of orange-colored pus. The patient's condition forbade an extended operation, and no surprise was excited when the post-mortem showed a rupture of the gall-bladder from multiple calculi. The second case was that of a man who had suffered attacks of hepatic colic, but in whom the tumor was found below the umbilicus and to its right, in the situation of a perityphilitic abscess. This was incised about the third day, letting out about three or four ounces of laudable pus. In this case the appendix had not been found, and really no attempt had been made to find it, for fear of disturbing the limiting adhesions. The fatal result of what was apparently a promising case showed a rupture of the gall-bladder. In the third case the tumor had been higher up and close to the gall-bladder, but this patient had recovered.

Dr. F. LANGE said that he had experienced considerable difficulty with one case in finding the appendix. After some tedious search he had found it lying across the caecum and to the right. The patient had been presented at a previous meeting.

Dr. WEIR said that, though the appendix was occasionally found bound down by a webbing of adhesions after repeated inflammatory attacks, yet it was in the majority of cases found free and swollen, looking somewhat like the erect penis of an infant.

Dr. C. K. BRIDDON had seen many cases in which the organ was found lying over the upper part of the pelvis, and one in which it occupied the floor of the cavity. He should consider the region just above Poupart's ligament as rather low. He thought that, from the fact of its being often found over the brim of the pelvis, an examination *per rectum* would throw some light on the cases.

Dr. McBURNEY said that it seemed to him a matter of small moment in what direction the appendix pointed, or how long it was. What was really important was to locate, if possible, the situation of the inflamed portion, and, as this was almost invariably near the point of attachment of the appendix to the caecum, and the perforation generally occurred within an inch of this point, examination *per rectum* was of little value. But by the method of examination of which he had spoken it would always be possible to discriminate these cases from peritonitis due to other causes and from inflammatory conditions of the pelvic organs in women.

Dr. BRIDDON said that, whether the method he had suggested revealed the trouble or not, it would not influence him in regard to operating.

Dr. FRANK HARTLEY presented a patient and reported the history of his case. (See p. 684.)

**Officers for the Ensuing Year** were elected as follows: President, Dr. C. K. Briddon; vice-president, Dr. Robert Abbe; secretary, Dr. Frank Hartley.

#### ROYAL ACADEMY OF MEDICINE IN IRELAND.

##### SECTION IN MEDICINE.

*Meeting of November 15, 1889.*

The President, Dr. LOMBE ATTHILL, in the Chair.

**Morphinism.**—Dr. Foot drew attention to the increasing prevalence of the use of the hypodermic syringe as a medium for the vicious introduction of morphine into the system. Morphinism (a word introduced by Levinstein) was, in some parts of Europe, at present almost a matter of fashion, gifts of handsome syringes in silver cases were exchanged on festive occasions, and reciprocal injections of morphine made on favorable opportunities. The subject was one of special interest to medical men, because of the number of their colleagues who had fallen victims to it. Some said this was a just retribution upon those who were responsible for the practice. Dr. Foot thought it more charitable to attribute the habit to (1) the relief of pain, (2) insomnia, (3) melancholia, (4) curiosity, or (5) imitation. A receptivity for morphine was not possessed by every one; all its effects were unpleasant to many. Few morphinists were satisfied with less than three grains in the twenty-four hours; many used more than ten times that amount. The diagnosis or detection of the morphine habit was discussed, and stress laid upon the peculiar untrustworthiness of the patient's own statements as to the amount or frequency of the dose. The prognosis in morphinism was not at all favorable; the probability of a cure might be estimated by attention to the following points: the duration of the habit, the persistence or not of the exciting cause, the physical and nervous constitution of the patient.

Relapses were very frequent; successful treatment, unless under the most favorable circumstances, was hardly possible in the patient's home.

As to the treatment, emancipation from morphine slavery was unattainable by voluntary effort. The process of cure, or of demorphinization, required more moral and physical courage than was at the disposal of a morphine habitué. The treatment was considered under the heads of the *deceptive* plan, the *substitution* plan, the *tapering-off* plan, and the *abrupt withdrawal* plan. The two first methods were not to be seriously considered in the treatment of confirmed morphinism. The tapering-off plan involved prolonged misery during the weaning process. The abrupt plan was frequently followed by the dangerous group of *Abstinenzsymptome*. A modification of the two latter methods might be adopted—the complete withdrawal of the morphine, not abruptly, but in from six to twelve days. The fœtus *in utero* felt the demorphinization of the mother, and also, when separated by birth from a morphinist mother, exhibited reactionary symptoms such as prolonged insomnia. In some cases morphinism need not be interfered with, in others it was even beneficial to acquire the habit. Allusion was made to the occurrence of morphinomania in animals.

Dr. MACSWINEY recalled a case recorded in Anthony Todd Thompson's text-book on *materia medica*, a laudanum-drinker who, though he was in the habit of taking a wineglassful at a time, was cured by the gradual elimination or deprivation process. A quart-bottleful was procured, and for every glass of the drug taken out a glass of water was substituted, with complete success.

Dr. FALKINER mentioned the case of a school-teacher whom he had seen take five ounces of laudanum at a draught, and who afterward gave up the habit.

Dr. EUSTACE advocated the abrupt and sudden total withdrawal of the drug in morphinism, and of the spirits in alcoholism, as the best and most scientific treatment. As a rule, only a partial cure was effected, for sooner or later temptation led to a relapse.

The PRESIDENT's experience led him to advocate gradually diminishing doses.

Dr. WALTER G. SMITH said it was difficult, in regarding the action of drugs of a certain class on the higher parts of our nervous system, to restrict consideration to any particular drug, such as morphine, without bringing into consideration also the effects of other drugs of allied action. Thus there were two groups which might be arranged in the ascending scale of action—one, the alkaloids, and the other the members of the fatty series, including chloral, ether, alcohol, etc. Dr. Foot had adverted to this class distinction, indicating that the prolonged use of one of the members of the fatty series was liable to induce general tissue change and lead to death, whereas members of the alkaloid series affected chiefly the higher or psychical, emotional, and intellectual nerve centers, causing death by their action on the respiratory and cardiac centers. With regard to treatment, he did not think any amount of discomfort entailed on the patient was a good reason for objecting to the sudden total withdrawal of the drug.

Dr. JAMES LITTLE thought that Dr. Enstace had sufficiently answered his own recommendation by giving an account of his own sufferings. Even though the ultimate good of the patient was in view, he did not believe in disregarding the horrible torture, the intolerable suffering produced by sudden total withdrawal; and, on the contrary, he thought the nervous system of the patient never recovered entirely from the wreck of misery and wretchedness produced by such treatment. For his own part, he had seen patients get on very well by gradually stopping the drug.

Dr. FOOT said he thought Dr. Eustace had given the keynote to the discussion. There were two classes of cases to be considered. Thus, Chareot drew a distinction between what he called morphinism and morphinomania, the former being the state of a person who had recently acquired a taste for morphine, whether from temptation, imitation, curiosity, or for relief of pain; and the latter the condition of mental deterioration only known to exist in those with such a craving, insufferable hunger that destroyed body and soul, they would jump into hell to get their morphine. The morphinomaniac in his periods of satisfaction would bewail his condition, but would otherwise have no real desire to be cured, and would seize the first opportunity of getting morphine. He must therefore accordingly be treated as a lunatic. On the other hand, the morphinist wished to be cured and would assist in carrying out the graduated, or tapering-off plan, which was the advisable treatment in such a case, for experience showed that total withdrawal was followed by what the Germans called "*Abstinentzsymptome*," or reactionary effects, which had sometimes proved fatal.

#### ROYAL ACADEMY OF MEDICINE IN IRELAND.

##### SECTION IN SURGERY.

*Meeting of November 8, 1889.*

The President, Mr. AUSTIN MELDON, in the Chair.

**The Operative Treatment of Tubercular Disease of the Knee Joint.**—Mr. THOMSON read a paper on the operative treatment of tubercular disease of the knee joint. Having referred specially to the infective character of tuberculosis, he pointed out that where the condition of the synovial membrane demanded operation the disease was rarely so limited as to be removed by simple erosion. In some cases where the cartilages were apparently quite healthy, the bone was found on section to be diseased, and yet this was the sort of case which the thoroughgoing eraser would regard as typical for his treatment. The securing of movement after erosion was being abandoned, and that being so, ankylosis could be more surely and quickly secured between two level bone surfaces, as in excision, than by the opposition of two irregular cartilage-covered surfaces. Shortening sometimes occurred where no operation was done, so that this objection could not be fairly argued as a result of excision. If the disease was extensive enough to lead them to the epiphysary line, they must go there even at the risk of shortening. He maintained that excision was safer and more satisfactory than erosion. He had excised the knee seventeen times without a death; but in two of his cases, before adopting the combined methods of fixing by Thornley Stoker's dowels, and the use of his own hoop-iron splint, he had to amputate. In his hospital in fifty successive cases of excision of the knee joint there had only been one death—a result which left little to be desired.

Mr. TOBIN thought that Mr. Thomson had not indicated clearly what cases ought to be submitted to operation, nor had he suggested an answer to the difficult question, "Shall I operate at once, or wait, and, if I wait, how long?" It was important to determine whether an operation should be performed at once in every case diagnosed as tubercular synovitis, or whether it would be desirable to wait till the bones were attacked, or still longer, till suppuration had set in. For his own part, he would wait longer than Mr. Thomson seemed to approve, having regard to the fact that by the use of Thomas's splint, complete rest, and change of air, he had seen great cures effected. Moreover, he did not see that a resected knee had much advantage over an amputated leg supported by the modern improved artificial appliances. He sometimes found that while

a straight limb was obtained for three or four years, it afterward got crooked.

Sir W. STOKES indorsed Mr. Thomson's views as to the superiority of excision of the knee over the operation of erosion or arthrectomy. As to the time for operation, it was impossible to lay down a rule, but, speaking from his own tolerably large experience of the operation, he held that as soon as the surgeon satisfied himself he had to deal with tuberculous disease of the joint, the earlier the operation was performed the better was likely to be the result. He repudiated the statement put forward in more than one hand-book of operative surgery that knee-joint resection would soon be an operation merely of history. On the contrary, the operation never enjoyed a greater reputation than at present, and he believed its reputation was likely to increase. He preferred a splint which he himself had devised to Mr. Thomson's, as insuring absolute fixation and rigidity of the limb, and also as rendering unnecessary the doweling as recommended by Mr. Thornley Stoker.

Mr. J. K. BARTON, referring to the question raised by Mr. Tobin of the general advisability of the operation, mentioned the case of a housemaid upon whom excision had been performed, and who discharged her duties a whole year without her mistress being aware that there had been anything the matter with her, while he submitted that had she suffered amputation, the mistress could not possibly have remained ignorant of the fact.

Mr. TOBIN intervened to deny that he had questioned the advisability of excision, an operation which he frequently practiced himself, and said his point was as to the cases suitable for that operation.

Mr. BARTON said the real point was as to the procedure, and he had no doubt there were cases of disease of the synovial membrane in which erosion might be profitably performed instead of excision; but erosion could not be favorably compared with, or take the place of, excision in cases of tubercular disease.

Mr. LENTAIGNE concurred with Sir W. Stokes that excision was the best treatment for tubercular disease of the knee joint, and ought to be performed as soon as the disease was recognized; and if the limb became crooked afterward it was the fault either of the surgeon or the patient, and very often of both.

Mr. BENNETT questioned the dictum that excision was the proper and right treatment once the diagnosis was tubercular disease, and contended that Mr. Thomson had not committed himself to such a proposition once he admitted that he dealt with excision in reference to hospital patients and not the treatment of patients of the upper classes. Indeed, Mr. Holmes's challenge had never been accepted as to any case of excision having been done in private practice. (Mr. Thomson: "I have had one.") The vast majority of such cases in the upper classes were treated without excision. Patients had recovered from white swelling of the knee with all the due care and rest that could be given in private practice. But where tubercular disease was running riot there was no longer the alternative of palliative treatment, and it then became a choice between excision and amputation. At the same time he had seen cases of recovery take place even after suppuration had set in.

Mr. SWAN remarked that the spontaneous cure alluded to by Mr. Bennett was the established practice of a great many eminent London surgeons, including Howard Marsh and Owen, the latter of whom had extensive practice with children, and believed in letting the joint suppurate; but the average period of cure was three years—a longer time than could be afforded for hospital patients.

Mr. FRANKS took up Mr. Holmes's challenge and said he had

himself operated by excision for tubercular disease of the joint in the case of a female patient with success. Patients could not be kept in hospitals for years awaiting the result of spontaneous cure when, probably, as good a result could be had in a few months.

Mr. THORNLEY STOKER held that, whereas excision was an operation of established repute, that of erosion was on its trial, and accordingly no decisive opinion could be expressed about it. For the past two years he had been anxiously watching to get a suitable case for erosion, but in every instance where he commenced the operation he had been obliged to complete it by carrying out excision.

Mr. CORLEY said, as regarded when to operate and what cases to operate on, there was no test but experience, nor could the surgeon tell, until after the joint was opened and a prepared section placed under the microscope, whether the disease was tuberculous or not.

Mr. WHEELER held that where excision was necessary it should be done early. The bones should be always cut. He had himself performed the operation of excision of the knee joint in two private cases, and now one of the patients was able to walk nine miles at a stretch.

Mr. THOMSON had advisedly narrowed the scope of his communication by omitting conditions anterior or preliminary to the question of excision *versus* erosion, two operations which he found pitted against each other. As to the time to operate, the sooner the better, once the surgeon saw distinct pulpy degeneration of the synovial membrane.

## Miscellany.

**Report of the Sanitary Committee on the Manure Question, with Recommendations.\***—It is only necessary, we trust, in order to emphasize the sanitary importance of the manure question in this city, to invite the attention of the commissioners to the large number of complaints that are made by the people of all stations of life, calling the attention of this department to the annoyance to them from the foul odors caused by the present method of handling manure. All of these people assert that they are seriously annoyed by the odors—some, of course, more so than others. It is maintained by many that these odors enter their living, sleeping, and eating rooms, interfering with rest, causing nausea, loss of appetite, and consequently leading to depreciation of the vital forces that depend for their proper vigor on physical and mental rest, good appetite, and good digestion. Reputable physicians complain frequently in similar terms in behalf of patients, not infrequently using vigorous methods of expression as indicative of disgust or distrust on their part with the seeming indifference of the sanitary authorities of the city. While it is true that much has been done already to lessen the burden of the people in this respect, still complaints of a similar tenor are made continually, and therefore it appears to be high time for the department to take such action as will give to the people, if it be possible, freedom from the annoyances and ill results caused by the foul and offensive odors that arise from the present method of handling stable manure. The foul and offensive odors resulting from other classes of business carried on in the city are subjected to rigid control and strict surveillance by the department when their source is ascertained. In the manure business, however, in which no question can arise as to the genuine cause of foul odors, or that their effects on the human system are parallel with the results of foul odors from other causes, no such comparatively decisive steps have yet been taken to abate or abolish them.

For the practical consideration of the problems that arise in con-

nexion with the disposal of the manure made within the city of New York, and the relief of the people of the city from the foul and offensive odors arising from it, it seems well to divide the interests directly associated with the production of it into three distinct classes—viz., (1) the producers of manure; (2) the manure merchants, or “riders” of manure; (3) the consumers of manure.

The direct producers of this product are horses, of course. Of these there are in round numbers about 60,000 below One Hundred and Thirty-fifth Street. It is estimated that a horse will drop about 15 pounds of manure *per diem* on the stable premises, which will make the entire daily product of manure about 900,000 pounds, or 450 tons. Estimating each load of manure “ridden” from the stables at about 1,000 pounds weight, we find that on this basis about 900 loads daily are removed from the city. The fact is, however, that the nearer amount is about 1,200 loads daily, irrespective of the weight of a single load.

The close association of the owners of horses with these animals is the excuse for making now a change of statement by considering the owners themselves as the practical producers of this product. The owners of these animals can be separated into certain definite and well-recognized divisions, for the purposes of the remarks that are to follow: (1) Persons of leisure, to whom the horses are but another means of pleasure and enjoyment; (2) persons engaged in business in which these animals are employed as an aid, convenience, or necessity; (3) the poor men who, by thrift alone, secure to themselves the ownership of one or two horses, upon the proceeds of the direct use of which they themselves and their families depend for livelihood and support. The horses of the first class are kept in private stables and in first-class boarding-stables, the expense in the latter instance being from twenty-five to thirty-five dollars a month for each horse. Those of the second class are also kept, as a rule, in boarding-stables, but of a less pretentious character than the former. In this instance the expense varies from twenty to thirty dollars a month for each horse. The horses of the third class are kept either on the premises occupied by the owners and their families for living purposes, or in stables of a humbler class, opening into alleys, lanes, and yards. From fourteen to twenty dollars a month for each horse is a fair estimate of the cost of stabling in the places last mentioned. The manure is removed from all the stables in the same manner—that is, in carts, at specified intervals, for a stipulated compensation. The stipulation prices for removal vary from one to twelve dollars *per annum* for each horse. In a fair percentage of instances (twenty-five) the manure produced by the humblest class of owners is removed by the manure “riders” without charge.

It is of special interest at this time to note the fact that, when the horses are stabled on the living premises of the owner, the wagons, carts, etc., are commonly parked in the street in front of the premises; but when the horses are aggregated in a common stable located elsewhere, the vehicles are then parked in the stable-yard and in the lane or alley adjoining the stable; sometimes, of course, in the street, as before. The sanitary advantages of the aggregation method of stabling horses are obvious at a glance, for by this plan the number of stables in the city are lessened, and their proximity to dwellings is reduced to a minimum; the parking of vehicles in the streets in front of human habitations is much diminished, together with the nuisances dependent on their presence in the streets.

The manure merchants or “riders” of manure are, as a rule, most estimable and law-abiding citizens. In many instances the amount of money invested, as well as the energy and enterprise displayed by these men, is calculated to entitle them to the respect of those engaged in other and more fastidious occupations. It is the custom of those engaged in riding manure to make such terms with the producer as are mutual, as is elsewhere shown. The frequency of the removal of manure depends on the amount made and the ability to properly store it on the premises, etc., together with the interruptions dependent on the exigencies of the weather. It is important to notice the manner of removal. It is forked from the manure vault or pit to the floor of the stable, or the sidewalk, or into the cart, as best suits the convenience or fancy of the laborer engaged in the work. The time occupied in the transfer from the pit to the cart is from thirty to forty-five minutes for each load. Always one and sometimes two laborers are engaged with each cart, the number depending, of course, on the difficulties of load-

\* Read before the Section in Public Health and Hygiene of the New York Academy of Medicine, December 6, 1889.

ing, as modified by the size, shape, and situation of the manure vault. The loads of manure are drawn through the streets to a "dump" at the river front, where the manure is transferred, directly or indirectly, to a scow for removal from the city.

The markedly unsavory nuisances that are unavoidably associated now with this branch of the business are caused, first, by the storage and bandling of loose manure on the premises, causing odors in and about the stable building which taint the textile fabrics of the carriages and of the occupants of the stables, and it is asserted by some that even the varnish of the carriages is tarnished and often permanently disfigured. The escape of these offensive odors into the external air annoys the passers-by and also the occupants of the contiguous dwellings. Second, the streets are littered by the falling of manure and straw from the carts while *en route* to the "dump," and often the offensive odors of manure are plainly discernible in the streets through which the loaded carts are passing. Third, the dumping or unloading of the manure at the docks is complained of by many as being offensive to the sense of smell and by all as offensive to sight. The collection and the removal of manure to the scows that transport it from the city requires, as before remarked, a considerable outlay of money, together with much energy and enterprise. Thus employment is furnished to about four hundred laborers (396). These men receive each about \$1.75 *per diem* for services. Nearly three hundred carts (296) of all sizes, mostly single, are employed for the purpose. Each horse and cart hauls from two to six loads a day, the number depending on the distance drawn and the convenience of handling. The great majority (226) of the carts haul five loads in a day. It now becomes a comparatively easy matter to estimate approximately the amount invested in this business directly, together with the amount paid for labor to establish the practical application of it. The four hundred (396) laborers earn about \$1.75 each *per diem*, which earning (about \$207,900 *per annum*) forms the principal item, no doubt, of the annual support of three times that number of persons. The three hundred (292) horses can be safely estimated as costing \$200 each, or a total of \$60,000. The carts (296) cost about \$113 each, making a total of \$33,448 for these vehicles. Three hundred (292) sets of harness, estimated at \$38 per set, add \$11,400 more to the outlay. The expense of shoeing the horses, wear and tear of the vehicles and harness, etc., can not be less than \$7,500 or \$8,000 per annum additional—making a grand total of about \$320,000, including the yearly wages paid for help. If to this amount be now added the yearly expense incurred for the leases of premises for "dumps" and for emergency storage, this total will be increased much more. The expense of scows, if they be owned by the manure merchants, or the expense of the hire of them if they be not, becomes a fixed matter under any system of action, since they are loaded to the fullest capacity at all times. It is reported that from twenty-four to forty-eight hours elapse from the time of the removal of the manure from the stables of the city before it is sold by the "rider," or stored by him outside the city limits for the purpose of "ripening" for sale. Long Island, New Jersey, and Westchester County furnish the principal markets of disposal.

The consumers of this manure are those who till the soil, and they reside principally in the parts of the country contiguous to the city, as just indicated. They receive the product in the form of bales, or in the loose state, as the occasion demands or their fancy directs. As yet, but a comparatively small amount of manure is baled.

In considering the question of the policy of baling manure, it seems proper that the subject should be divided into three distinct parts: 1, the baling itself; 2, the handling after baling; 3, the effect of baling on the fertilizing qualities of manure. The last of these divisions will be considered first. This division directly interests the consumers of manure. They will naturally inquire as to the effect of baling on the fertilizing powers of the product. If it shall appear that manure, when baled, is as serviceable as when unbaled, then, certainly, no reasonable objections to baling can be urged by the tillers of the soil; on the contrary, they should welcome the change as one that facilitates their labor, and consequently adds to their personal comfort. As to the effects of baling on the fertilizing properties, it is not necessary to theorize at all, since the science of chemistry can settle the fact beyond dispute.

The following report of the comparative analysis of baled and unbaled manure, made by Mr. E. W. Martin, Chemist of the Board, speaks not only for itself, but also for the committee, regarding the matter:

NEW YORK, June 15, 1889.

E. H. JANES, M. D., Assistant Sanitary Superintendent:

SIR: I have the honor to make the following report with regard to changes in the commercial value of horse manure through baling the same. The method of analysis employed was that recommended by the Association of Official Agricultural Chemists, Washington, 1888.

*First Set of Experiments.*—One bale of manure, put up at the stable of the New York Cab Company, Forty-fifth Street and Fifth Avenue, and a quantity of the same manure, unbaled, were sent to the disinfecting station at the foot of East Sixteenth Street on March 28, 1889, and kept under cover.

Samples of the above specified manure were taken, and analyzed by Assistant Chemist Beebe on May 3, 1889, with the following results:

Analysis number.	Character of sample.	Ammonia on dry basis.		Total phosphoric acid on dry basis.		Insoluble phosphoric acid on dry basis.	Moisture.	Remarks.
		Per ct.	Per ct.	Per ct.	Per ct.			
5,867	Unbaled manure.	2.55	1.54	0.26	51.73	Very slightly molded.		
5,869	Baled manure ...	2.44	1.40	0.25	50.82	Completely molded; "fire-fanged."		

*Second Set of Experiments.*—Two bales of manure, put up at the same place as in the first experiment, together with loose manure, were taken to the disinfecting station on May 8, 1889, and treated as follows:

Loose manure inside.

One bale exposed to weather outside.

One bale inside.

Samples of the above specified manure were taken, and analyzed by Assistant Chemist Beebe on June 4, 1889, with the following results:

Analysis number.	Character of sample.	Ammonia on dry basis.		Total phosphoric acid on dry basis.		Insoluble phosphoric acid on dry basis.	Moisture.	Remarks.
		Per ct.	Per ct.	Per ct.	Per ct.			
5,891	Loose manure inside.	2.72	1.68	0.21	49.64	Molded.		
5,892	Bale exposed outside.	3.10	1.83	0.21	44.80	Molded completely from center out—still warm.		
5,893	Bale inside.	3.07	1.64	0.17	31.17	Molded completely; cold.		

From the above-given results, I am of the opinion that the baling of horse manure and keeping in bales for thirty days does not injure its commercial value, nor is there reason to believe that baling for a longer period than this will lessen the commercial value.

Respectfully submitted,  
[Signed.] EDWARD W. MARTIN,  
Chemist.

This report has been examined by so eminent an authority on chemical and sanitary matters as Professor Charles F. Chandler, of Columbia College, and a former president of this department. In a communication to me regarding this report, Professor Chandler says:

SCHOOL OF MINES, COLUMBIA COLLEGE,  
Corner Forty-ninth Street and Fourth Avenue,

NEW YORK, August 22, 1889.

DEAR DR. BRYANT: The manure question has always been one which has been a source of a great deal of discussion and difficulty. It came up every year while I was connected with the Health Department, and no plan was ever proposed that gave satisfaction to all concerned. When the subject of baling manure was first suggested it struck me favorably, and I visited the yard on the East River where the process was being carried on, and it seemed to leave nothing to be desired in the way of simplifying the handling of the material. It was suggested by some parties that the fertilizing properties of the manure would be injured by the process, but I was satisfied at once, without making any analysis, that this could not be true. The manure was not wet enough to have anything squeezed out of it in the process of baling, consequently it could lose nothing in this way, and there was no more reason

for its losing valuable fertilizing constituents in haling than in rotting. I am glad to find that the very complete analyses which have been made by Mr. Edward W. Martin, your chemist, and his assistant, Mr. Beebe, entirely confirm this opinion, and show that the manure suffers no loss by the baling process. There is no reason why it should. I can not think of any suggestion to make beyond what I have said in favor of haling. I hope you will insist upon this process; it is the only radical improvement that I can think of in this connection.

Very respectfully yours,

[Signed.]

C. F. CHANDLER.

Professor Maurice Perkins, Professor of Chemistry of Union College at Schenectady, a member of the State Board of Health, in a verbal communication to me, confirms all the above-named gentlemen have said. It is surely a supererogation to seek further facts in the matter in face of the positive statements of these eminent and distinguished scientific gentlemen.

The molded or "fire-fanged" appearance of baled manure naturally excites doubt in the minds of the consumers as to the integrity of the fertilizing qualities. This doubt, too, is settled by the analysis of "fire-fanged" manure made by Mr. Martin, as will be seen in his report. It is the opinion of the Committee that no good reason exists why the consumers of manure should object more to the baling of manure than the consumers of hay object to the baling of that product. In fact, it appears to the Committee that the consumers ought to hail such a measure with delight for the following reasons: 1. Baled manure is more easily and rapidly handled than the unhailed, and the handling is attended with no offensive odors or defilement of vehicles. 2. The fertilizing properties are not impaired by haling (see Martin's report), and, if necessary, it can be unbaled and "ripened" or combined with other fertilizing agents more quickly, conveniently, and economically than when in the loose state. 3. Farmers who market their produce in the city can return home with a load of baled manure without causing any offense, and with a practical financial advantage to themselves.

*Second: Handling after Baling.*—This division of the subject directly concerns the manure merchants or "riders" of manure. It is perfectly fair to assume that these people, like other business people, will be pleased with a proposition that will enable them to attend to their business in a shorter time, and at less expense to themselves, than is now done, provided the market value of their labor be not impaired by the method adopted. That the fertilizing properties of manure are not impaired by baling is already irrevocably proved; and that the market value depends almost entirely on these properties can not be denied. If, now, the properties be preserved, and at the same time the manure be presented to the consumer in a convenient, practical, and inoffensive form, then indeed should the market value be increased; certainly it can not be diminished.

The business can be done in a shorter time for the following reasons: 1. A given amount of baled manure can be handled more quickly than the same amount of unbaled manure, and without any offense. The same is true, also, of baled and unbaled hay. 2. Heavier loads of baled manure can be drawn during the same length of time than of unhailed manure. Twice as much (weight) haled as unbaled hay can be easily drawn at a load; and there is no good reason for the belief that practically the same relation will not hold good in connection with manure. 3. As no offense is created by the drawing of baled manure, the time of drawing can be modified to conform to the recognized customs of other businesses.

*Less Expense to Themselves.*—1. If it be true that a greater amount of haled than unhailed manure can be handled in the same length of time, it follows logically that a lesser number of horses, carts, etc., will be required to accomplish the given purpose; consequently the expense of handling will be proportionately reduced. 2. If it be true that heavier loads of baled than unbaled manure can be drawn in the same length of time, then it follows undeniably that the expense of hauling is lessened proportionately to the amount drawn. 3. If the relation between baled and unbaled hay, as regards the amount drawn in a given time, exists also between baled and unbaled manure, the expense of "riding" manure will be reduced at least one half by the baling process.

If, now, attention be directed to the amount invested by the manure

merchants in horses, carts, harness, wear and tear, etc., it is apparent that the gain for them, even with a less favorable estimate, will be immense, if compared with the amount now invested. It is well to notice also the probable fact that with this system bales of manure, like those of hay, can be marketed directly, thus doing away with the special cars, scows, sloops, dumps, etc., which are necessary on account of the offensive nature of the product while in the loose or unbaled state. These results will lessen the outlay of the manure merchants, thereby enabling them in turn to lighten the expense of it, as related to the producer and the consumer.

The baling itself affects those engaged in all phases of the manure business, and concerns indirectly also all classes of the community. It directly affects the pockets of the former, and indirectly concerns the senses of the latter, and, as a rule, the effect on the pockets is productive of the more potent results of the two. The securing of the apparatus to hale manure properly can not in any way seriously incommod the first two divisions of persons mentioned in the beginning of this report, viz.:

"Persons of leisure and of business, who own horses as aids to pleasure and profit." I will not, therefore, question the sincerity of their good citizenship by a further consideration of themselves in connection with this point; they should be staunch supporters of whatever plan is shown to be productive of the greatest good to the greatest number.

How will the persons of the third division be affected by baling manure? It will be remembered that to this class belong:

"The poor men, to whom the proceeds of the use of one or two horses are the principal means of support of themselves and families." To expect each of them to make the outlay necessary to bale the manure of the horse or horses that belong to each is absurd and impossible of accomplishment; and, if it were possible, the requirement of it would be as unwise and unjust as it is burdensome, and as inconsistent as it is unnecessary. These persons should be permitted to put the manure in cheap barrels or other proper receptacles, in which it should be removed to the dump by the manure merchants, and the receptacles returned by them to the producer. The cost to this class of producers need be but little, if any, in excess for each horse of the price of the barrels—about \$3.65 per annum, or one cent each day. It may be said that the manure merchant will not take the manure thus harreled and return the barrels without extra expense to the producer. Let us look for a moment at this phase of the subject. The producer will purchase and fill the barrels. A barrel will cost not to exceed ten cents; it will contain the "droppings" of one horse for from seven to ten days, equal to about 100 to 150 pounds, according to the size of the barrel, including the stable straw that will naturally enter into it. The producer will willingly give the manure to the "rider" and will pay him from five to ten cents for the barrel when returned. It is shown that the average number of loads of unbaled manure drawn daily is five, each weighing from 1,000 to 1,500 pounds. We will select the lesser estimate. Each load will then represent ten barrels of manure, each barrel containing 100 pounds. At this figure the "rider" receives 5,000 pounds of manure daily from the producers for nothing, and is paid for returned barrels \$2.50 to \$5 each day.

It is estimated that the gain in time of loading barreled manure over forking loose manure into the cart will be substantially offset by the greater length of time taken to empty the manure from the barrels at the dump. Surely the manure merchants, who will gain so much from handling baled manure, can well afford to remove the barreled manure, even if they themselves furnished the barrels and return them. It is an enterprise, surely, that many, independent of the manure merchants, would grasp at once, to say nothing of the farmers, who would return from the city with manure after having marketed their products. There is no doubt that many worthy and enterprising persons would appear at once who would gladly accept the opportunity to remove the manure inoffensively for the modest remuneration that would follow. Not a thing is wasted in this city, except by those who do not need it, or those who do not appreciate its value. The same enterprise that gathers rags from the gutters will satisfactorily solve this element of the subject. In view of these facts, and the demand of the people of this city for relief from the foul and offensive odors that constantly

arise as the result of the present method of handling, the committee respectfully recommend that the Sanitary Code be so amended as to conform to the spirit and purpose of the following resolution:

*Resolved*, That on and after the fifteenth day of May, 1890, it shall not be lawful to remove stable manure from any stable or premises in the built-up portion of the city of New York, or to cart the same within the city limits, without a permit from the Health Department, unless the manure be pressed and baled as required by the Board of Health, and be properly covered while being removed and carted, or be inclosed in tightly-covered barrels or receptacles approved by the Board of Health, so as to prevent the escape of all offensive odors and liquid matter.

Respectfully submitted,

[Signed.] JOSEPH D. BRYANT, M. D., Chairman,  
WILLIAM M. SMITH, M. D.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the abstract of sanitary reports received by him during the week ending December 13th:

CITIES.	Week ending—	Estimated popula-	Total deaths from	DEATHS FROM—								
				Cholera.	Yellow fever.	Small-pox.	Varioloid.	Vaccinia.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.

**The New York Academy of Medicine.**—At the next meeting of the Section in Obstetrics and Gynaecology, on Thursday evening, the 26th inst., Dr. A. Brothers will read a paper on "The Subsequent Behavior of Cases of Extra-uterine Pregnancy treated by Electricity."

At the next meeting of the Section in Laryngology and Rhinology, on Friday evening, the 27th inst., Dr. W. H. Daly, of Pittsburgh, Pa., will read a paper on "The Relation of Naso-pharyngeal Disorders to Deafness."

**California Tokay Wine.**—In the discussion of an interesting and suggestive paper on "Infantile Therapéutics," by Dr. John A. Larabee, of Louisville, read at the recent meeting of the Mississippi Valley Medical Association, and published in the December number of the

"New England Medical Monthly," Dr. Love, of St. Louis, said: "In the matter of stimulation I have found Tokay wine, or Hungarian Tokay wine, to be very valuable, but it has been high-priced—from \$3 to \$5 a bottle—so high as to be almost prohibitory, and beyond the reach of the majority of families. There was presented to me within the last year a bottle of Royal Tokay wine, a California production, bottled by the California Vintage Company, of 21 Park Place, New York city, at \$1.50 a bottle, which gives exceptionally satisfactory results, and is just as good as any Tokay I ever used; therefore I think it is sheer nonsense to give families who can not afford it a prescription for a three- or five-dollar wine."

#### ANSWERS TO CORRESPONDENTS.

**No. 304.**—From the facts given in your letter, it is not likely that the trouble is due to the psoriasis; it probably depends on some affection of the central nervous system. Treatment is not very promising. A course of general tonics, especially the use of arsenic, seems indicated. It would be well to protect the nails with rubber or leather cots, and to apply to them some stimulating ointment, such as one of tar or of sulphur.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inscribed when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

## Original Communications.

### THE RADICAL CURE OF VARICOSE VEINS OF THE LEG BY MULTIPLE LIGATION.\*

BY CHARLES PHELPS, M. D.,

ATTENDING SURGEON TO ST. VINCENT'S AND TO BELLEVUE HOSPITALS.

SOME years ago my attention was specially directed to the dangers and inconveniences of varicose veins of the leg. In the course of examinations for civil appointment I had been very frequently compelled to reject candidates for this form of disease who were in every other respect physically well fitted for the position to which they aspired, and often when the varicosities were comparatively unimportant from any other point of view than this.

The frequency of crural varices has not, so far as I know, been made the subject of statistical research. That it is of great frequency is evident, not only to those who have had occasion to submit large bodies of men to physical examination, but to all those who have had under observation the inmates of alms-houses and hospitals for the care of chronic diseases. Perhaps no surgical disability will be found to exist more frequently unless it be chronic ulcer or haemorrhoidal tumors. They are of acknowledged frequency in women and in those whose circulation is enfeebled by age or general debility. In my own experience they have occurred even oftener in young men, and especially in those of vigorous physique. No cause is more frequently operative than occupations like those of carrying-porters, truck-drivers, or car-drivers, which involve prolonged and severe strain upon the crural muscles by which the blood from the intermuscular veins is constantly forced into the superficial vessels. Car-drivers, I am told, habitually suffer from this condition, and the statement is confirmed by my own observation.

Contrary to the opinion of Mr. Callender,† that these varices are "not serious in their consequences," I have found that they do often involve the patient in serious and even fatal danger. How serious and dangerous these ordinary varicose veins may become is unhappily exemplified in more than exceptional instances. Since January, 1888, within less than two years, five cases of haemorrhage from rupture of crural veins have occurred within my immediate knowledge or observation. One of these patients died in the ambulance upon arrival at St. Vincent's Hospital; another was brought into the ward at Bellevue in a moribund condition, and was resuscitated by transfusion, which resulted subsequently in gangrene and amputation of the arm. Two others reached the hospital in a condition of collapse, and could only be restored by hypodermic injections of digitalis and whisky. In the fifth case, occurring in the practice of Dr. S. G. Cook, profuse and repeated haemorrhages were controlled with the greatest difficulty. And these

were all varices of ordinary size. Within the same length of time I have operated in some score of cases where varices were so large and the tegumentary coverings so thin that, beyond the danger of practically spontaneous rupture, the patient was in constant and imminent danger of profuse or even fatal hemorrhage from any trivial wound or contusion to which every person is at any moment liable. In several cases in which great pools of blood existed, formed by the aggregation of largely dilated and tortuous subcutaneous veins, I doubt not that death would result from a wound almost as speedily as from opening an artery of the first class. The profusion and force of the haemorrhage may be estimated from that which often occurs from pricking some small vein in the course of the operation to be hereafter described; and it is to be remembered that neither prompt nor intelligent aid can be expected in a majority of cases of accidental haemorrhage. The statement repeatedly made in surgical text-books, that placing the patient on his back and raising his leg will stop the flow of blood, is untrue and misleading, and liable to occasion a fatal result.

Aside from this consideration of actual danger to life, there are numerous cases in which the inconveniences from ulcer, eczema, oedema, or weakness of a varicose limb seriously embarrass the patient. Every practitioner is familiar with them. I may mention as an extreme instance a case at Bellevue when I was *interne* in which recurrent and intractable ulcerations, confining the patient to bed and hospital during years of the best portion of his life, finally led him to beg for amputation. This was eventually conceded, and, in the hands of a careful and accomplished surgeon, death resulted from septicæmia. But, short of such despair and lamentable result, patients suffering from varices are often enough absolutely unfitted for the active pursuits of life.

It seems, therefore, that the cure of this condition is more important than we have been taught to believe. I have also found it quite practicable when sufficiently thorough and effective measures are employed.

In cases where radical cure has been heretofore attempted the operative methods resorted to have been sometimes objectionable and almost always ineffective. Operation by ligature, if done at all, has been infrequent, and the ligatures have been placed at few and distant points. As in all other forms of operation recommended for radical cure, the design has been, even in the longest veins, only to effect obliteration at one or two selected points. There has been an apparent fear of purulent phlebitis, although veins have always been freely ligatured whenever their incidental division has made it necessary. Even when pyæmia was regarded as a legitimate accident of surgical interference it was not often directly chargeable to ligature applied to the veins themselves. With usual antiseptic precautions or without them, there seems no good reason why free ligature of veins should involve more danger when made with a direct purpose than when made incidentally in the course of other operations—*e. g.*, in the removal of large and vascular tumors where a great number of venous ligatures have always to be applied.

\* Read before the Society of the Alumni of Bellevue Hospital, November 6, 1889.

† Holmes's "Surgery," vol. iii, p. 384.

The frequent anastomoses of superficial veins, not only among themselves, but with others situated in the deeper structures, and often imperceptible even upon careful examination, is the fact upon which I have based my opinion of the necessity of occluding the vein not only at occasional points, but throughout the whole length of every trunk involved. If there were no such anastomoses, obliteration of the vein at a single point high up in its course would serve to close it in its whole length below, and, whether excision, chemical coagulation, pressure, or the ligature were resorted to, would be a mere matter of convenience, modified by the operator's view of their comparative safety and efficiency. But, with constant intervenal communications, and many of unknown size and importance, it seems obvious that occlusion must be made at many points to insure probable stability of clot. In this view excision and chemical coagulation are, of course, impracticable. Aside from any question of purulent phlebitis, here, as elsewhere, the ligature is undoubtedly the most efficient agent of permanent occlusion, and, applied at sufficiently frequent intervals, the indication ought to be fulfilled and radical cure attained or at least approximated.

The result of numerous operations which I have since undertaken has fully justified this anticipation.

I selected at first very simple cases, where only a short length of vein was enlarged and only a few ligatures were required. In my first operation, which was at Bellevue Hospital in November, 1886, only two ligatures were used—one immediately above and one immediately below a single varicosity. In this and in the next half-dozen cases the vein was exposed by incision at each point and the ligature applied in the wound, which was then closed by a single suture. In these cases the wound usually suppurated to a trifling extent. Since that time the ligations I have done have all been subcutaneous and the formation of a single drop of pus has occurred only here and there in exceptional instances. I except three cases in which suppuration resulted at each point of ligature from the use of septic catgut.

In the ligation of varicose veins, as in all other operations, antiseptic methods and precautions in preparing the limb, in operating, and in dressing should be scrupulously observed. If, however, by neglect of these, some suppuration occurs, I have not found it to do serious harm beyond the trouble it occasions in multiplying dressings and detaining the patient in bed. The distance between the ligatures should vary in accordance with the size and varicosity of the vein and its apparent or probable anastomoses. In long stretches of large but comparatively straight veins the intervals should be not greater than from one to two inches. Where there are masses of dilated and convoluted veins forming a tumor, it is impossible to include it in the ligatures, and they must be applied all around it and as closely as possible to it, embracing every immigrant and emergent vein that can be discovered. I use a catgut suture taken directly from the juniper oil and as small in size as possible consistent with necessary strength. The ligature should be carried by a straight needle, preferably the Keyes-Reverdin, immediately behind the vein, and the needle unthreaded

and withdrawn. The needle is then carried immediately in front of the vein, through the openings which it has previously made, and the end of the ligature caught up and brought back. The vein is thus subcutaneously included in the ligature, which is then tied and cut short, and, if the catgut is fine enough, the knot pushed back beneath the skin. If, however, the vein is larger and coarser catgut has to be used, no trouble results from leaving the knot in the orifice of the wound; in fact, I prefer it. It occasionally happens that a large anastomotic vein, passing vertically inward to the intermuscular vessels, will prevent occlusion of a superficial vein at a given point, leaving a globular varix. In that case it may be necessary to tie the anastomotic branch. This may be done in the manner devised by Dr. E. W. Clarke, house surgeon at the New York Hospital, for approximating the fragments of a fractured patella. The ligature is carried deeply along one side of the vein; the needle is re-entered at the point of exit and with the ligature carried at right angles to the first line of puncture; it is then re-entered at the second point of exit and carried at right angles to the second line of puncture; it is again re-entered at the last point of exit and brought out at the original point of entrance, thus surrounding the vein.

After the dressings have been applied, the limb should be placed upon a posterior splint and the patient kept in bed for about ten days or two weeks, after which he should wear a roller bandage for two months.

The number of ligatures necessary to be applied is a matter of absolute indifference. The patient will recover just as rapidly whether he has few or many. I have often used from twenty to thirty upon a single limb. In one case forty-two were applied upon the two legs at one time, and sixteen more in a secondary operation. Few cases require less than ten or twelve, and the average number is greater. Usually both legs are involved, but one is always much less seriously affected than the other, and will require comparatively few ligatures and perhaps none.

I am unable to state with precision the number of cases in which I have operated. I can recall upward of one hundred in hospital and private practice, and, including those operated upon by gentlemen of the house staff, the whole number is probably upward of one hundred and fifty and the number of ligatures applied from two to three thousand.

For a time I did this operation in many instances for the simple purpose of observing results, and I still believe it justifiable in any case of crural varix where no special contra-indication exists. I now restrict it to those cases in which there is some direct purpose to accomplish, and which may be very well classified as follows:

1. Cases where this condition constitutes disability in physical examination—as for admission to the army or navy, or for appointment in a municipal department.
2. Cases where the size of the veins, the formation of venous tumor, or the attenuation of the coats or tegumentary coverings threaten hemorrhage.
3. Cases where chronic ulceration or eczema exists.
4. Cases where circulation has been so far impaired as to occasion swelling of the feet or loss of power in the limb.

I have already said directly or by implication that this

procedure is devoid of danger, and the number of successful operations reported seems to warrant the statement. Sometimes, in passing the needle deeply, profuse haemorrhage follows, from puncturing some neighboring vein, but this usually ceases when the ligature is tightened; if not, the next ligature applied immediately below always controls it. In the first of those cases, in which the veins were excessively large and the ligatures at the same time numerous, I feared some difficulty in the re-establishment of the return circulation, but it did not occur, nor has it occurred in any subsequent case. The elevation of temperature is moderate and the pain inconsiderable. In but five cases has there been any retardation of recovery. In one there was partial anaesthesia with paralysis, as I believed, from impaction of a nerve in the popliteal region. These symptoms gradually disappeared after the solution of the catgut. There need be no danger of including a nerve of any considerable size, and if by chance some smaller filament be implicated, the effect is likely to be transitory and relieved as in this case mentioned. In three other operations, to which reference has been made, every point of ligature suppurred. I was able to trace this accident to the use of defective gut, by careful observation of other operations done at about the same time and in the same wards, with the same material. In another case occurring very recently, suppuration also took place at each point of ligature. It was at first attributed to an existent ulcer of fourteen years' standing, and to a considerable extent of surrounding unhealthy tissues. But in a few days each ulcerated point assumed an exact circular outline, clean cut as by a punch, suggesting another possible explanation. Everything healed, however, including the original ulcer, and the patient was discharged from the hospital, cured, four weeks from the time of operation. In some instances I have thought trivial suppuration, with some diffused inflammation of the leg, to be due to sepsis from an ulcer which ordinary antiseptic treatment had failed to cleanse. In others, where one or two points of ligature out of many have afforded a drop of pus, I have been quite unable to account for the fact. I have never had occasion to suspect pyæmic poisoning, and I can see no sufficient reason for its occurrence.

It has been suggested that a special danger is incurred in this operation from the formation of thrombosis, and that excision is therefore a safer procedure. It has not been my intention to compare multiple ligation with other methods of operation except in regard of efficiency and certainty of cure. I may say, however, that, while relying upon so great a number of cases without accident to support my belief in its safety, I can see no reason why thrombosis should be more to be feared in this than in any other method of securing occlusion. Even excision requires two or more ligatures, and in using a greater number of ligatures, however many, the danger, whatever it may be, inheres only in one, the proximal one. In excision of large varices, moreover, a serious and bloody operation replaces a simple one and involving much greater liability to suppuration and infection.

I have operated upon patients of various ages and in various conditions of health, and, while the simple nature of

the procedure makes only ordinary caution necessary, there are, of course, constitutional conditions which should preclude any form of surgical interference. There are also local conditions and causes of which these superficial venous enlargements and varicosities are only symptomatic and which exclude them from the class of ordinary crural varices that have been considered.

Finally, this operation in its results, immediate and remote, has proved generally successful. The cure is complete in proportion to the completeness of the operation, and, so far as can be judged at the expiration of two or three years, the cure is radical. In some cases where the veins to be treated are numerous and not of great size, some points at which ligation is required may be overlooked on account of the completeness with which the vessels are often unloaded and collapsed when the patient assumes the recumbent position for operation. This may be avoided by tying in the erect position when an anaesthetic is not employed; or by marking with nitrate of silver or iodine before the patient is put upon the operating table. Even then such marks may be washed away by the irrigating fluid, and a secondary operation becomes necessary. In some other cases, where the varices form a considerable tumor, secondary operation will always be required to effect entire obliteration. In each of four such cases which I have had, the tumor, though in one instance originally as large as a lemon, had become after a few weeks small enough to be included directly in the ligatures.

I have never observed a collateral venous circulation set up and afterward becoming varicose, such as has been asserted to always follow any attempt at radical cure. It is probable that the excess of blood from the intermuscular veins—which, from being forced into the superficial vessels, has dilated them—is now directed into the still deeper veins, and by them continues to be returned. I have sometimes seen after operation in severe cases one or more veins still moderately dilated, and not infrequently those upon the feet, which I have not been accustomed to ligate. These are not likely to occasion any inconvenience, and it is better to abstain from interference. If, however, any of these vessels continue to enlarge, a few additional ligatures will suffice to make the cure practically complete.

The obliteration of the veins is attended by corresponding relief of the morbid conditions which the varices have occasioned. Eczema disappears and intractable ulcers heal often under the primary dressings applied after operation, as ought to happen if these conditions are produced or maintained by the sluggish circulation. When the varicose condition has lasted long and the structure of the tissues has been profoundly altered, it can not be expected that chronic ulcer and eczema will be instantly and permanently cured; but they are at least soon relieved, and if, after healing, they recur, they cease to be intractable, and, so far as we have yet had opportunity for observation, they are eventually permanently healed, which they never are while the varicosity persists. It goes without saying that obliterated vessels will not bleed, and that limbs enfeebled by lack of nutrition will grow strong as the movement of the blood is restored.

I have only maintained for this operation that it effects a cure which seems radical within the limits of two or three years. Whether such cases will eventually relapse and again require surgical attention is, of course, conjectural. Should such prove to be the case, the operation is sufficiently simple, safe, economical of the patient's time, and productive of relief, to have fully justified itself and to warrant its repetition. Not more can be said of many of the more pretentious and accepted efforts of conservative surgery.

I trust I have made plain the intent and principle of the treatment of crural varices which I have advocated. The essential point in this operation, as I have tried to describe it, is not in the use of the ligature or in its subcutaneous method of application, but in the complete obliteration of the whole length of the veins affected. The ligature was long since used in the treatment of crural varices and subcutaneously employed elsewhere. I have resorted to the subcutaneous ligature here simply as the most convenient and effective means of accomplishing the principal object in view.

**NOTE.**—I observe in the report of the proceedings of the Alumni Association of Bellevue Hospital, published in the "New York Medical Journal" of December 14th, that I am credited with saying, at the close of the discussion which followed the reading of this paper, that I "considered the method by excision about as good (as multiple ligation) except that it was very tedious." This is an entire misapprehension of what I did say. I reiterated the statement that the essential point of the operation which I advocated was the entire occlusion of the whole length of the affected vein, and that any operation which would accomplish this purpose was adequate. I know of no other method which will do this except multiple ligation with catgut. As a matter of fact, I believe excision, where the varices are large, to be not only tedious but often dangerous, and to cut out portions of vein at sufficiently frequent intervals to effect the continuous obliteration which I have indicated would be so formidable an operation as to be obviously impracticable. Excision would be more properly comparable with ligation at a single point.

BACTERIOLOGICAL INVESTIGATIONS OF  
A CASE OF YELLOW FEVER  
TREATED AT ST. JOHN'S HOSPITAL, BROOKLYN, IN 1888,  
WITH REMARKS ON  
YELLOW FEVER AT KEY WEST, FLA., IN 1862.\*  
By ARNOLD STUB, M.D.,  
BROOKLYN.

I WILL preface the few short remarks I am able to make upon the micro-organisms I found in the liver and black vomit of a case of yellow fever treated at St. John's Hospital, Brooklyn, with a history of the epidemic of yellow fever as observed by me personally at Key West, Fla., in the year 1862.

The literature on the micro-organisms of yellow fever is so scanty, the results of the investigations still so obscure, and my own researches narrowed down to the limit of a single case, that for the present it will be almost impossible to place any value upon the revelations by the microscope in the study of this disease.

Whatever organism you may find upon the slides I present to you this evening, I make no pretension of showing you something that has never been seen before by others; neither do I pretend to have discovered the yellow-fever microbe.

Although I am convinced that such an organism exists, the discovery of the right one I naturally must leave to later and more able investigators.

I also beg leave to state that in 1862, when I had the misfortune to witness an epidemic of yellow fever, carbolic and salicylic acid as well as jaborandi were not in use, and Professor Wunderlich had not yet written his work on the thermometer as a means of diagnosis and prognosis.

The following history of the fever is collated from notes written during and immediately after the subsidence of the fever, and consequently some of the physiological views expressed will not altogether coincide with the views of today.

The geographical situation and the climatic circumstances of the island of Key West are so well known that I need only state that the island has a slight elevation toward its center of about ten feet above the level of the sea, and lies in  $24^{\circ} 30'$  latitude and  $80^{\circ} 40' 30''$  longitude.

The command stationed at the island consisted of four hundred and forty-eight enlisted men of the Ninetieth N. Y. V. and several detailed men of other regiments, who enjoyed, previous to the 27th of July, 1862, comparatively good health. The thermometer during the month of July averaged  $85^{\circ}$ , and the hygrometer  $82^{\circ}$ , an excess of heat which in itself is sufficient to harbor and regenerate the yellow-fever poison, if once brought there. Key West, though situated in a near vicinity to Havana, has always had the name of a healthy locality, and fever has only seldom, and after long intervals of healthy seasons, extended its devastating power to the island. During the year 1861 the difference between the height of the thermometer and hygrometer, also the average temperature, had been the same as in 1862. A number of unacclimated men (several hundred) arrived in the spring of 1861, and remained during the summer, but no case of yellow fever occurred. As in 1862, the wind blew nearly constantly from a southern direction, and the fever was, as usual, severe in Havana. The winter of 1861-'62 had been unusually mild, which caused a partial postponement of the decay of the vegetation until this summer. Large tracts of land, overgrown with brush and underwood, had been cleared during the spring and early part of summer for military purposes, which, though the most part of the vegetable matter had been burned up, left still a large quantity of rubbish to spontaneous decay. Portions of land of smaller dimensions in the neighborhood of the Marine Hospital and the buildings erected for a machine shop by the navy were fenced in by the owners, and the ground had been broken for gardening purposes. The United States Engineer Department, on the other side of the island, caused the resurrection of the corpses of Africans buried on the south beach two or three years previous, being obliged to use that portion of ground for military purposes. The graves were opened and the bodies transferred to another locality. I have been told

\* Read before the Medical Microscopical Society of Brooklyn, December, 1888.

that the removal of the corpses caused an almost insupportable stench, which infested the locality for some time. The work was done by laborers, mostly composed of Irish lately arrived from Europe. The wind, constantly blowing from the south or southeast, had caused the sea on the south beach of the island to deposit large quantities of decomposing vegetable and animal matter, which constantly exhaled miasma.

On the 21st day of July, six days before the first case of yellow fever occurred among the troops stationed at Fort Taylor, Key West, Fla., two cases of fever were admitted to the Marine Hospital from the bark Adventure, coming directly from Havana. One of the patients died on the 22d of July with black vomit.

At the commencement of the epidemic I was in charge of the General Hospital, Key West, Fla. The fever, beginning on the 27th of July, reached its height in the latter part of August and commencement of September. Seven deaths occurred in my hospital on the 4th of September, four deaths on the 6th, and five deaths on the 8th. From this day the fever abated, and gradually assumed a milder type. The number of patients treated by myself amounted to two hundred and seventy-eight; of these, I lost fifty-seven. (This record takes in the time from July 27th to September 30th; after the latter date I was taken sick with the fever myself, and kept no private record.)

The first case, as already stated, occurred among the troops at Fort Taylor, Sunday, July 27, 1862.

The man, Private W. C., Co. K, Ninetieth Regiment N. Y. V., reported himself sick early in the morning at sick call, and the physician in charge sent him to the General Hospital at Key West Barracks, Florida. He arrived July 27, 1862, at 2 P. M. Early in the morning of the 28th I was called to his bedside; found him almost pulseless, skin cold, lying on his back, and throwing up black vomit with such a force that it soiled the ceiling above him. He died in the afternoon of the same day. No private record of his treatment kept.

The next patient was found on the morning of the 30th of July in his tent with black vomit, and died in the evening.

On August 2d two more cases occurred, and one of the patients died August 9th. Another reported sick August 3d and died August 6th. From the 3d of August until the 15th the fever made a pause, and though a good many, from want of experience, not knowing the treacherous character of the enemy they had to deal with, exulted in the belief of its entire disappearance and pronounced the fever of a mild type, on the 15th of August two new cases occurred, and from that date until the 8th of September I had an increase of from five to ten fever cases per diem—some mild, others of the worst type.

(From a sanitary point of view it will be of interest to relate that the regimental quartermaster occupied for his office a small block-house situated near the regimental *stables*, and seven men, detailed in succession as quartermaster sergeants or clerks, took the fever, and, with the exception of one, died.)

The almost daily prostration of my nurses convinced me at once that colored persons born on the island would be the only ones fitted to act in such capacity, and, upon my urgent request, the commanding officer ordered the employment of negroes as nurses in our hospital.

Throughout the whole of the epidemic premonitory symptoms were generally absent. In a few single cases the patient complained, for days previous to the attack, of pain in the head and constipation. In two cases diarrhoea ushered in the black vomit without previous fever. The same matter was discharged from the bowels, and death by coma soon closed the scene.

Nearly every case presented throughout the whole of the epidemic a different series of symptoms, much influenced by the constitution, temperament, and idiosyncrasies of the patient. In opposition to observations made by others in almost all other epidemics of yellow fever, there was no particular time during the twenty-four hours of the day when the attack occurred. Men were seized at all hours—some early in the morning or evening, others during midday or at night. In most of the cases the attack came on suddenly. The victim was seized with a severe pain in the head, mostly across the supra-orbital region, often preceded by a regular chill, sometimes merely by a feeling of cold. The pain soon extended to the eyeballs, and was combined with intolerance of light.

Pain in the back and neck and across the knees caused extreme restlessness. In a few cases the brain symptoms reached a high degree in the beginning, and delirium soon commenced; but I found that these yielded easier to treatment than others where meningitis manifested itself in a later period. The adnata of the eye was generally watery, and gave to the patient the peculiar appearance of being inebriated. The skin was generally hot and dry; sometimes, and particularly in those cases which speedily terminated fatally, I found the skin cold and covered with a clammy perspiration. The pulse varied from 85 to 109, and was full and incompressible, except in those cases whose skin was cold and clammy, where I found the pulse small and gaseous. The tongue was almost always covered with a white fur, with red tip and edges. The latter, I mean the red tip and edges, corresponded exactly with the pulse and febrile excitement. The higher the pulse, the stronger the fever, the redder the tip of the tongue. Only in two cases during the whole epidemic did I meet with a dry tongue; in one case only it had a brown, dirty coating. Almost always the tongue was covered with a white fur and punctated red, on account of the enlarged papillæ. The bowels were sometimes constipated and hard to move; sometimes open, even too loose. The evacuations were generally natural in the beginning of the disease. After the administration of a cathartic, bilious evacuations soon followed; only in one case I observed, after calomel and oil had been given and no evacuation resulted, that an enema caused the discharge of a light-colored fluid, and a whitish-gray looking mass, resembling the stools often seen in ieterus. This patient soon died. In not a few cases the stools after the administration of calomel remained for days of an inky color and very frequent. The urine in most cases in the beginning of the attack was normal, in the severest type scanty, and the little that did pass dark-colored, and threw down a heavy, brick-colored sediment.

Nausea sometimes, but not always in the worst cases, commenced early in the first febrile stage, and the stom-

ach yielded its contents of food occasionally mixed with bile.

These symptoms, as described in the foregoing, continued for a longer or shorter period. Sometimes the fever remained on for twelve, twenty-four, or forty-eight hours, sometimes longer; in a few cases that terminated fatally, seventy-two or seventy-three hours. During the prevalence of the fever, headache, pain in the back and eyes, with insatiable thirst, formed the most distressing symptoms. Generally after the application of hot baths, with warm diaphoretic drinks, perspiration was soon established and continued during the prevalence of the fever.

In some cases, however, all remedies failed to excite the skin to proper action, and perspiration, if momentarily established, soon gave place to a hot and dry skin. This state lasted until the second stage of the disease, which, as above stated, according to the violence of the attack, began at the twelfth, twenty-fourth, or forty-eighth hour. During the beginning of the second stage the patient was free from headache and fever, but generally complained of a slight pain in the back. The stomach was more or less irritable, and often yielded its contents without the least effort; sometimes retching distressed the sufferer. A pain more or less acute, according to the severity of the attack, particularly felt on pressure, manifested itself in the epigastrium. I noticed that men felt comfortable, and expressed themselves willing to leave the bed, but on slight pressure they felt a severe pain in the epigastrium and soon black vomit came on. Generally the worst symptom presented itself after the patient had been for about five or six hours in the second stage. The pain in the epigastrium increased, a severe burning thirst troubled the sufferer, vomiting soon commenced—first of the fluid taken to alleviate the thirst, often clear and transparent, sometimes mixed with bile. This stage lasted for about three or four hours, when the fluid assumed more the color of water, with a brownish-black sediment on the bottom.

On examining it closer, it was aropy flocculent mass suspended in the fluid; some, of greater specific gravity, sank to the bottom, and with considerable tenacity adhered to the sides and bottom of the vessel. Often the quantity of fluid thrown up increased, the stomach apparently yielded its contents without the least effort, and, throwing the vomitus sometimes several feet away from the bed of the patient, appeared to act like a force-pump.

The matter thrown up resembled now more a thick chocolate, and, after standing, it deposited a coffee-ground-like, grumous mass, which, expressed through filtering paper, lost considerable of its dark color. Bicarbonate of potassium thrown into the fluid gave off carbonic acid with effervescence, and blue litmus-paper dipped into it became at once of a red color. If put into a test tube and heated over a spirit-lamp, the fluid, if previously transparent, became opaque, with masses of albumin floating in it. In those cases where uræmia was present—and in nearly all cases of vomitus niger uræmia existed—the black vomit, first neutralized with bicarbonate of potassium, if heated in a test tube, gave off ammonia; and a glass rod dipped into hydrochloric acid and held over the vapors arising from the

heated fluid, developed white cloudy fumes, evidently the chloride of ammonium. The urine, if secreted at all, was invariably albuminous, and sometimes more than one half of it was blood.

Often blood alone was discharged from the bladder. During the whole of the epidemic I observed as one of its characteristics that the matter was not ejected in large quantities at a time from the stomach, and only in a few cases did the matter thrown up at once exceed two quarts. Hiccough troubled the patients considerably. The matter, in consequence of its acrimonious nature, frequently excoriated the tongue, throat, and lips; the stools also, often consisting of a similar matter, caused a painful sensation in the anus, at the same time having a very offensive smell. The time from the commencement of the black vomit until its termination in health, or death, of the patient, differed considerably; sometimes, though seldom, it ended fatally in twenty-four hours; often it lasted longer, and in one case it was protracted for four days; it ended in recovery of the patient. Although I always considered its appearance as a very grave symptom, it has been my fortune in twelve well-marked cases of vomitus niger to restore the patients to health. Out of 278 patients, 69 presented the symptoms of black vomit—57 died and 12 recovered. During the last stage, above described, I found the pulse generally below the natural standard of health. It varied from fifty to sixty-five pulsations in a minute, and was generally small and easily compressed. In two of the cases which terminated fatally the pulse reached one hundred and nine beats in a minute.

The color of the skin differed considerably in the different cases. Sometimes it was natural; seldom it presented the different shades of yellow, but, generally speaking, the yellow color, if it appeared at all, showed itself shortly before death took place. In two patients, who afterward recovered, I noticed a third, or, as some may call it, a fourth stage of the fever. The matter thrown up changed its color; in place of having a tarry appearance, it became mixed with streaks of blood; the tongue in several places became scabbed, and blood began to ooze from it, as well as from the gums and lips. Epistaxis and bloody stools made their appearance, and the yellow color of the skin, previously pale, assumed a dark orange-color. The hæmatemesis I succeeded in checking, in the one case with half-drachm doses of tincture of chloride of iron every hour, and in the other case the liquor ferri persulphatis (Squibb's) had an excellent effect. The ten other remaining patients with black vomit passed rapidly, after the vomitus had been checked, into a state of convalescence, and improved faster, and sooner resumed their duties, than others who, from a severe attack of yellow fever, passed from the first stage to convalescence without going through a second and third stage.

In the fatal cases the patients generally died on the fourth or fifth day. The recovery after the yellow fever was usually rapid; ten days after the first attack the patients commonly resumed their duties again.

In five cases endocarditis was the consequence of the yellow fever; three of these patients took the fever twice in the course of five weeks, and the second attack was more violent than the first. One, after the yellow fever, had symp-

toms of phthisis pulmonalis, and died five months afterward. Another the fever left with nyctalopia, and in one case an attack of acute hepatitis followed a severe attack of yellow fever. The rest, as already above stated, recovered rapidly.

I exceedingly regret that throughout the whole of the epidemic I was so constantly employed at the bedside of my patients that I could find no time to make post-mortem examinations.

In the treatment of the yellow fever I followed the theory (1862) that the poison, similar to that of malarial fevers, attacked the ganglionic system. The latter, which penetrates through the whole of the human body, runs in branches throughout the whole of the arterial and venous system, both the ganglionic and arterial system depending upon each other for their vitality. It (the poison) attacks first that portion of the ganglionic system which supplies the external capillaries. These lose their vitality or tone, and cause a concentration of the blood toward the center of the body.

The fever in its first stage I considered caused by the irritation of the capillaries of the external skin. The natural consequence is heat of the body and absence of perspiration. To restore the tone of the external capillary system, and to prevent a concentration of the blood toward the center of the body, seemed to me the first object to attain in the commencement of the treatment; the next, to remove the cause of the evil—I mean, to counteract the morbid influence of the treacherous poison absorbed by the nervous system and causing the results mentioned. To meet the first indication, I found that nothing would answer better than the hot bath and sinapisms. To act as an antidote against the poison, I used large doses of quinine by the mouth, as well as locally by friction all over the body. The quinine acts as an apyretic, as a tonic and stimulant on the ganglionic system, besides combining the properties of a sedative, if administered in large doses, and reducing the palpitation of the heart, which, in yellow fever, often was a prominent symptom.

The same poison which attacks the ganglionic system of the external skin also in many cases involves the capillary system of the intestines, and causes the peristaltic movement to be suspended, and a purgative will be required to clear the alimentary canal and to prepare the system for a prompt absorption of the quinine. In a similar manner are the other organs—the kidney, the liver, and sometimes the spleen—affected, to which I ascribe the local pains often felt in those regions. If the indications above mentioned have been fulfilled, the patient will pass at once into a state of convalescence; if not, the second stage commences. The capillaries, either partially or entirely, according to the more or less severe action of the poisonous influence upon their ganglionic system, have lost their tone, contract, and cause the blood, in leaving them, to concentrate more toward the internal organs. This retrograde movement of the blood is not effected at once, but it takes place gradually, in harmony with the advance of the fever poison on the ganglionic system. It leaves the patient, for a short time at least, comparatively free from pain. This I consider the most critical period of the malady. This is the moment

when the physician is to concentrate his attention on the patient, and by judicious measures to prepare the network of capillaries of the lining membrane of the stomach for the shock that awaits it. The poison is now about to center its malignity on the capillary system of the stomach. It excites the organ first to spasmotic action, resulting in vomiting, and causes an abnormal secretion of the gastric juice; eventually the capillaries lose their tone, and in the mildest cases haematemesis is the consequence, or, *in extremis*, the vomitus niger.

The latter, I believe, is principally caused by the blood entering the stomach through the walls of the capillaries, meeting there with a fluid which, in regard to some of its constituents, resembles the gastric juice in its normal condition, and by this the fluid is decomposed. I believe that the apparatus producing the gastric juice has suffered by the invasion of the yellow-fever poison to such a degree that its product becomes changed in regard to the proportionate combination of the different materials composing the normal gastric juice; because, if this is not the case, why does not the stomach always in simple haematemesis discharge the blood decomposed and transformed into the mass called black vomit, as the stomach at all times contains more or less of gastric juice, which, if it alone in its normal condition were able to decompose the blood, should do it then also? And why, I ask, is it that in a case of black vomit the first sign of haematemesis is hailed as a favorable symptom?

J. Baptista Lacerda describes, in No. 4 of the "Annals of the Academy of Rio de Janeiro" of 1887, bacteria which he found in the parenchyma of the liver, in the gall-ducts, the veins and arteries, the lymphatics, and the convoluted tubes of the kidneys of six individuals who had died of yellow fever. He considered them to belong to a different species from any other bacteria before known. He describes them as cylindrical granules, forming among themselves chains, and representing under the microscope the appearance of a tree with three branches—the central branch straight upward, the side branches a little curved. He mentions, however, that sometimes they present a different picture, but under all circumstances they show a decided inclination to ramification.

Professor Sternberg, of Baltimore, found in two cases out of nine the same bacillus described by Lacerda and Baker. Professor Sternberg also found the micrococcus described by Dr. Freire and named *Cryptococcus xanthogenicus*. He states that it fluidifies gelatin very slowly and forms upon the surface of agar-agar a milk-white coating.

Its morphology is represented upon the drawing I herewith take the liberty to circulate, which Dr. Sternberg made after a preparation from Dr. Freire's laboratory in Rio de Janeiro. The magnifying

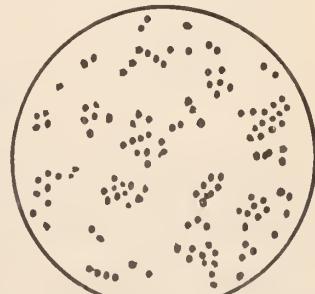

FIG. 1.—Cocci found by Dr. Sternberg  
Drawing copied from the "Centralblatt für Bacteriologie," vol. iv,  
No. 18.

power is about 1,000 diameters. The views of Dr. Sternberg are published in the "Centralblatt für Bacteriologie," etc., No. 18, vol. iv, and his letter is dated September 2, 1888.

A previous article of Dr. Sternberg's, published on page 449 of the "Medical News" of 1888 and entitled "Investigations relating to the Etiology and Prophylaxis of Yellow Fever," disproves the prophylactic utility of inoculating people with the coccus discovered by Dr. Domingo Freire.

Professor Sternberg, however, seems to be of the opinion that our present knowledge of infectious diseases entitles us to the belief that yellow fever is caused by a living micro-organism, and that, if we are able to discover the latter, we shall be able to protect ourselves by inoculation against the fever. I also understand that Professor Sternberg has discovered a coccus heretofore not described in relation to yellow fever. I have seen a cultivation of the same, but, as I have not found anything about it in literature, I do not consider myself justified in entering into a description of it.

The specimens I have the honor to present before the society consist, in the first place, of black vomit stained by Gram's method. If you examine the same you will find a bacillus resembling closely the one described by Lacerda, and perhaps you may find also the cocci which Dr. Freire and Dr. Carmonay Valle describe. The latter, however, you perhaps will find better represented in the specimens of urine I shall endeavor to demonstrate. In these specimens you will find a large number of granular casts, blood casts, blood-corpuscles, and leucocytes all broken up, besides

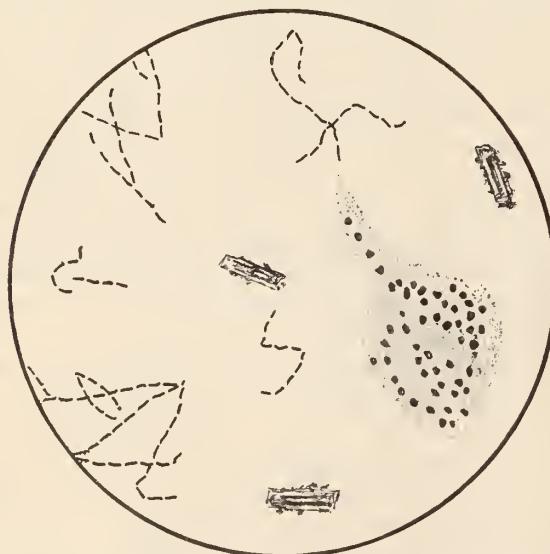

FIG. 2.—Bacilli and cocci found in the vomitus niger; the former identical with those described by Dr. Lacerda, Dr. Freire, and Dr. Carmonay. Coccii resembling those found by Dr. Sternberg. With Zeiss's homogeneous (oil) immersion, 2 mm., and apochromatic ocular, No. xii.

numberless epithelia from the pelvis of the kidney, also tyrosine and leucine. At least I found them, and if the urine is not entirely decomposed, in spite of my endeavor to keep it, you will find the same that I did. Dr. Thomas, of St. John's Hospital, has kindly furnished me with the specimen of urine from a yellow-fever case. Dr. Bliss has furnished me with a specimen of the black vomit, al-

though I miss some of the features I noticed in the appearance of the fluid I observed in 1862—for instance, theropy, sticky mass adhering to the sides of the vessel; in the main, it resembles the vomitus niger I have seen before, although it looks blacker. It also was highly acid, and bicarbonate of sodium caused effervescence. I have not examined the fluid unstained, but Dr. Kemp, of the Hoagland Laboratory, has, and I hope he will show us the specimens. I mentioned before that I stained some of the specimens after Gram's method, and found bacilli closely resembling those described by Lacerda. But I also stained some specimens with a solution of methylene blue and aniline water, also with a watery solution of fuchsine. The last I shall not present before you, because I hardly found anything upon the covering glasses. The specimens stained with methylene blue I submit to your inspection, and I am of the opinion that the micro-organisms differ somewhat

FIG. 3.—Section of liver from the case of yellow fever in St. John's Hospital. With Zeiss's homogeneous (oil) immersion, 2 mm., and apochromatic ocular, No. xii.

from those stained after the method of Gram. Besides the bacilli and cocci already described, you will find in the different fields by moving the slides numberless small cocci, some of them arranged in clusters, also a very peculiar chain coccus. Dr. Bliss sent to Dr. Heitzmann a specimen of the liver, and the latter examined the specimen and reports as follows:

NEW YORK, November 9, 1888.

The piece of the liver of Captain Fellan, brought for examination by Dr. Bliss, after having been hardened in a tenth-of-one-per-cent. solution of chromic acid, under the microscope exhibits the following features:

With low power a marked swelling of the lobules is discernible, whereby the interstitial connective tissues appear compressed, the portal vein being empty and likewise compressed, the bile-duets unchanged.

With higher powers (500 to 600 diameters) the liver epithelia appear on a large scale, broken up to lumps of coarse granules,

and medullary or inflammatory corpuscles. Scarcely a single epithelium is found unchanged.

The lumps into which the epithelia are split up exhibit all stages of transition into fat, from the appearance of a yellow, slightly glistening mass up to the presence of highly refracting granules or lumps, or globules of fat. In some places the liver epithelia are entirely transformed into fat globules. The fat, where fully formed, is not visible in my specimen, owing to the treatment with alcohol and ether for imbedding in celloidin. But the transition stages from protoplasm to fat are plainly marked. The hollow spaces, corresponding to previous fat-globules, in many places show needle-shaped crystals of margaric acid.

The intense swelling of the liver epithelia has led to compression of the capillaries between them to such an extent that the walls of the capillaries appear as solid tracts, mostly lacking calibers. The hepatic veins are likewise much reduced in caliber.

The interstitial connective tissue, being reduced in bulk, as mentioned above, is in the condition of a retrograde change into protoplasm and medullary tissue.

*Diagnosis.*—Intense parenchymatous hepatitis, with intense acute fatty degeneration of the liver.

I have never seen this morbid condition in such a high degree, though similar changes I have observed in the liver of a person that killed himself with phosphorus, and in a liver from a person that died with so-called black vomit or swamp fever of the South, sent to me a few years ago from Charlotte, N. C.

[Signed.]

Dr. C. HEITZMANN.

Dr. Bliss also handed to me a specimen of the liver for bacteriological investigation. I hardened the pieces in absolute alcohol. The sections were also put into absolute alcohol, and I at once stained them after Gram's method. Some I gave a second stain with eosin. You will observe, gentlemen, particularly upon one of the sections, that the identity of the liver cells is almost completely destroyed, but a large number of round or oval cells are visible, studded with very distinctly marked bluish-black roundish bodies, which I consider to be cocci. I admit that the question if these bodies may not be pigment granules is an open one, but I wish to state now, before the discussion opens, that in all previous cases where I have stained specimens of liver by Gram's method the pigment granules have, of course, been visible and darker than any other substance, but in no case have I seen them take the distinct stain that the cocci do upon these specimens. I also should like to call your attention, gentlemen, to the fact that you find those cells studded with cocci in groups upon these specimens, and by moving the slides you will notice that large fields show no evidence of cocci-like formations. The pigment granules, however, are, in all other specimens of liver I have examined, evenly distributed upon all the cells of the preparation. In some of the specimens you will find occasionally small piles of cocci lying outside of the cells, and evidently belonging to another species. Baeilli I have found none. I have made no cultivations, because I have been told that specimens of the vomitus and of the liver had been sent to the Hoagland Laboratory for that purpose, and, if you are familiar with the laborious task of making cultivations from such specimens as we have under consideration to-day, you will understand the almost insurmountable diffi-

culties a physician in general practice has to conquer if he undertakes it, provided he wants the work to be of real scientific value. A few weeks after the patient with yellow fever died in St. John's Hospital, Dr. Wallace informed me by telephone that he had a patient with black vomit under treatment, and I requested the doctor to send me specimens of the vomitus and of the urine. He did, and when I examined the vomitus I found it of a similar color to the vomitus from the case in St. John's Hospital, but not quite so dark; more of a coffee-brown color where the former was altogether black. The former, if you will please remember, was of acid reaction; Dr. Wallace's specimen, however, was neutral, almost alkaline. Upon inquiry I learned, however, that the patient shortly before he vomited had taken several doses of bicarbonate of potassium. I proceeded to prepare cover-glass preparations and stained after Gram's method, and used for the second stain vesuvin. A few cocci baeilli in rod shape, single and in clusters, was all I found, but nothing like the micro-organisms I found in the vomitus from the St. John's case.

The urine was acid, of the specific gravity of 1.025, of a straw-color, albuminous, and containing hyaline casts, some slightly granulated; no epithelia from the pelvis of the kidney, a few from the urethra and bladder, but a number of leucocytes upon each field. If you remember, gentlemen, I told you that the leucocytes found in the yellow fever case from St. John's Hospital were all broken up and the man died. But in the case of Dr. Wallace I found the white blood-corpuscles normal, only in a few instances a slight tendency to breaking up, and I told the doctor that his patient would get well. What diagnosis may have been made in this case I do not know, but the symptoms described to me by the kindness of the doctor were sufficiently grave to cause alarm; however, from the appearance of the leucocytes, I considered myself sufficiently justified in making a favorable prognosis, and I have learned since that the patient got well. I beg leave, gentlemen, to take this occasion to urge upon you the high practical value to be placed upon the theory of the appearance of the leucocytes found in the blood and in the urine of patients. This theory of Dr. Heitzmann's, who has given in his work on "Microscopical Morphology" a full explanation of his views, is not sufficiently understood and valued by microscopists in general, and I assure you that in various cases already I have been enabled to make a correct prognosis based upon the microscopic examinations of the pus-corpuscles or leucocytes found in the urine of patients suffering from kidney disease.

*Antipyrine as a Local Styptic.*—A French physician relates a case in which a boy of fourteen suffered from persistent bleeding after the extraction of a molar tooth. Perchloride of iron was without effect, and so much blood was lost that syncope was induced. On recovery, the hemorrhage again broke out and perchloride of iron was once more tried, but vainly. The cavity was then plugged with two or three pledges of lint steeped in solution of antipyrine. The bleeding at once permanently ceased. It was noticed that while the perchloride caused severe pain, the antipyrine was not objected to. It is suggested, not improbably, that the antipyretic action of this and similar drugs may possibly be due to the fact that they diminish the blood-supply by their astringent effect on the blood-vessels."—*Ohio Journal of Dental Science*.

## COCILLAÑA; A CLINICAL STUDY.\*

BY REYNOLD W. WILCOX, M. A., M. D.,  
INSTRUCTOR IN CLINICAL MEDICINE AT THE NEW YORK POST-GRADUATE  
MEDICAL SCHOOL; PHYSICIAN TO THE DEMILT DISPENSARY.

IN May of this year there was placed in my hands a supply of the concentrated tincture of cocillaña. My studies of apomorphine, the results of which had modified the treatment of acute bronchitis and given a clearer idea of the characteristics which an expectorant should possess, led me to seek further to find one which should be effectual in doses given at longer intervals and without the addition of a bromide, which is frequently objectionable.

The source of the drug cocillaña is the bark of an undetermined species of *Guarea*, which was discovered in Bolivia in 1886 by the eminent botanist, Professor H. H. Rusby, of the College of Pharmacy, who first brought specimens to New York. This species was first described by Dr. N. L. Britton, of Columbia College, in the "Bulletin of the Torrey Botanical Club," 1887, page 143, under the name of *Sycocarpus Rusbyi*, on the supposition that it was a new genus belonging to the natural order *Anacardiaceæ*. On the subsequent acquisition of complete specimens, Dr. Britton at once recognized the true affinities of the plant as being with the genus *Guarea*, natural order *Meliaceæ*, and referred it with some doubt to the species *Guarea trichilioides* (Linnaeus). While it is certainly a *Guarea*, there is much difference of opinion as to the species. Dr. Rusby is quite positive that its characters render it distinct from all known species of that genus, in which, I may remark, nearly all the species are separated by very minute differences of structure. The tree is described as reaching an extreme height of some thirty or forty feet and a trunk diameter of nearly three feet. It is low and broadly spreading in habit, reminding one considerably of a large apple-tree. The bark is thick and ash-colored, becoming rough only with considerable age. The larger branches are horizontal, the ultimate ones somewhat erect and bearing the leaves erect, clustered at their ends. The leaves are pinnate, bearing some resemblance to those of the common sumach, but much larger, being a foot and a half or more in length by two thirds of a foot broad, and bearing from five to ten pairs of oblong, obtuse leaflets, the larger of which are six or eight inches in length. In the axils of these leaves appear the loose racemes of flowers some eight or ten inches in length. The flowers are small, scarcely larger than the head of a small carpet-tack, with the parts in fours, of a dull-greenish color, very inconspicuous, and are succeeded by a somewhat woody, fig-shaped fruit, as large as a walnut. It contains four cells, one or more of which are commonly obliterated as it matures, and one or two erect seeds.

Professor Schrenk described and figured the bark in the "Druggists' Bulletin," 1887, page 222. The characteristic peculiarity, upon microscopical examination, is the appearance of large resin or latex cells containing a peculiar yel-

low viscid substance, on which the medicinal properties of the bark may perhaps depend.

No adequate chemical investigation has yet been undertaken, so that it is impossible to say with certainty to what constituent its medicinal properties are due.

Its physiological action, when the drug has been given in the crude state—i. e., in the form of the powdered bark—is the production of nausea and a desire to vomit, with a metallic taste in the mouth, within about half an hour after the administration and lasting an hour, the nausea being accompanied by an early discharge of mucus and afterward by dryness of the throat. It may be accompanied by slight dizziness, but not by headache. There is a desire to defecate, which, however, may be restrained. Further, slight perspiration has been observed. Its action, then, may be stated to consist of stimulation for some hours of the vessels and glands of the mucous surfaces, more especially of the respiratory tract, with subsequent diminution of activity (sedation). This action probably takes place because the drug is eliminated by way of these tracts. In the administration of the drug in the form of the concentrated tincture sneezing and discharge of nasal mucus have not been observed, and the effect upon the throat is not so marked as when the powder is used.

The preparation employed was the concentrated tincture of the bark,\* the dose varying from half a fluid drachm to two fluid drachms, administered every two to eight hours. This preparation was the one with which the experiments were commenced, and for the sake of uniformity it was continued. I believe, however, that the fluid extract, in doses of from five to twenty-five minims at the above-mentioned intervals, would, on account of the avoidance of alcohol, be more satisfactory in acute and probably also in chronic diseases. Many of the cases reported were demonstrated before my class of matriculates in clinical medicine of the Post-graduate Medical School, who have had abundant opportunity to verify both the physical signs and the results of treatment. The cases are recorded as briefly as possible, and many ordinary symptoms and signs are omitted in the statements.

CASES OF ACUTE BRONCHITIS.—CASE I.—May 24th.—A. L., merchant, thirty-five years old, has suffered from repeated colds in the head for the last eight years, and as a result has extensive catarrhal disease of the naso-pharynx and middle ear. For the last three days he has had a teasing cough, inappetence, at times nausea, and constipation. Temperature, 101° F.; pulse, 110, of fair volume; breathing, 26. Cough dry and expectoration scanty. Inspiration and expiration are roughened. Pitch of respiratory act not raised. Many dry and very few moist rales, the latter only in cough. He was ordered to take half a drachm of cocillaña every two hours, to have a mustard foot-bath, and to apply cotton wadding to the chest after rubbing in camphorated oil.

26th.—Great relief from cough. A profuse watery expectoration appeared about six hours after taking first dose. Rales are now chiefly fine and mucous and are few in number.

28th.—Great improvement. This patient has been frequently treated with apomorphine for attacks of bronchitis,

\* Read before the Section in Theory and Practice of Medicine of the New York Academy of Medicine, December 17, 1889.

\* This preparation is made by Parke, Davis, & Co.

but says that more relief has been obtained in a shorter time than with that drug when begun so late as the third day.

**CASE II.—June 6th.**—A. Z., eighteen years old, has had a cough for two days, after exposure to drafts. Temperature, 100.5° F.; pulse, 108, of fair volume; respiration, 24. He complains of loss of appetite, constipation, and soreness in the chest. His cough is without expectoration, frequent, disturbing his rest, and causing headache. He has also pain in the right side, stiffness in the chest, few mucous but many dry râles distributed over the chest. Respiration harsh and exaggerated. He was directed to take a drachm of cocillaña every three hours and apply cotton batting to the chest.

**8th.**—Expectoration established at the third dose. The pain in the side remained for twenty-four hours. Chest feels clearer; respiration, 20.

**11th.**—Complete relief; slightly harsh respiration, with no raising of pitch. Appetite good and bowels moved daily.

**CASE III.—June 26th.**—R. N., aged twenty-five. Has always been well, with the exception of occasional colds in the head, until three days ago, when he began to cough incessantly and had chilly sensations in the back. He is of fair muscularity. His tongue is pale and flabby. His bowels are regular. Temperature, 100.5° F.; pulse, good, 110; respiration, 24 and superficial. The cough is teasing, preventing sleep, and without expectoration. The chest is well developed; no abnormal dullness; slightly increased vocal fremitus, with increased resonance and roughened respiration, more particularly in inspiration. Many sibilant, some sonorous, a few fine moist râles. He complains of soreness under the sternum, especially in coughing. He was ordered to take cocillaña, ninety drops every three hours, to partake of hot soups, rub the chest with a liniment of oil of wintergreen, and afterward apply cotton batting.

**27th.**—Small amount of expectoration. Pulse, 90; temperature, 99° F.; respiration, 22; cough markedly diminished.

**28th.**—Great improvement; diarrhoea.

**July 3d.**—Reports that he is well, and that his cold has disappeared more rapidly than ever before in his experience.

**CASE IV.—June 28th.**—Miss S. B., seventeen years old, has had a cough for four days, preceded by cold in the head. Now has scanty expectoration, with headache from coughing. Vomited last night. Soreness in the axillary regions, but no distinct pain. Vocal resonance and fremitus are slightly increased; harsh inspiration and expiration, especially inspiration; pitch not raised; has loss of appetite. Was directed to take two drachms of cocillaña thrice daily.

**September 30th.**—Reported that she was cured in four days, that her appetite returned, and the cough and expectoration disappeared. Iron ordered for her anaemia.

**CASE V.—October 25th.**—A. S., sixteen years old, has had a severe cough for the last four days, accompanied by thoracic pains. The respiratory sounds are roughened over all the pulmonary areas except at the bases, and plentiful and fine mucous râles are heard. The cough and dyspnoea are so severe that he is obliged to sit up at night. Has no appetite and is constipated. Ordered cocillaña, half a teaspoonful every three hours.

**28th.**—Reports that the cough was cured on the second day of treatment and that his dyspnoea is much relieved. The first dose of the cocillaña was followed by emesis.

**CASE VI.—October 30th.**—Miss L. F., aged seventeen. Has always been in delicate health. Two weeks ago was taken with a dry, hacking cough, which was severe enough to keep her awake at night and was accompanied by much pain in the chest and headache. Physical examination showed only roughened and exaggerated respiration over both lungs, with sibilant and some fine mucous râles. She was directed to take a teaspoonful of cocillaña every three hours.

**November 1st.**—Cough much better, appetite greatly improved, expectoration scanty.

**CASE VII.—November 2d.**—T. T. B., twenty-four years old, for the last week has suffered from a dry, hacking, painful cough, with a scanty expectoration of clear mucus. Over both lungs it was found that the respiratory sounds were roughened without change of pitch or note, nor was there dullness or change in the vocal resonance. At both bases were heard abundant fine mucous râles. He was directed to take half a drachm of cocillaña every four hours.

**4th.**—Reports entire relief from cough.

**CASE VIII.—November 7th.**—W. F., a school-boy, seven years old. For one day has suffered from soreness in the chest, incessant cough without expectoration, and headache. He has no appetite and his bowels are constipated. On examination, a weak pulse of 120 and a temperature of 102° F. are found. He is an anaemic, nervous boy of fairly good flesh. His chest expands well, there is no abnormal dullness, his respiration is puerile, exaggerated, and harsh. There are no moist, but a few sonorous and many sibilant râles. There is no change in vocal resonance or in fremitus; respiration, 24. He was ordered to take fifteen drops of cocillaña every hour, to remain indoors, and to have cotton batting applied to the chest after inunction with camphorated oil.

**8th.**—Cough loose; loud, coarse, moist râles on expiration as well as on inspiration; no dry râles; sleeps well at night and his bowels have moved well.

**12th.**—Much relief, with cure on the 14th. This patient has had repeated attacks of coryza and bronchitis, and usually expectoration is established with difficulty.

**CASE IX.—November 13th.**—Mrs. W., twenty-five years old, has suffered from a dry bronchitis for six weeks. The coughing is incessant by day and night, and now has caused much muscular pain. She can not sleep and has lost her appetite. Physical examination reveals a large number of dry and coarse mucous râles over both lungs. She was directed to take two teaspoonsfuls of cocillaña every six hours.

**15th.**—The cough is diminished in frequency and much looser, and the appetite has improved.

**25th.**—For four days past she has had no medicine and the cough has returned, but not so severely as at its first visit.

In comparing these cases with a similar series treated with apomorphine, it can be said that apomorphine acts more upon the blood-vessels, cocillaña more upon the glands; hence the secretion produced by the latter is more mucoid. So, again, in cases seen before forty-eight hours of the disease have elapsed, apomorphine will relieve more quickly, but in cases seen for the first time at a late period cocillaña should be preferred. While watery secretion is not established usually under three to six hours from the first dose, in place of the half to one hour after apomorphine, yet the effect of a single dose will last at least three times as long as after the use of the latter drug. Consequently the intervals at which cocillaña is given can be prolonged, or expectoration can be quickly established by apomorphine and continued by cocillaña. The rhythm of the respiratory act is affected only so far as freer expectoration lowers the respiratory rate. That the expectorant effect of cocillaña is not the first stage of nausea is shown by the fact that an increase of appetite is usually observed even under the administration of full physiological doses, and under them indeed the fullness of the pulse is not changed.

**CASES OF CHRONIC BRONCHITIS.**—In addition to the cases

recorded below, in seven others the patients came complaining of a dry, ineffectual cough, which was doubtless relieved, since they did not return for further treatment.

**CASE I.—November 11th.**—Mrs. L., twenty-five years old, has had a dry, hacking cough for two months, especially in the morning, which causes vomiting and pain in the head and chest. Physical examination reveals a large number of dry râles with very few moist ones. Respiration harsh and exaggerated. No change in resonance, fremitus, or percussion note. Is to take two teaspoonfuls of cocillaña every six hours.

**15th.**—Can only find a few moist râles. Vocal resonance and percussion note normal. Has experienced great relief.

**CASE II.—November 18th.**—F. N., twenty-nine years old. Two years ago suffered from a severe attack of acute bronchitis which lasted for two months, and in which expectoration could not be established by apomorphine, ipecac, lobelia, or any other of the so-called expectorants. For the last week has had a severe cough with wheezing, no expectoration, loss of sleep and rest, with pain in the epigastric region. Physical examination shows slight dullness and distant respiration at the right apex, whispering bronchophony and high-pitched inspiration, increased vocal resonance at both apices to the third rib. Respiration is jerky. Many fine, dry râles, with some mucous râles. Ordered to take two teaspoonfuls of cocillaña every four hours.

**22d.**—Reports great improvement in the amount and character of the cough. Physical signs of infiltration and exudative pleuritis of the right apex remain.

**December 13th.**—Reports that cocillaña gives him entire relief from the paroxysms of cough.

It is probable that in subacute and chronic dry bronchitis we find the larger field for the use of cocillaña. The facts are that its expectorant effect is surer than that of either apomorphine or ipecacuanha in liquefying bronchial mucus; that it increases the appetite, not because the drug itself acts like a simple bitter or its menstruum (alcohol) irritates the stomach, for the fluid extract is equally reliable in that direction; and that the drug is a laxative, perhaps by stimulation of the intestinal muciparous glands. Further, the expectoration is not so much influenced by warm diluent drinks as that of apomorphine, ipecacuanha, or carbonate of ammonium is, although cocillaña itself will produce a slight perspiration. In chronic bronchitis with viscid expectoration cocillaña will render the sputum liquid somewhat more surely than ipecac, and it has the further advantage of not causing nausea. At times also the formation of mucus seems to be checked.

On the other hand, in cases of senile bronchitis, particularly in cases of calcified costal cartilages, it may so markedly add to the bronchorrhœa that it becomes absolutely dangerous, and particularly because it is not a stimulant to the respiratory center, like belladonna and strychnine. In these cases, then, it is useful only so far as it liquefies secretion. It is in these cases, and particularly those with dilated right heart, that we find strychnine and carbonate of ammonium so useful. Cocillaña is not an antiseptic any more than ipecacuanha, so in cases of foul expectoration neither drug is a complete remedy.

**CASES OF CHRONIC DISEASE OF PULMONARY TISSUES.—CASE I.—November 15th.**—Mrs. G., thirty-four years old, has suffered from cough, with slight morning expectoration and loss of flesh and appetite, for six months. Physical examination shows a

chest contracted in the antero-posterior diameter, dull to the bottom of the second rib at both apices, over which area there is increased vocal resonance, with whispering bronchophony, harsh, prolonged inspiration, and many crepitant râles. The cough is teasing and prevents sleep. Ordered a teaspoonful of cocillaña to be administered every three hours.

**20th.**—Reports improvement in the cough and appetite. Physical signs unchanged.

**CASE II.—May 27th.**—Miss M. D., single, twenty-one years old. Has been ill for three months. She complains of pain in the left side, and cough, which was dry until recently, especially on sitting up. No expectoration except in the morning. Is losing flesh, has a poor appetite, with regular bowels, but occasional headaches. At the right apex there are sibilant and sonorous râles, also over the upper chest to the fourth rib, with roughened, high-pitched respiration. Over the left apex there is roughened inspiration with fewer râles, vocal resonance increased over the right area, in which there is marked dullness, with no increase on the left side. Pain in the left axillary region. Directed to take two drachms of cocillaña three times daily.

**June 10th.**—Expectoration quite profuse, coughing less, but she feels weak on rising, sometimes nauseated. The dry râles have now disappeared, but we find abundant coarse and fine râles, especially on the right side. The acute exacerbation is apparently relieved.

**November 11th.**—Reports great improvement. The medicine will relieve the teasing cough, changing it into one which is less frequent and which yields frothy expectoration.

**CASE III.—July 3d.**—P. M. K., twenty years old, has had night-sweats for five months, with loss of flesh, but until within two weeks has had no noticeable cough. Complains of lassitude and anorexia. For the last two weeks has had a cough which does not produce expectoration save in the morning, when it is muco-purulent. He is very anaemic. At the right apex, extending to the third rib, there are dullness, normal fremitus, and increased vocal resonance. Quality of respiration not markedly changed. Subcrepitant râles at the right apex. Elsewhere large mucous râles. Temperature, 101° F. at 3 p. m.; pulse, 120. He was ordered to take half a drachm of cocillaña three times daily.

**8th.**—Cough loose and less frequent; appetite better and night-sweating markedly diminished.

**24th.**—Appetite is now good. Expectoration markedly increased. No cough. Bowels regular.

**CASE IV.—November 11th.**—Mrs. K., thirty-seven years old, has suffered from asthmatic attacks, dyspnœa on exertion, and cough with tenacious expectoration for a year. The physical signs are dullness at the right apex, extending downward as far as the third rib; high-pitched, prolonged inspiration and expiration; increased vocal resonance. A few coarse and many fine râles. Is to take a teaspoonful of cocillaña every two hours.

**13th.**—Reports considerable relief. Physical examination shows a cavity emptied of pus, the signs being a vesiculotympanic percussion-note over the former area of dullness, amphoric respiration, bronchophony, and coarse mucous râles. The dyspnœa has disappeared with the rapid expectoration of a large amount of pus. The asthma has remained absent.

In these cases cocillaña has almost its only use in liquefying secretion and relieving the acute exacerbations of associated chronic bronchitis. Under its use the cough and expectoration diminish, and the night-sweats, inappetence, and constipation are relieved. In general, for the reasons given above in discussing chronic bronchitis, cocilla-

ña is preferable to ipecacuanha. Naturally, when cough is due to pleuritic exudation or is laryngeal or pharyngeal, cocillaña will fail, as will all the other expectorants. In the latter instances, I doubt if local applications of cocillaña would be effectual.

I believe cocillaña to be superior to apomorphine except in the cases of acute bronchitis when taken within the first forty-eight hours. It is certainly preferable to ipecacuanha in that it does not so readily cause nausea and a metallic taste in the mouth, and assists the regular movement of the bowels. It must yield to carbonate of ammonium in chronic senile bronchitis, although the heart beat and the pulse become stronger under its use, and it can not stimulate the respiratory center as strychnine does. It is immeasurably safer in any stage of acute bronchitis than pilocarpine, because it does not depress the heart's action.

In conclusion, I believe that it can fully replace ipecacuanha, which is now becoming expensive from exhaustion of the supply, in every sphere of action, and in many cases can be substituted with advantage for apomorphine, carbonate of ammonium, strychnine, and other drugs classed with more or less reason as expectorants.

690 MADISON AVENUE, December 14, 1889.

THE RELATIONS OF THE SO-CALLED  
"CHRISTIAN SCIENCE CURE" AND "FAITH CURE"  
TO PUBLIC HEALTH AND BOARDS OF HEALTH, AND TO  
THE MEDICAL PROFESSION.\*

By J. C. BIERWIRTH, M. D.,  
BROOKLYN.

THE advocates of Christian science cure and of faith cure have existed in all ages and in all countries, and have belonged to all religions. Being the children of superstition, they have kept pace with their parent, and their number has become less as the world has become more and more enlightened. But yet from time to time they seem to increase in strength and numbers, and the daily papers relate the wondrous cures achieved in apparently hopeless cases. Some one of a highly emotional nature imagines himself to have been "cured" by the agency of prayer, and he loudly proclaims the result. This draws others, for the number of real or supposed chronic sufferers is large at all times, and, if then some further "cures" are effected, the sect flourishes for a time, until either the interest dies out or some one "cured" by prayer dies of the original malady. At times also these Christian scientists are made the dupes of some plausible scoundrel, who coins money from their superstitions by the aid of "magnetism," mesmerism, or anything else which tends toward a concentration of the mind. When the fraud is discovered we hear no more of faith-healers for a while.

Within the last ten years the daily papers have contained more recitals than usual of miraculous cures by the aid of prayer, anointing, or laying on of hands. In a few instances, where a fatal result followed, the authorities have

stepped in and investigated the circumstances, but I am not aware of any conviction or punishment inflicted.

It is somewhat difficult to define accurately the exact position of these people, but for the purpose of this paper it will suffice to state that they do not believe in physicians and their medicines, relying in case of illness upon faith in the efficacy of prayer to bring about a cure. The different sects and societies vary a good deal with regard to the sincerity of their belief and the degree to which they adhere to it. Some only invoke divine help when there is no danger to life, but they will send for a doctor as soon as there seems to be a real or supposed danger approaching. Others, however, are more consistent. They will refuse medical aid and medicines under all circumstances, preferring death to any help which medical skill might afford them. Their only guide is the Bible, and their only relief from suffering must come through prayer.

Recently, in my official capacity as physician to the Brooklyn Society for the Prevention of Cruelty to Children, I have come in contact with members of a sect of "faith-healers" calling themselves New Evangelists, who hold their meetings on Hamilton Avenue. They are mostly Scandinavians, all belong to the laboring classes, and are of less than average intelligence. Their faith is a most simple one, but in sincerity and strength they rival the religious fanatics of past ages. They do not believe in ministers of the Gospel, nor do they have any leaders. Their meetings are conducted much after the manner of Quakers—i. e., any one who has a communication to make gets up and speaks. They also unite in common prayer and singing. For information on everything they turn to the Bible, whose teachings they interpret to the best of their ability and understanding. They do not believe in medicines and physicians, and positively refuse medical aid. The reason which they assign for this refusal is that all disease is sent by God either as punishment or trial, and it would be a sin to interfere with His will by any attempt to relieve the suffering or cure the illness. If the person afflicted dies they say it was God's will, and should recovery ensue, this again will be regarded as a manifestation of divine Providence. They believe in caring for the sick by looking after their bodily welfare and by keeping them properly fed and clean. Among their number there are a few nurses who go out among the sick and attend them, and who profess to have had experience in hospitals here and at home. For these services they expect no pay, but they receive food and clothing from their "brothers and sisters in Christ." The members of this sect also do not believe in holding property or keeping any money beyond that which they need for their daily wants. All their possessions go into a general fund, out of which all expenses for the society are paid and the poor and sick assisted. One of their number, before he became a member, bought two city lots, on which he paid one hundred and fifty dollars—all his savings. After he joined, as he could no longer consistently hold property, he wished the real-estate agent to take back the land and refund the money; the latter refused to grant his request, and he then told him to keep both the land and the money.

I am of the opinion that these people are entirely sin-

\* Read before the Kings County Medical Association, December 13, 1889.

cere and honest in their belief, but I am equally certain that their practices endanger public health and public morals, as will be seen from the histories of the following two cases:

CASE I.—On November 29th the Superintendent of the Brooklyn Society for the Prevention of Cruelty to Children consulted me in regard to a case reported to him by the Board of Health, the facts in regard to which were as follows: On November 27th Dr. Prendergast, of Clinton Street, was called upon by O. E. Larsen, of 43 Woodhull Street, to see his child, who had been ill with a sore throat for a week. The doctor went as requested, and found a little girl four years old suffering from diphtheria. He prescribed for the patient, and returned the next morning to find the child much worse in every way. Upon asking whether the medicines ordered had been properly administered, the father informed him that "it was no use to give the child any medicine; she was God's child and in His hands; that if He intended her to recover she would get well without medicine, and if she should die it was His will." He then refused to send for the medicine or administer it. The doctor thereupon left, telling Larsen he would have nothing further to do with the case, and reported it to the Board of Health. The authorities here told him that they had no jurisdiction in the matter and could not force medical attendance upon any one, but they would send word to the Society for the Prevention of Cruelty to Children.

At the request of the society I then went to the residence of Larsen, where I was informed by him that neither he nor his wife would give the child medicine, for the reasons stated to Dr. Prendergast. He furthermore told me that he had called in the latter only to comply with the regulations of the Board of Health, which provide that medical attendance shall have been given at least twenty-four hours before death in order to obtain a death certificate from the physician in charge, and not for the purpose of treating the child. He had no objection to my seeing the child, whom I found very ill indeed; the breathing was labored and stridulous, the voice reduced to a whisper, and the appearance of the little patient certainly alarming. It was evident that the membrane had extended to the larynx, which was not the case when Dr. Prendergast saw the patient the last time. I did not make any examination of the child's throat. The next morning I made inquiries at the Board of Health as to their power of interference, and was informed by the deputy commissioner, Dr. Young, that the department had no jurisdiction in the case. The same answer was obtained at the office of the Commissioners of Charities and Corrections. I next went to the office of the District Attorney, where I was informed that the offenders could be arrested and prosecuted under Sections 288 and 289 of the Penal Code, as had been suggested by the superintendent of the society. On the afternoon of this day, Saturday, November 29th, the father was arrested, but it was thought best to try and keep the mother at the house to look after her other child, an infant twenty months old. I then took forcible possession of the sick child, placing her in charge of two trained nurses, one for the day and one for the night, and assumed medical attendance myself. I prescribed the necessary medicines and instructed the nurses to report to the nearest police precinct any interference on the part of the mother or any one else. Upon my next visit later in the evening, I found that my orders had all been carried out, and had met with no opposition.

The following day I had the first chance to thoroughly examine my little patient, and found a much graver condition of affairs than I had at first supposed. Her tonsils, uvula, palate, both nostrils, and vault of the pharynx were covered with membrane, the breathing was very labored and stridulous, the whole chest and abdomen heaving in the effort to get sufficient air, and

the voice was almost entirely lost, making it certain that the membrane had also invaded the larynx. In addition to the diphtheria I also found the child suffering from scarlet fever. Her temperature was 103.5° F.; pulse 138, intermittent and very weak; respirations 58. The mother told me that the patient had received but very little nourishment in the past week—not more than about eight ounces of milk in twenty-four hours, and nothing else; it had been impossible to give her more, because it hurt her so much to swallow. On the second day of my attendance I examined the urine, and found the kidneys also involved. The improvement of the child was evident after the first twenty-four hours of treatment, and, I am happy to say, has continued uninterruptedly up to the present writing. All evidences of diphtheria have disappeared, the temperature and pulse are normal, the condition of the kidneys is steadily improving, and, barring accidents and complications, I think she will make a good recovery from the scarlet fever and the accompanying kidney lesion.

On December 7th, a week after my first visit, the baby, a girl twenty months old, was also taken ill; temperature 102.5°, pulse 160. Upon examining the throat, I found her also suffering from diphtheria, and placed her at once under the care of the nurses without meeting with a protest from the mother. In this case the tonsils only are involved, and she is much improved to-day (December 12th); temperature 98.5°, pulse 120, and the membrane looks as if it would be shed in a day or two.

CASE II.—A man by the name of Jansen called at my office, Saturday, December 7th, and asked me to call and see his sick baby, who he thought was suffering from scarlet fever, telling me, however, that he did not believe in medicines. When I asked him if he would give the medicines prescribed, he said he would not, nor would his wife, who was also sick with a sore throat. He furthermore stated that he only called me in because I had charge of the cases at Larsen's, and in order to satisfy the regulations of the Health Board in regard to a death certificate in case this should be needed. I called his attention to the existing laws, which he was violating by refusing medical aid to his child, and pointed out the probable punishment in store for him. But, of course, this all had no influence upon him, and he gave the same answer to all my objections—namely, that he was in God's hands, who would take care of him.

I then reported the case to the society and proceeded to the man's house in company with an officer of the society. I found a child, six months old, suffering from scarlet fever, and also from a purulent eruption of the face and scalp. The mother, who submitted to an examination of her throat willingly, was suffering from diphtheria. Nursing these two patients were two women of the same sect, one of whom I had found in charge of the first case. She had been in the family of Jansen for a week, going there directly from Larsen's when I sent her away. It was on the seventh day after her arrival at Jansen's that the disease broke out there, the regular period of incubation in scarlet fever, and there is no doubt in my mind that she conveyed the disease from one to the other. It seemed to me that something should be done to destroy this source of infection, as the nurse might continue to spread the contagion among a large number of people, and with this view I called again upon the health authorities.

I stated my case to Dr. J. Griffin, the commissioner, who told me that I had been misinformed at my former visit, and that the Board of Health had the power to interfere in these cases on the ground that the public health was endangered. I expressed it as my opinion that both mother and child were in a condition to be transferred to the County Hospital at Flatbush, and requested him to do so if it met with his approval. He entirely coincided with my views, and promised to send an

inspector to the place at once, with instructions to remove the patients to Flatbush in case he found the conditions as represented by me, and the husband and wife still persisting in their refusal to accept medical aid. The inspector corroborated my statements, and removed both patients to the hospital late in the evening. He also placed the floor where the cases occurred under quarantine, and forbade Jansen and the two nurses to leave the house until the quarantine was raised. The next morning these three disobeyed this order by going to their place of meeting, which was crowded with adults and children, and consequently were arrested on the charge of endangering the public health.

These cases are of interest chiefly from their medico-legal aspect. The sections of the Penal Code under which the offenders will be prosecuted are as follows:

**SECTION 288.** A person who willfully omits, without lawful excuse, to perform a duty by law imposed upon him, to furnish food, clothing, shelter, or medical attendance to a minor, is guilty of a misdemeanor.

**SEC. 289.** A person who, having the custody of a minor, either—

1. Willfully causes or permits the minor's life to be endangered, or its health to be injured, or its morals to become depraved; or—

2. Willfully causes or permits the minor to be placed in such an occupation that its life is endangered, or its health is likely to be injured, or its morals likely to be impaired;

Is guilty of a misdemeanor.

**SEC. 675.** A person who willfully and wrongfully commits any act which seriously injures the person or property of another, or which seriously disturbs or endangers the public peace or health, or which openly outrages public decency, for which no other punishment is expressly prescribed by this code, is guilty of a misdemeanor.

Among the city ordinances relating to the Department of Health the following two sections are also applicable to the cases under consideration:

**SECTION 8.** That no person shall carelessly or negligently do, or advise, or contribute to the doing of any act or thing dangerous or detrimental to the health of any human being; nor shall any person knowingly do, or advise, or contribute to the doing of any such act or thing not actually authorized by law except with justifiable motives and for adequate reasons; nor shall any person omit to do any act, or to take any precaution reasonable and proper, to prevent or remove danger or detriment to the life or health of any human being.

**SEC. 140.** That no person shall within the built-up portions of the city, without the permit of this board, carry or remove from one building to another, or from any vessel to the shore, any person sick of any contagious disease. Nor shall any person, by any exposure of any individual sick of any contagious disease, or of the body of such person, or by any negligent act connected therewith, or in respect of the care or custody thereof, or by a needless exposure of himself, cause or contribute to or promote the spread of disease from any such person, or from any dead body.

Any one violating these sections of the Penal Code and of the city ordinances is guilty of a misdemeanor, the extreme penalty for which is imprisonment for one year and a fine of five hundred dollars.

In the event of a fatal termination resulting in the case of a child the parents are guilty of manslaughter. The

English courts in the case *Reg. vs. Downes*, 13 "Cox's Cr. Ca.," 111, held that "It is no answer to the charge of manslaughter that the parent so neglected from a conscientious religious belief that it was wrong to call in medical aid, and that medical aid was not required, and not from any intention to disobey the law."

From these quotations it will be seen that the provisions of the law are ample to reach at least some of the wrongdoings of these religious fanatics. In every case where a child is concerned, the Sections 288 and 289 are sufficient to bring the offenders within the reach of the law, and when the case is one of a contagious disease in either a child or an adult the boards of health of this State have the power to interfere and compel medical care and attendance. If all the cases belonging to these two classes, which may come to any one's notice, are reported to the proper authorities, the believers in faith and prayer as a panacea for all ails will receive a wholesome check. I believe it is useless to attempt a reform in the present adherents to the faith cure; they are deaf to all reason and logic, and will continue to be guided only by their superstitions. But the legal interference in their practices and a few severe punishments will frighten off new-comers, and thus we may hope to prevent an increase in their number. Those who may be punished will be strengthened in their belief and regard themselves as martyrs of their cause, as were Christ and His apostles, whose lives these fatalists try to emulate. As I stated before, I believe they are honest and sincere in their belief. Most of them are kind and peaceful, and it may seem that the punishments for their offenses are harsh and too severe. But, as they refuse to be taught, they must be treated as children and punished when they do wrong. The penalties inflicted can not be considered too severe when we regard for a moment the seriousness of their offense. Their practices create hot-beds for two of the most dangerous and fatal diseases of childhood, and add to the already too large number of cases of contagious diseases which are constantly occurring among the poorer classes and which are never attended by a physician. Many of the poorer people never think of sending for a physician in a case of measles or of sore throat (diphtheria), and not even in a case of scarlet fever; and I think in this fact is found, to a great extent, the explanation of the large number of cases of these diseases annually occurring. The members of families in which cases of contagious diseases exist mingle in the course of the day with a large number of people, both at school, in public conveyances, and in their crowded tenements, and thus they may produce a large number of new cases.

The cases cited here have pointed significantly to the good work that is being done by the societies for the prevention of cruelty to children. Had it not been for the existence of our local society, these cases would have passed unnoticed, as has been shown by the difficulties experienced to find the proper authorities who would take action in the matter. The chief trouble was that no precedent existed, but now that this has been established, future cases, if discovered, will encounter no difficulties.

From this recital it appears that medical men will

be called in only to furnish death certificates, when these seem likely to be needed, and it will be only in this way that cases will come to public notice. I would suggest to the members of this association to disseminate widely the facts presented in this communication, and to report to the proper authorities any cases which may come to their notice. They will thus not only promote public health, but aid greatly in preventing the spread of harmful superstitions and fanatical beliefs.

NOTE.—Since the reading of this paper the cases have come up for trial before Police Justice J. G. Tighe, who found all the defendants guilty, and imposed the following sentences: Larsen, to pay a fine of \$500 or stand committed one day for each dollar; Jansen, \$200 fine or imprisonment; Maria Peterson, \$100 fine or imprisonment; Anna Jensen (the nurse who was first at Larsen's), \$150 fine or imprisonment.

## A CASE OF ACTINOMYCOSIS IN MAN.\*

BY J. M. BYRON, M. D.,

DIRECTORY OF THE BACTERIOLOGICAL LABORATORY OF THE  
UNIVERSITY OF THE CITY OF NEW YORK.

THE case which I present to the society to-day is one of actinomycosis in man. I am unable to relate a complete history of it, for I understood its importance rather late. When I first saw the patient my diagnosis was different from that made later—after I had examined the pus and found the characteristic fungus—the *Actinomyces bovis*.

This disease is not so rare as was once supposed. If relatively few cases have been observed, it is principally due to the difficulty of diagnosis and a symptomatology that makes it resemble a great deal other diseases, principally peripleuritis and empyema.

The *Actinomyces bovis* was first described by Böllinger, in 1876, who described it as the cause of a special disease in the bovine species. Israel, in 1878, found it in man. After Israel, Bizzozero, of Italy, made a very accurate study of the disease, and in a very short time had the opportunity of observing thirteen cases.

The fungus was successfully cultivated for the first time by Oscar Israel, in coagulated blood serum, and afterward by others and by myself in different media—such as potatoes, sweet agar-agar, etc. The growth is very slow, and from four to seven weeks elapse before any noticeable portion of it can be seen. The best temperature is about 37° C. It forms on potatoes small, round lumps, of a yellowish-white color, resembling very much colonies of tubercle bacilli on the same media. It is inoculable, and the animals inoculated are fatally attacked by the disease.

The lesions produced by the actinomycetes vary a great deal, from the production of pus to the formation of a neoplasm; but all of them bear a striking resemblance to those of tuberculosis.

The symptomatology is variable, according to localization. It may produce exactly the same lesions and symptoms of an ordinary tuberculosis of the lung as a prevertebral abscess, an empyema, or a cold abscess, etc. In all cases a careful microscopical examination of the products

offers the only means of formulating a correct diagnosis and directing a proper treatment.

The patient whose case is presented in this paper came to me about the last days of last June, complaining of a pain in his right side. He was a young man of twenty-eight, strong, and had always been healthy. No family history either of syphilis or of any other diathetic condition. About a month before coming to me he had chills and after-fever, symptoms that have ever since continued. On percussion I found a limited dullness extending for about four inches square, from the fifth to the seventh rib, between the anterior and the posterior axillary lines. There was no deformity of the chest. Auscultation showed diminished vesicular murmur, a few very fine râles, and a pleuritic friction. My diagnosis was that of lobular pneumonia and pleurisy. I ordered him to bed, and gave him some stimulants. I did not hear from him for more than two weeks, when I found his condition worse. In the place of dullness I could see now the intercostal spaces rather prominent and oedematous. I made a puncture and obtained pus. When the patient heard that an operation had to be performed in order to extract the pus, he refused and went away for another fortnight, to return again. He had been to several other physicians, who pronounced it a case of empyema. Examining the pus which I extracted with an aspirator, my suspicions were awakened by its peculiar appearance; it contained very minute lumps, like grains of sand, which made me immediately think it a case of actinomycosis or, better, a case of *peripleuritis actinomycotica*, and the microscope confirmed my suspicions. The pus contained millions of the fungi. The treatment had to be changed accordingly. I proposed an operation, which was permitted, and performed on the 23d or 24th of July last. I extracted a piece of the seventh rib, and then scraped and drained the cavity; but, notwithstanding this, the suppuration continued, and the man, fearing his end was near, sailed to his native country, hoping to find there better opportunities of recovery.

As I stated when beginning, this is not a complete clinical history of such an important case, but I confess it was due to my mistake in diagnosis. Had I examined the pus at first, as I usually do in every case that comes under treatment, I should have to-day the pleasure of submitting to you something worth your attention.

Actinomycosis is a new disease and is an infectious disease, the symptoms of which are, as I have stated, similar to those of other diseases, and probably a great many cases of it pass under other names.

When localized it is not difficult to treat it with success, but if the internal organs are invaded by the germs it is as fatal as tuberculosis. The only way to avoid its spreading is to destroy all animals that are diseased. An examination of the slaughter-houses by intelligent men, who will report every case of actinomycosis in the cattle, is absolutely necessary in this and other diseases that seem to have been transferred to man from the lower animals.

**Transmission of Disease by Brushes and Dental Instruments.**—“A discussion recently took place at the Conseil d'hygiène concerning the transmission of certain diseases by hair-dressers and dentists, the brushes and instruments being used in common for all their clients. M. Lancereaux wished to have stringent measures enforced, and cited a case of phthisis which Dr. Cochrane, an American dentist, alleged was transmitted by a dentist's instrument. M. Dujardin-Beaumetz and others declared that there were great difficulties in the way, but recommended great care in schools and public institutions.”—*Brit. Med. Jour.*

FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, DECEMBER 28, 1889.

ELECTRIC CATAPORESIS AS A THERAPEUTIC MEASURE.

In an article with this title published in our issue for April 27, 1889, one of our contributors, Dr. Frederick Peterson, described some of the results obtained by him in the use of cocaine, aconitine, chloroform, and helleborin, in varying solutions, with the galvanic anode. His experiments demonstrated the value of the cataphoretic method for the production of local anesthesia and for the relief of pain in neuralgias of the superficial nerves. He suggested its employment with other drugs, such as iodine, whenever it was desirable to use them topically, or where they were to be introduced into the system for general purposes.

The growing recognition of this method is illustrated by two recent contributions to the literature of the subject. One is a preliminary report made by Dr. Gärtnér and Dr. Ehrmann to the Imperial-Royal Society of Physicians of Vienna, on November 22, 1889 ("Wiener med. Blätter," Nov. 28, 1889), upon the cataphoretic use of corrosive sublimate. An electric bathtub with two compartments, invented by Dr. Gärtnér, was employed for the purpose. From four to six grammes of corrosive sublimate were dissolved in the water of the bath and a current of 100 milliamperes was passed through the person experimented upon for from fifteen to twenty minutes. The urine of the patient was examined both before and after the bath. It was shown that, while previously entirely free from mercury, the urine subsequently contained this metal in as large a quantity as 1.3 milligramme, and, furthermore, that the mercury was to be detected for even so long as from four to six days after the bath. The authors expect good results on the grounds that it is an efficacious method of cutaneous mercurial medication, that the receptive surface presented to the drug is much larger than by any other means, that mercury may thus be made to influence localized morbid foci, and that exact dosage is possible, since the introduction of the medicament is in exact proportion to the current strength and duration of contact.

At a meeting of the Harveian Society in London, on November 7, 1889 ("Brit. Med. Journal," Nov. 16, 1889), Dr. Cagney read a paper on the administration of certain drugs by electricity. He had made use of iodide of potassium in this way for the treatment of labyrinthine deafness and lead palsy. He speaks of the method as best adapted to the treatment of local disease of the skin and mucous membranes and subjacent tissues, and believes that iodine and the potassic iodide will be of particular value employed in this way. Cataphoresis had proved useful in syphilitic and other affections of the throat, and especially in chronic pharyngitis.

This method, therefore, seems to present many advantages

in the way of medication, and is perhaps destined to take a very important position in the therapeutic procedures of the future. It opens a way not otherwise attainable for influencing tissue metabolism and for changing morbid nutritive processes by sending the drugs into direct and immediate contact with diseased parts through a force which in itself must greatly enhance their active medicinal properties.

**MINOR PARAGRAPHS.**

THE PRESBYTERIAN HOSPITAL.

THE accident that lately happened to this institution, whereby one of its buildings was partly destroyed by fire, seems likely to prove a blessing in disguise, for it is bringing before the public the resources and energy of the governing body, and it has demonstrated the intrepidity of the gentlemen of the house staff as well as their humanity and faithfulness to duty. When a citizen arrived in haste, under the supposition that he was the first to acquaint the house officers with the fact that a fire was in progress, he found them engaged in providing for the safety of the inmates, a task which, we are glad to be able to say, was accomplished without the slightest accident and with no approach to a panic. The very sensible course pursued by the medical house officers has met with due appreciation on the part of the governing body, and they, for their own part, have shown such energy that it was evident some days ago that comfortable quarters in the institution would be ready for a great number of patients by Thursday of this week. In short, the excellent management of the hospital has been made so manifest to the community that certain important additions in the way of new buildings are sure to be accomplished more speedily than they might have been without the occurrence of the fire, for it has been the means of bringing in notable additions to the funds.

THE VAGINAL SPECULUM AMONG THE ANCIENTS.

ACCORDING to the "British Medical Journal," Dr. Ali Cohen describes a passage in the Talmudic treatise called the Niddah, in which the physician is instructed to introduce a "siphopheroth" when in doubt whether a haemorrhage is from the uterus or from the vagina. It is said that, on passing in a "mechnl" (long wooden rod) covered with "mouch" (a preparation like charpie), the latter will be covered with blood if the haemorrhage is uterine. The "siphopheroth" was a leaden cone, its orifice bent inward, in order not to wound the vagina. The name of the instrument is manifestly of Greek origin, but the evidence is inconclusive that it was actually employed to inspect the cervix.

RICORD'S MEMOIRS.

THE memoirs of Ricord's life and professional career are said to have been left in a good state of preparation for the printer. They will bear the striking title of "The Nineteenth Century seen with the Speculum."

"ACCIDENTAL DEATH" BY FOOTBALL.

THE "British Medical Journal" insists that new rules should be framed for the game of football. In the "Journal" for December 7th the death of a theological student from fracture of the spine is recorded as consequent upon a scrimmage in that game, and it is stated that a coroner's jury returned a verdict of "accidental death." About the same time a man had his leg

broken and was otherwise injured in the course of regular play. He escaped an "accidental death," but he has probably played his last game. The reports of football matches in England are continually affording fresh evidence that the existing rules of play must be amended.

#### "JUMPERS" IN SOUTH AFRICA.

DR. BENNETT, of Griqualand, writes to the "South African Journal" that a nervous affection is met with among the natives closely resembling that which the late Dr. G. M. Beard described as observed among the French Canadians who are known as "jumpers." The involuntary activity in the African victims to this affection is incited by the sharp word of command or sudden exclamation by some one near at hand, very much as in the case of those among the Canadians. All the cases observed by Dr. Bennett were in males.

#### SEXUAL DEBAUCHERY AND SEXUAL PERVERSION.

AN esteemed correspondent, who desires that his name should not be mentioned in the matter, expresses his appreciation of Dr. Holder's article on "The Bote," lately published by us, but points out the injustice of including sexual perverts with sexual debauchees, for the former are born with defects that impel them to repulsive practices, while the latter adopt them deliberately. Our correspondent expects to be able some time to publish some autobiographical notes by a pervert whom he describes as "a cultivated gentleman," and he thinks they will be of much literary and professional interest.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending December 24, 1889:

DISEASES.	Week ending Dec. 17.		Week ending Dec. 24.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	21	5	14	2
Scarlet fever.....	71	5	57	6
Cerebro-spinal meningitis....	1	1	0	0
Measles.....	70	2	43	6
Diphtheria.....	109	30	99	16
Varicella.....	1	0	8	0
Influenza .....	0	0	7	0

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 15 to December 21, 1889.*

ALEXANDER, CHARLES T., Lieutenant-Colonel and Surgeon, will be relieved from duty as medical director, Department of the Columbia, on receipt of this order at the headquarters of that department, by direction of the Secretary of War, and will report in person to the commanding general, Division of the Atlantic, for the purpose of preparing for and becoming familiar with the duties of attending surgeon in New York city. He will also, upon his arrival in New York, assume the duties of examiner of recruits in that city.

WATERS, WILLIAM E., Major and Surgeon, will take temporary charge of the office of medical director, Department of the Columbia, upon the relief of Lieutenant-Colonel Alexander, and perform the duties pertaining thereto. S. O. 291, A. G. O., Washington, December 14, 1889.

MACAULEY, C. N. B., Captain and Assistant Surgeon. With the approval of the Secretary of War, the leave of absence granted in S. O. 166, November 8th, Department of the Missouri, is extended one month. Par. 10, S. O. 294, A. G. O., December 18, 1889.

ROBINSON, SAMUEL Q., Captain and Assistant Surgeon (Fort Hamilton, New York Harbor), will proceed without delay to Fort Warren, Massachusetts, and report to the post commander for temporary duty. Par. 5, S. O. 289, Division of the Atlantic, December 18, 1889.

MCCREERY, GEORGE, Captain and Assistant Surgeon (Fort Warren, Massachusetts), is granted leave of absence for one month, to take effect upon the arrival at that post for temporary duty of Captain Samuel Q. Robinson, Assistant Surgeon. Par. 6, S. O. 289, Division of the Atlantic, December 18, 1889.

BALL, R. R., First Lieutenant and Assistant Surgeon, is relieved from temporary duty at Fort Sill, Indian Territory, and will return to his proper station, Fort Riley, Kansas. S. O. 182, Head-quarters Department of the Missouri, Fort Leavenworth, Kansas, December 12, 1889.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending December 21, 1889:*

KITE, J. W., Assistant Surgeon. Promoted to be a passed assistant surgeon.

STONE, E. P., Assistant Surgeon. Promoted to be a passed assistant surgeon.

NORTON, O. D., Assistant Surgeon. Promoted to be a passed assistant surgeon.

HENRY, CHARLES P., Assistant Surgeon. Placed on the retired list.

PICKERELL, GEORGE MCC., Assistant Surgeon. Ordered to Navy Yard, Washington, D. C., for temporary duty.

## Letters to the Editor.

#### A SWINDLER.

230 WEST 135TH STREET, NEW YORK, December 20, 1889.

To the Editor of the New York Medical Journal:

SIR: It may be of service to some of the profession if you would print a notice warning them of the rascal who visited my office to-day. Pretending to represent his brother, who he said was a patient of mine whom I had advised to go south, he requested a receipt and tendered a check for \$35, the supposed bill amounting to \$20. Now, he had evidently posted himself in regard to some of my affairs, and watched the house to be sure of my absence, when the only members of the family in were females. I learned afterward that he had been seen loitering around during the early part of the day. Having only ladies to deal with, and pretending to be very anxious to settle the bill before they left the city, he very nearly accomplished his purpose. He is tall, thin, middle-aged; hair very dark and very slightly tinged with gray, and thin almost to baldness on the top of the head; face long and thin; eyes black; a grayish mustache, whiskers, and beard which is parted in the middle and brushed to either side; wore a pepper-and salt business suit, no overcoat, and a black Derby hat.

H. SCHROEDER, M. D.

#### POISONING BY ILLUMINATING GAS.

1519 JOHN STREET, BALTIMORE, December 17, 1889.

To the Editor of the New York Medical Journal:

SIR: I scarcely know whether to notice the obscure imputations in the article on "Poisoning by Illuminating Gas," by a Dr. Crossland, in your issue of the 14th inst., or to let them pass.

The doctor speaks of "false impressions contained in Dr. Klobman's article," the meaning of which I am too obtuse to decipher. A writer may want to create false impressions, but how they can be "contained in an article" is too much for me. Again, the doctor accepts my statement in regard to the percentage of carbon monoxide in one paragraph, and in the very next says the "comparative amounts do not seem in accord." Nor does he define his meaning of these, to me, obscure observations. However, the doctor agrees with my idea that treatment by nitroglycerin is "the remedy par excellence." The idea just now occurs to me that perhaps the doctor may wish to state that I was not the first person to suggest or use this treatment. This may be so, but, if so, I am unaware who mentioned or used it earlier, and shall be very glad to be informed. The doctor seems to have had a very unreliable preparation of nitroglycerin on hand, judging by the effect. Tablets for hypodermic use are far more reliable than solutions.

WILLIAM C. KLOMAN, M. D.

## Proceedings of Societies.

### NEW YORK ACADEMY OF MEDICINE.

#### SECTION IN LARYNGOLOGY AND RHINOLOGY.

*Meeting of November 26, 1889.*

Dr. CLARENCE C. RICE in the Chair.

**A Laryngeal Growth.**—Dr. J. H. BILLINGS referred to the case of laryngeal growth presented at the previous meeting. The patient, three days afterward, had been taken to the hospital. It would be remembered that much uncertainty had surrounded the case and a diagnosis had been withheld pending treatment for an assumed specific origin to the growth. It would also be recollected that the growth had already threatened the patient's life. At the hospital he had been put upon large doses of iodide of potassium. The stenosis had become so great that tracheotomy was resorted to. After the tube was inserted the iodide was vigorously pushed. The neoplasm had then begun to get smaller and the patient was again present, so that those who had examined him previously might observe the result of the specific treatment.

**Papilloma of the Vocal Cord.**—Dr. S. SHERWELL, of Brooklyn, cited the case of a young girl with papilloma of the left vocal cord. She had been put under treatment which had proved more or less ineffective. The tumor had commenced to grow larger. Spasm had occurred now and then. Treatment by insufflation of salicylic acid and sugar of milk, though it did not reduce the bulk of the tumor, had seemed to render it softer. Another physician, who was attending to the above-named treatment, had happened one day last week to pass a closed forceps into the throat. Spasm had immediately resulted with the apparent effect of drawing the tumor down until suffocation became imminent. The speaker was hurriedly summoned and had found the child *in articulo mortis*. Though no time was lost in making an incision into the trachea, the patient was to all intents and purposes dead. Ten minutes elapsed after the tube was inserted before any perceptible breathing occurred. A few days later thyrectomy was performed and the tumor removed. In bulk it was about one cubic inch. The patient had so far progressed nicely. Her vocal cords were open and there was a good lumen, with a fairly hoarse whisper. He had not removed the tracheotomy tube, but had withdrawn the inner tube to allow all the ingress of air possible.

**A New Inhaling Apparatus.**—Dr. J. W. GLEITSMANN demonstrated the working of a new inhaling apparatus, invented by Dr. Jahr, of Europe. The apparatus had been used during the past year in Bavaria. The principal point made in favor of the contrivance was that its internal arrangements were such as would allow of the delivery of a spray or vapor at any desired temperature. It could also be used for medicated solutions and volatile substances, and dry or moist air.

Dr. B. ROBINSON said that the apparatus seemed to fill all possible requirements. His experience had led him to think that warm-air inhalations, though of undoubted advantage, should be used with extreme caution from the liability of the patients to suffer from subsequent atmospheric changes. He thought that the profession at large should be made aware of this danger, and patients, after receiving vapor inhalations, should be warned to be extremely careful.

Dr. J. M. W. KITCHEN said that he could corroborate what Dr. Robinson had said as to the danger following warm inhalations. He was in the habit of following these up immediately by cold water spray, and this obviated the difficulty and enabled patients to go out without danger from the atmospheric change.

**The Indiscriminate Use of Cocaine.**—Dr. H. HOLBROOK CURTIS read a paper on this subject. He said that the long-predicted reaction against cocaine had finally assumed definite proportions, and the journals were plentifully supplied with cases of cocaine habit and cocaine poisoning. Little stress had, however, been laid upon the more important question as to the responsibility involved in prescribing small doses of cocaine for acute coryzas and for the relief of conditions of nose and throat in which the discomfort was but slight and other remedies nearly as efficacious. Two years had elapsed since the writer had reported several cases of stoppage of the nostrils due to the continued use of a cocaine spray, and the consequent alteration of nasal function and nutrition. Such conditions, then a rarity, had been so frequently encountered of late that he was prompted to sound a note of warning to the profession in general and join in the hue and cry against a drug so insidious in its captivating allurements, so instantly relieving, but from whose bondage it was so difficult to become freed. The cocaine habit had already a full literature, but the number of cases in which poisonous symptoms had occurred from even minute doses would be surprising to many who had become over-confident in their estimation of the drug. In a paper read before the Ninth International Medical Congress, the writer believed that he was the first to recognize that the continued use of the drug by nasal atomization in very small quantity would produce a nasal stenosis and over-stimulation and contraction of the erectile plexus giving place eventually to permanent dilatation due to vaso-motor paresis. In this condition the nasal mucous membrane became dull-gray in color and presented an edematous appearance; or it might, on the other hand, retain its normal color, but become tumefied, no longer contracting even upon the application of cocaine crystals, suggesting a transition to true hypertrophy by increase of the connective-tissue elements at the expense of the vascular. This was the picture now constantly presented to the rhinologist. Besides this, the constitutional symptoms deserved also special consideration. As regarded dose, there existed the greatest difference as to individual susceptibility. Some patients became affected with giddiness, exhilaration, and loss of muscular co-ordination when less than a grain of the drug had been absorbed in the nasal cavities. Other patients might tolerate ten grains without a symptom other than local anesthesia. Toleration of the drug increased with use; one patient under the writer's observation had used three ounces of a ten-per-cent. solution daily, with results as

below stated. As to how little of the drug we might employ and not produce harmful results, he was unprepared to say. Many persons were advised by their physicians to employ a two-per-cent. solution of cocaine, perhaps with camphor-water, for the relief of an acute coryza, or to overcome the feeling of oppression caused by congested turbinated bodies. The effect was immediate, and the feeling of relief was attributed entirely to the free passage of air through the nose by reason of contraction of the erectile tissue. Unfortunately, this was but the smallest element of their satisfaction, for the increased mental activity, the elevation of spirits, the quickening of circulation, and general exhilaration were due directly to the effect of the drug itself, and a continuance of the custom would inevitably lead to the dire results that we were to-day becoming too well acquainted with. The profession could not become too quickly impressed with the fact that the indiscriminate use of cocaine among the laity threatened to introduce, and he might say already had introduced, a condition which might be designated as *cocaine heart*, the symptoms of which were a feeling of fullness in the praecordial region on rising in the morning, flashes of pain, and consciousness of the possession of a heart. This paræsthetic condition persisted almost constantly, but was accentuated directly after using the drug. Then followed in a short time palpitation and enfeebled action, the result of enervation of the sympathetic nervous system. Aside from this cardiac complication there were observed great restlessness and increasing prostration; the patient became pale, sallow, and mentally dejected; to remedy this condition the dose of the drug was increased, and alcohol and tobacco were usually indulged in to excess. This condition, together with the resulting nasal stenosis, generally brought the patient to the office of the specialist. He had encountered many such patients recently in whom the habit had been the outcome of using a spray of a weak cocaine solution to relieve an acute coryza or a passive hyperæmia of the nostrils. In the cases, some seventy of which had been collected as typical, he had endeavored to show the symptomatology, and more especially to demonstrate the peculiar susceptibility of certain individuals to poisonous effects from small doses of cocaine, as well as to cite instances of marked toleration of the drug. In a history of over five hundred cases in which he had used cocaine in the nasal cavities—an average of three grains left *in situ* on a pledget of absorbent cotton for ten minutes previous to operation—he had observed faintness in about one in five; but it was difficult to distinguish the cocaine symptoms from those of shock from the operative procedures. The speaker then cited a large number of cases in illustration of the theories he had advanced.

Dr. H. KOLLER, the discoverer of the anæsthetic properties of cocaine, who was present by invitation, was then asked if he would give the Section the benefit of any experience he might have had as to the possible dangers of the drug. He said that he had made it a rule never to give cocaine into the hands of patients, and indeed he never prescribed it, but always used it himself upon his patients. One did not, he said, give chloroform and ether to patients to be used by them indiscriminately, and why make cocaine an exception? Then, again, cocaine should, he thought, not be used in the nostrils in greater strength than a five-per-cent. solution. He knew he could produce with this just as useful effects as with a twenty-per-cent. solution—it was only a question of taking a little more time. The effect of the first application of a weak solution to the mucous membrane of the nose was a superficial anaesthesia, with contraction of the smaller blood-vessels. The circulation of the part became more or less limited and the blood was not carried away. By several subsequent applications of the same solution an effect was then produced exceeding that of a single applica-

tion of a twenty-per-cent. solution. He had found it advisable when making subcutaneous injections of the drug to discriminate between the strength of the solution used in the limbs and that employed upon other parts of the body, the latter calling for the weaker solution, for the avoidance of intoxicating effects. For making plastic or skin operations he never used a solution stronger than two per cent. As an instance of the deleterious effects of the persistent use of the drug he narrated the case of an eminent professional man in Vienna. This gentleman had become addicted to the use of morphine, and a friend of the speaker's had endeavored to break the habit by the administration of cocaine. One of the symptoms produced had been very marked. The patient had had the hallucination that all over his skin were pimples out of which little animals were creeping. This seemed the only mental disturbance produced, but no reasoning could shake the patient's conviction in this respect. In another case, treated heroically by the drug, the same symptom had been produced. The speaker contributed this experience, as he believed it might not be generally known.

Dr. M. J. ASCH said that his experience differed from that of Dr. CURTIS. While using the drug freely in a large outdoor clinic and in private practice he had seen but very few cases in which any bad effects had resulted from local applications, and these had been cases of nervons, hysterical women. He was in the habit of using a ten-per-cent. solution in treating the larynx and in endolaryngeal operations, and had found it perfectly harmless.

The CHAIRMAN said that his experience would substantiate the conclusions of Dr. ASCH rather than those of Dr. CURTIS. He used cocaine in a solution of about ten per cent. for the nose, putting in two or three pledgets of cotton wet with the solution, and allowing them to remain in the nostrils for ten or fifteen minutes. While he had never given the matter very careful attention, and had never questioned patients as to sensations produced about the limbs, head, or body, he certainly had never heard them complain. He had, however, seen it produce irritability of the nostrils. It caused a sort of vaso-motor paralysis, and set up a condition very much resembling hay fever.

Dr. ROBINSON thought that there was no evidence to show that cocaine exercised anything like a toxic influence when it was used locally. There might be some slight exhilaration for a short time after the cocaine spray. When it was given internally, however—for instance, as a cardiac stimulant—decided and durable effects were observable. The very weak solutions seemed in some instances to exercise a more poisonous effect than the strong ones.

After the question had elicited some general discussion, Dr. CURTIS remarked that he seemed to have been misunderstood by some of the speakers. He was an enthusiastic believer in the therapeutical properties of cocaine, and had a profound respect for its discoverer, to whom he felt in a manner personally indebted in that he had honored the meeting with his presence. All he wished to elucidate was that, indiscriminately used, the drug possessed properties which, if not fully recognized, might cause undesirable and deleterious results.

**Lupus Erythematosus of the Face and Oral Cavity.**—The history of a case was reported by Dr. GEORGE H. FOX, who said that it was one of considerable interest, and had been under observation for eighteen months. When the patient was first seen the condition was diagnosed as being eczematous in character, and was believed to be such for several months. But the surprising obstinacy of the eruption and the frequent occurrence of erysipelatous inflammation, with a dry, pitted appearance of the cheeks, had finally led to the conclusion that it was one of lupus erythematosus of the acute disseminate type. Upon sending recently for the patient, with a view to making a more

careful examination of the oral cavity, as the basis of a report upon the case, the speaker had learned from the family physician that she had suffered from acute pulmonary disease, which had in a few days proved fatal. It might be remarked that the relation of *lupus erythematosus* to *lupus vulgaris* had long been an unsettled question in dermatology. Although a certain kinship might exist between them, it was generally admitted that they were clinically distinct affections. The application of the term *lupus* to both was to be regretted, as it had led many into the erroneous belief that the two affections were simply varieties of one disease. Whereas *lupus vulgaris*—*i. e.*, the ordinary tubercular form of *lupus*—was not infrequently observed upon mucous surfaces, a case of *lupus erythematosus* of a mucous membrane had never been reported in this country to the speaker's knowledge. The cases reported by European observers were extremely few. Kaposi, in an excellent chapter on erythematous *lupus*, spoke of having seen three cases in which the eruption upon the face had been accompanied by an analogous condition of the oral cavity. The termination of these cases was not mentioned, but reference was made to eight cases of the disseminate form of the disease accompanied with erysipelatous inflammation, of which four of the patients had died of pneumonia.

Dr. SHERWELL then presented a girl aged fifteen who he said had first appeared at the clinic of the Eye and Ear Hospital, Brooklyn, in 1887, asking for relief from long-continued aphonia and some pain in her throat. On examination of the throat, the tonsils of both sides had been found to be tumefied and infiltrated; the same condition had existed in the pharynx, but more marked on the left side. Laryngoscopic examination had shown signs of irritative tumefaction and erosions of the larynx and epiglottis, this condition being more marked on the left side, with ulceration of the tip of the free border of the epiglottis. There had been paresis of the left vocal cord, the ventricular band on that side being swollen and infiltrated and presenting a worm-eaten looking erosion. The family history had been good. In spite of this, the patient had presented protean characteristics, which had inclined to the belief that the condition was due to latent specific disease. The patient had for a time been put upon tentative treatment, but with negative results. The disease had progressed slowly, without increasing in intensity, until the upper part of the pharynx and the palatine arch had become involved. The diagnosis of *lupus* of the milder type (*lupus erythematosus*) had been made, and afterward established. The patient had been kept under observation, and was doing well without treatment. The infiltration had now left the side of the larynx first attacked and had gone over to the right side, which now presented pretty much the same conditions as the left side had done four years ago. The slight and characteristic scarring left by the trouble could easily be seen over the whole extent of the pharynx and hard palate. The patient's general health was much better than when she had first presented herself. No treatment was being given.

A brief discussion on Dr. Fox's paper closed the proceedings.

#### NEW YORK ACADEMY OF MEDICINE.

##### SECTION IN OBSTETRICS AND GYNECOLOGY.

*Meeting of November 27, 1889.*

Dr. J. E. JANVRIN in the Chair.

**General Observations on the Use of Electricity in Gynaecology.**—A paper with this title was read by Dr. A. D. ROCKWELL. He said that until a recent period the advances in the therapeutic uses of electricity had been more especially along

the line of those destructively nervous affections that were neither specific nor structural in their nature. Cases of the latter type had always yielded but meager results under electrical treatment, and the speaker did not know of any competent authority who seriously alleged for electricity, in most cases of structural diseases of the central or peripheral nervous system, more than temporary and palliative effect. The statement that as a therapeutic agent “the effects of electricity are limited” must indeed seem a rash observation to those who had had repeated evidence of the wide range of its influence in the relief of nervous symptoms, and especially to those who had witnessed the really remarkable relief so often afforded by intra-uterine applications of the galvanic current. The speaker did not propose so much to give the results of his own experience in gynaecological electro therapeutics as to allude to some points in the rationale of its effects. He called attention first to the faradaic current. Its effects were mainly mechanical, and according to the construction of the helix, the length and thickness of the wire, did we measure its action on the muscular tissues of the uterus. Applied directly to the uterus of an animal in physiological experiments, the organ visibly contracted, although not to such an extent as the intestines, which, on application of the electrodes, could be seen to gradually draw up, very much after the manner of a woman's work-bag. Its action on the smooth muscular fibers of the human uterus, when applied therapeutically, was analogous to that of ergot, although manifestly more prompt and energetic, especially under the influence of the positive pole, which possessed a far greater power over the involuntary muscles than the negative. By this action a veritable interstitial massage was obtained. It was potent in overcoming the primary inertia of the uterus and in preventing an arrest of retrograde metamorphosis, through which came subinvolution and its inevitable and persistent sequelæ. When the processes that went to make up the graver and more chronic diseases of the uterine parenchyma and its lining membrane had continued a long time, as was usually the case when medical interference was sought, the simple mechanical effects of the faradaic current would be altogether misdirected. Here we resorted to the electrolytic influence of the galvanic current, or rather to what might be more fitly termed its galvano-chemical cauterizing effects, through which were destroyed the granulations and fungoid growths of the diseased mucous membrane. By the interpolar influence of the current we corrected a languid nutrition and hastened the absorption of exudation. Just as the positive pole of the faradaic current had an action of its own superior in effect to the negative in causing uterine contractions, so the positive pole of the galvanic current had an action peculiar to itself. Here oxygen was generated and acids accumulated which rendered this pole directly haemostatic. It was therefore indicated in all haemorrhagic conditions as well as where there existed an excess of the natural secretions. At the negative pole the alkalies were precipitated, imparting caustic properties and causing effects fluidifying rather than haemostatic. The absorptive process was undoubtedly more active under this pole than under the positive, and was especially indicated in indurated chronic metritis and for the resolution of fibroids. That the galvanic current often completely dissipated fibroid tumors of the uterus few would, the speaker believed, affirm. The symptoms could be relieved to a greater or less extent by electrolysis, and sometimes so completely relieved as to lead to the belief, so far as the patient was concerned, that the tumor had entirely disappeared. He was a firm believer in the great utility of the galvanic current in the absorption of the thickenings and infiltrations resulting from inflammation of the pelvic cellular tissue. He had seen the treatment, persistently carried out, result not only in the absorption of large pelvic

deposits, but in the cure of the most obstinate and severe sciatica, and in the restoration of power to partially paralyzed limbs. There were two methods of action through which we obtained results from electrolysis. The first and most apparent was the absolute destruction of tissue which took place at the time of treatment. Some suppuration might follow, and thus, by an actual loss of substance apparent to the sight, the tumor decreased in size. The electrolysis of organic substances started a process that continued long after the current had ceased to flow, and induced various important changes beyond and beneath the eschar. These combined agencies did far more in many cases to diminish the size of morbid growths and prevent further development than an actual destruction of a limited area. The effect of either current in dissipating the uterine and ovarian pains was sometimes remarkable. The speaker related a case in which the patient had suffered intensely from dysmenorrhœa for six or seven years, and had finally resorted to extirpation of the ovaries for the relief of it. The flow had gradually diminished, but the pains had increased in severity. Under the internal applications of the galvanic current, ranging from 25 to 50 milliampères in strength, the paroxysms had yielded rapidly and in a few months recovery was complete. If an agent like the galvanic current possessed such marked influence over so many forms of pain of obscure origin, why should not this treatment precede rather than follow severe operative procedures for their relief?

**The Treatment of Certain Pelvic Tumors by Galvano-puncture and Drainage by the Vagina, and Intra-uterine Galvanization.**—A paper on this subject was read by Dr. AUGUSTIN H. GOELET. The speaker desired to be understood as referring only to such tumors as were easily accessible by the vagina for galvano-puncture, and those which were so intimately associated or connected with the uterus as to be influenced by the chemical galvano-caustic application to the endometrium. He also included under this caption pyosalpinx and hydrosalpinx. The speaker then exhibited the instruments that he used in these operations, and briefly described the methods of their application. For the galvano-puncture, a fine silver cannula, size No. 4 of the French scale, with a steel trocar, was used. The trocar was covered with a slide of insulating material which could be fixed by a screw to the shaft of the cannula, so as to limit the degree of penetration. It was also arranged for connection with the battery. The cannula was so made that it could easily be attached to an aspirator. The method of application was simple; after deciding upon the degree of penetration necessary, the slide was fixed, and the trocar point drawn within the cannula. The vagina and the vulva being doused thoroughly with a solution of bichloride, the index finger was introduced, and, taking care to avoid any pulsating vessel, the most dependent point was selected. Then the cannula, with the point of the trocar concealed, was passed along the finger until it impinged against the spot selected. The trocar was pushed down into place, and the cannula was made to penetrate to the limit fixed by the slide. The trocar being withdrawn, if no fluid escaped, the slide was readjusted lower down and the cannula, without the trocar, was introduced a little farther. When the fluid was evacuated the trocar was partially reintroduced and connected with the battery, the circuit being completed by a large clay electrode on the abdomen or back. In hydrosalpinx the negative pole was used through the cannula, with not more than fifty milliampères for five minutes. In pyosalpinx the cavity must be washed out with an antiseptic solution, as an extra precaution. The positive pole was to be preferred because it was less irritating, and was believed to be more antiseptic. When applied, a cannula made of platinum should be used, as the silver would be acted upon and unnecessary irritation

provoked. The cauterization of the track of the puncture by the current shut it off from the surrounding tissues and rendered the absorption of septic material through that channel impossible. If a dressing of iodoform gauze was kept constantly renewed in the vagina there was nothing to be apprehended from that source. Resolution in the diseased tube was promoted by the influence of the current and was still further favored subsequently by mild positive galvanism of the endometrium. The speaker limited this treatment by aspiration to such tubes as were close to the vaginal wall, and where fluctuation might be distinctly felt. These tubes were usually fixed by a mass of exudation. This treatment of hydrosalpinx was suggested to the speaker by observations of three cases of radical cure of hydrocele, which had been accomplished by this method. The hydrocele had repeatedly refilled after ordinary tapping, but had never refilled after using negative galvanism through the cannula. Small cysts close to the vaginal wall were also successfully treated in this way. The fibro-cyst was sometimes more obstinate in yielding to this treatment, especially those lined with a secreting membrane. Some cases yielded to one tapping, and negative galvano-caustic application of one hundred milliampères through the cannula, but in other cases it had been necessary to make the application directly to the cavity. This was done by enlarging the opening with gradually increasing sizes of conical electrodes connected with the negative pole until it would admit a bulb electrode into the cavity. This bulb was fixed upon a small insulated shaft which was flexible, and through it a current of one hundred and fifty to two hundred milliampères was concentrated within the sac. If drainage was not perfect through the opening, a rubber drainage tube was inserted and fastened in position. A dressing of iodoform gauze was kept constantly renewed in the vagina. The speaker related the history of a case of fibroid tumor that had been successfully treated by galvano-puncture. The patient had suffered with very severe periodical pains, which had compelled her to keep her bed for ten days or two weeks out of every month for about eight years. The tumor as found by the speaker was situated to the left of the uterus, to which it was attached near the cervico-vaginal junction and close to the vaginal wall, and was of about the size of a quart bowl. The treatment was commenced with galvanism, but this was not well borne. At the first galvano-puncture through the vagina, the negative pole, with two hundred and fifty milliampères for five minutes, was used. This puncture was followed immediately by a discharge of an ounce and a half of yellow fluid. As this did not continue, it was concluded that a small cyst had existed on the surface of the tumor which had been emptied. Eight days afterward the second negative galvano-puncture was made with two hundred milliampères of five minutes' duration, and no discharge followed. Menstruation appeared two days later with much less pain than before. At the third treatment, the positive pole was used with three hundred milliampères for five minutes. A week after the sixth puncture a copious watery discharge came suddenly from the vagina, and continued to flow away in gushes. Investigation showed that it came from the last puncture tract. The opening was enlarged and the sound passed up four inches into a cavity. All of the fluid was drawn off, but the discharge continued for two weeks as much as a pint a day. A bulb electrode was introduced and one hundred and fifty milliampères of negative galvanism applied to the cavity for eight minutes. Three days later all discharge had ceased. At present, six months since the last application, the patient presented every evidence of perfect health. She had no pain, and menstruation was normal. What remained of the tumor was of about

the size of a hen's egg. It gave her no inconvenience whatever. Dermoid cysts might be treated in the same way, when they contained only sebaceous matter. The condition known as chronic pelvic cellulitis, which was usually manifested by a mass of exudation in one or both broad ligaments, including the tube and ovary, and associated with salpingitis and endometritis, yielded very satisfactorily to galvanization of the endometrium. It was important to begin the treatment always with a small dose, from twenty to thirty milliamperes for three to five minutes every second or third day, using the positive pole. It was sometimes even better to begin with vaginal applications. The dose might be increased to fifty milliamperes as tolerance was established. Later in the course it might become necessary to substitute the negative pole or vaginal puncture to hasten absorption. This condition doomed the patient to a life of misery, and she was constantly threatened with peritonitis. Laparotomy did not cure; it mutilated. By galvanism she could be promptly relieved of pain, the deposits were softened and absorbed, the inflammatory complications were removed, and she was eventually restored to health with her ovaries and tubes intact, and with a chance of conception. Thomas Keith had truly said: "Apostoli's method, though slow, requiring much patience, tenderness of manipulation, and thought, is still sure in its results." This same writer had added also of electricity: "My confidence in its power to relieve disturbing symptoms of uterine fibroids, and to cure many chronic inflammatory conditions in the pelvis, continues to increase, and I have no fears for the future of electricity." He had said also: "Hysterectomy, remember, which is performed every day for a complaint that rarely of itself shortens life, kills every fourth or fifth woman that is subjected to it. This mortality must cease; it is not a question of surgery; it is a question of humanity. Every time that any disease can be cured without resorting to a bloody and dangerous operation, such as hysterectomy, progress is made in our art, and there is gain to humanity, while surgery is the better for being purged of a deadly operation. Even the fact that in my cases of hysterectomy the removal of the uterus and ovaries was sooner or later followed by insanity in ten per cent. of the whole number, is enough for me to condemn any operation that removes these organs." This was the mature opinion of a most successful surgeon—one who had been the first to lower the mortality of abdominal surgery. The speaker closed his remarks by paying a high tribute to Apostoli, and said that he did not think any one should attempt to pass judgment, in condemnation, on that gentleman's work until he had visited his clinic and witnessed it and its results.

**The Galvanic Treatment of Uterine Fibromata.**—A paper with this title was read by Dr. E. L. H. McGINNIS. The speaker described Apostoli's methods in detail, and also fully described galvano-puncture as practiced by himself at the Woman's Hospital. The speaker's methods did differ materially from those of Dr. Goelet. The negative pole was used in non-bleeding fibroids, the positive as a haemostatic. The speaker had had the satisfaction of stopping haemorrhage in several patients that had come to the hospital nearly exsanguinated. He not only had stopped the dangerous bleeding, but had prevented a return of it. He believed that the most obstinate haemorrhage could be controlled, provided a sufficiently strong current was used and every part of the endometrium brought in contact with the electrode. This was sometimes very difficult, as the canal might be tortuous, and the stiff electrode then failed to touch some spot where there was bleeding. This might be provided for by using a flexible electrode which was insulated to its platinum tip. Should there be fungosities present they would be destroyed at the same time, thus answering the purpose of curetting without leaving a fresh bleeding surface within

the uterus. The speaker gave the history of a case at present under his care. He had first seen the patient last February. Her history revealed the fact that she had first noticed the enlargement in her abdomen four years before; she had had all the usual symptoms, including several severe haemorrhages, which had left her nearly bloodless. She was emaciated to an alarming extent, her pulse was weak, and she felt perfectly certain that her next haemorrhage would be her last, and that she could not recover from the effects of a hysterectomy. The tumor was situated in the fundus, and extended to the ensiform cartilage. Her waist measured forty-four inches in circumference. The depth of the uterus was five inches and a half. Fortunately, the canal was straight, and there was little trouble in introducing the electrode and thoroughly cauterizing the endometrium. This treatment was continued at intervals of two weeks. The patient was obliged to leave town, and the speaker lost sight of her for some months. She reported in October that she had had no return of the haemorrhage. The tumor was now down to the umbilicus, was not tender, and gave her no pain. The canal was three inches and a quarter long, and the patient could walk to the speaker's office, which was nine-blocks from her home, three times weekly for her treatments. The experience of the speaker with Dr. Apostoli's methods had been more than satisfactory. In conclusion, he urged that the method be given a proper and thorough trial before taking patients to the operating-room, there to undergo the dangers of the knife.

**Notes regarding the Treatment of Fibromata by Electricity.**—Dr. A. H. BUCKMASTER, of Brooklyn, in a paper on this subject gave the results of some practical experiments for testing the direct effect of electricity on various tissues. He said that it was desirable to know how these growths were affected by the current. As fibro-myomata were made up for the most part of non-striated muscular fiber, and as it was difficult to obtain an animal with this exact pathological condition, he had selected the heart of the dog as the nearest approach to the tissue required. While the dog was living the heart was exposed, and a current passed through it. Then the portion in the direct line of the current was excised and carefully examined microscopically. At the same time portions a little distance from the track of the current were also removed. In those portions exposed to the full extent of the current the striae had become markedly granular. Outside this line but little effect was noticed. In the non-striated muscular tissue a marked interpolar change could be demonstrated, consisting in the destruction of the cell elements, a sort of retrograde metamorphosis of a degenerative character. A high current would develop changes in tissue, though its efficacy in this respect was still denied by some observers.

**The Value of Bipolar Faradization in Gynaecology.**—By Dr. A. LAPTHORN SMITH, of Montreal. This paper, in the absence of Dr. Smith, was read by Dr. J. R. Goffe. The author said that as they were aware it was Faraday who discovered that an induced current of electricity was set up in a conducting wire which was placed near to but did not touch another wire through which a current was passing, they were also aware that the appreciable effects of the passage of a current of electricity, either direct or indirect, were greatly increased by the interruption of the current. Thus, a continuous current of one hundred milliamperes could be easily borne, while if the same current were interrupted it would promptly knock one down. They were also aware that by making the primary wire into the form of a coil and placing a piece of soft iron in it as a core, the iron became magnetic whenever the current passed, and this body of magnetized metal in turn intensified the current in the primary coil. The latter should be made of medium

coarse wire, so as not to offer too great a resistance for the battery to overcome. The battery, which might best consist of two closed cells in a separate portable case, must have sufficient electro-motive force to push through the coil. The secondary or induced coil deserved special attention, because it would depend entirely upon the shortness and coarseness, or the length and fineness, of the wire, whether they would obtain those almost magical effects which were alleged for it. There were many who could not believe that these differences were of any real consequence, and yet there was no fact in medicine of which Dr. Smith was more certain than that the results of these two wires were totally different. The coils used by the writer were wound as follows: The short wire coil, which was about twenty-five yards long, No. 14 or 16 in diameter, was insulated with silk, and varnished between the layers. The fine wire was No. 40, and about a mile long. The short, thick wire gave out nearly the whole quantity of current which was indeed in it, and was therefore called the current of quantity. The long, fine wire offered a tremendous friction or resistance to the passage of the current, and was therefore called the current of tension. The current of quantity from the coarse wire coil had long been known to be an excellent tonic to muscular fiber. While it should be placed very high up on the list of tonics, the writer did not think that it possessed any miraculous virtues which were not to be found, to a greater or less extent, in gymnastics, regular exercise, strychnine, quinine, ergot, hydrastin, and cold and hot water. This much could be said for it, however, that in relaxation of muscles the tonic effect could be applied directly to the muscles or group of muscles which were mostly at fault. By means of Apostoli's bipolar electrode it was especially adaptable to the muscular organs in the pelvis. In post-partum haemorrhage prompt and permanent contraction of the uterus could be brought about by introducing the bipolar electrode and turning on the coarse wire current. Subinvolution, due to defective contraction of the uterus, yielded readily to the bipolar method. The advantages of this were: 1. It was less painful than the old method, because it did not require the current to pass through the skin, which was much more sensitive than the vagina. 2. It was easier to apply and precluded the need of an assistant. 3. It allowed a much stronger current to be tolerated. 4. It was consequently more effective, because the higher the intensity of the dose the more marked the effects. Bipolar electrodes were made with one pole at the extremity and the other separated from it by an interval of an inch or so of insulated material, so that the current had to go through the tissues to get from one pole to the other. In doing so it seemed to set up circles of induction in the neighboring structures, as proved by the following observation: When the current was started with a moderate strength from the fine wire coil, the patient, if asked what she felt, would say that there was a numbness of an area of about the size of a walnut. As the secondary wire was passed over the primary one more and more she would say that the area had increased to the size of an orange, and, finally, when the whole strength was on, the numbness would have invaded the whole pelvis, including the area of pain. The element of pain played an important part in the diseases of women, and very often existed where no organic lesion could be found. More especially was this the case with ovarian pain, a great many cases of which had been completely cured with fewer than a dozen applications of the fine-wire faradism. There were three kinds of cases in which the fine-wire bipolar faradization produced remarkable results: 1. In ovarian pain, where no organic disease could be found. The writer did not pretend for a moment that it would be of any use in even small ovarian cysts; the sooner they were removed by operation the better, and when he saw these presented at society meetings he felt no

regret that they had been removed. But when some of our surgeons took two or three pairs of healthy ovaries from their vest-pockets which had been removed on account of pain, he felt sorry that they were not aware how easily that pain could have been relieved by fine-wire faradism. 2. In cases of abdominal pain due to hysteria it acted very promptly, not only in rendering the abdomen insensible to pressure, but also in calming the general nervous crisis within a few minutes. 3. There were many women about the age of thirty who, though fleshy and apparently well supplied with blood, did not menstruate at all or only very slightly. These women felt very uncomfortable; their *embonpoint* made them weak, and they had many nervous symptoms, which placed them in the category of hypochondriacs. Anything that would bring on a full return of the menstrual flow gave them relief. This object would be accomplished by using the current of tension three times a week to the inside of the uterus. 4. In vaginismus it was remarkably effective. The worst case of vaginismus the writer had ever treated was cured in three applications, and the woman became pregnant at the next ovulation. There were some troublesome conditions of the bladder in which the bipolar faradization could be used with advantage. In conclusion, the writer disclaimed any intention of considering bipolar faradism as the only remedy in gynaecology. While we were calming a woman's pain with electricity, we should at the same time be removing the unhealthy conditions of the body generally, on which most often the local disorder depended. All that he wished to say for it was that it was a valuable addition to our therapeutic resources, especially in those diseases of women in which all other methods of treatment often failed.

Dr. P. F. MUNDÉ said that he had been for a number of years much interested in this subject of electrical treatment, and believed he had had ample opportunity to become acquainted with its practical working. He could speak most decidedly in favor of electricity as a therapeutical agent in gynaecology, and had published his convictions on this subject some few years ago. He had seen more benefit derived from galvanism than from faradism in gynaecological practice. He had also found that mild currents used for a long time were more efficacious than strong currents employed for a short time. He used a Leclanché battery of forty cells. For ordinary purposes he used a small meter registering only twenty milliamperes. He had another which registered five hundred milliamperes. This he had tried only a few days ago in treating a fibroid and had found it faulty. Using galvanism and placing the positive electrode next the sensitive spot in the pelvis, or on the abdominal wall, he had been able to obtain very efficacious results in relieving the pain incident to chronic pelvic peritonitis. In old cases of inflammation with adhesions, with more or less pain in the ovaries and tubes, he had found that the tri-weekly administration of electricity, with the positive current internally, was of decided benefit after some few months of treatment. On the other hand, quite a number of patients, after several months of such treatment, had complained of receiving no benefit whatever, and laparotomy had had to be resorted to. This proved that electrical treatment was not suited to these particular cases. Still he deemed it proper in all circumstances to give the patients every opportunity for possible benefit from electricity before submitting them to a radical operation, which, let it be done by whom it might, could never be without an element of danger. In obscure pelvic pain, due to some inflammatory deposit unrecognizable by digital examination, extending down the sciatic or crural nerves, he had seen instant relief follow the use of electricity when other treatment had failed. While he relied on this treatment, and had found it of great benefit, especially in relieving pain, he thought one might go too far. Very

often the radical operation was the only thing to do. He considered the length of time necessary to achieve palpable results a great drawback to the use of electricity. If it was clear that some good was being done, the time was, of course, not lost. He had been pretty severely criticised some four years ago about the milliampermeter. At that time this instrument was not used to any great extent—at any rate, he had not been able then to obtain a good one in New York. Even now, though he had two, he was by no means satisfied that it was at all necessary, and was inclined to look upon it as a sort of plaything. When using galvanism for the removal of pain the sensations of the patients would be sufficient guide as to the strength employed. When it came to using the galvanic current on patients under an anaesthetic or for the employment of the galvano-puncture, of course it was necessary to know what the battery was doing. The faradaic current he had found do a great deal of good in curing amenorrhœa by intra-uterine faradization three times a week. He had used electricity only once in extra-uterine pregnancy, in which he had employed the interrupted galvanic current. He had cured his patient after nearly killing her by the shock. In pyosalpinx and pelvic abscesses laparotomy and drainage were to be preferred to galvano-puncture. As to fibroids, he had very decided views. He considered that operative treatment of fibroids of the uterus and ovaries was overestimated. Out of one hundred and twenty-three cases under his observation, about fifty per cent. had required no treatment whatever, sixty-two had required treatment, but only eight of this number, in his opinion, had required Apostoli's method, and four others had called for galvano-puncture. Apostoli's method of treatment covered only the intra-uterine use of galvanism with the clay electrode on the abdomen, the galvano-puncture not being strictly his method. He had employed Apostoli's plan eight times in three years, and had also written about it. He could honestly say that, while he believed in it for the removal of pain and in hemorrhage, and admitted that the patients felt better for its use, not a single tumor had come under his notice that had been much reduced in size.

**A Portable Galvanic Battery.**—Dr. FRANKLIN H. MARTIN, of Chicago, exhibited a portable galvanic battery, upon the reliability and effectiveness of which he spoke at some length. He also went into the question of the treatment of inflammatory exudates in the female pelvis by galvanism, giving some of the results of his own cases and his methods of carefully noting the subsidence of these formations by measurement while under treatment.

Dr. G. BETTON MASSEY, of Philadelphia, said that, in regard to this new electrical treatment of the diseases of women, he was of the opinion that a forward movement of great importance had been initiated. So positive and striking was this progress that its degeneration into a fad was to be feared. But the fear of this should not blind us to important facts. During the last few years electricity had itself been revolutionized, and it would be strange indeed if our better knowledge of it did not lead to the better application of this force to the medical arts. There was one class of conditions in which the galvanic current possessed a value unique; that was chronic inflammation of the uterus or of the endometrium. This agent would act as an alterative to the diseased membrane, and at the same time reduce interstitial hypertrophy by promoting both absorption and contraction. In simple endometritis or uterine catarrh the galvanic current locally applied was practically infallible. The current need not exceed ten to thirty-five milliamperes, using the bare intra-uterine electrode and an external indifferent pole of proper size. The choice of currents was governed by the presence or absence of menorrhagia, the positive being

always used with this complication. When the endometritis was associated with slight cervical lacerations it would usually be found unnecessary to operate for repair, as all symptoms disappeared under this treatment. The speaker reported the result of treatment in twenty-six cases of fibroid tumors. Two had been cured anatomically and symptomatically, seven had been cured symptomatically and anatomic ally reduced, eleven had been greatly improved, four slightly improved, one unchanged, and in one death had occurred.

**Some Remarks on the Value of Electricity in the Treatment of Fibromata.** By Dr. ALEXANDER J. C. SKENE. As this gentleman was prevented from being present, his notes were read by Dr. Buckmaster. In estimating the value of electricity in the treatment of fibromata, Dr. Skene said that he had of necessity been guided by the opinions of others more than by his own observations. Owing to the extremely conflicting testimony of those who had expressed themselves, it had been very difficult to get anything definite. One class of men had condemned the treatment without mercy. Another class had obtained the most perfect results. There was another class who had had an intermediate experience. They had been able to relieve their patients of most or all of their symptoms, and had diminished the size of the tumors or retarded their growth. The writer had accepted the testimony of this latter class, because it appeared to have more truth in it and because it agreed with the results of his own practice. Perhaps the most important question in the whole discussion was as to the relative merits of this and other methods of treatment. The writer had hoped to get records to show that more patients had died from removal of the uterus and ovaries for the cure of fibromata than had died from fibromata without treatment of any kind. Up to the present time electro-therapeutics in its immature state had been competing with surgery, that had the advantage of being perfected by long experience. Great progress had been made in a short time. In a recent discussion in the Academy of Medicine of Paris, it had been shown that strong currents were not called for, and that it was necessary to puncture the tumor to get good results.

Dr. H. J. BOLDT, after going into the theory of the bipolar action of the current in the tissues, went on to say that those gentlemen who in no wise accepted electricity as efficacious were those who had never given it an honest trial. They had no right to operate on any patient until electricity had been given a thorough test. That it would not in every instance even alleviate the symptoms he thought he could vouch. As to pyosalpinx, he thought these cases were cured when the tubes were cut out. When the tubes were distended and the uterine extremities were closed, or where the tubes were agglutinated, what could be expected from electricity? All that could be done was to remove the tubes. But as long as the caliber of the tubes remained patent it was well to try everything, and a great many of the patients got well. Many mistakes in diagnosis were made, and it was not advisable to be too enthusiastic.

Dr. GOELET said that he had cured at least thirteen patients by galvano-puncture who could not have been relieved otherwise, except by laparotomy. That was to say, the patients would otherwise have been mutilated. He thought it only right to try to cure these patients before mutilating them. By emptying the tubes and the use of the current subsequently the tubes might be rendered patent. He thought that the pus could be first emptied and then the removal of the cause of the accumulation of that pus effected. The resolution of the proximal end of the tube could be produced by galvanism of the endometrium. He did not think we ought to say that the removal of the tubes was a cure of pyosalpinx. In many instances, indeed, the patient's condition was more harassing after the op-

eration than before. He thought that Dr. Mundé's failures with electricity, when they occurred, were to be laid to the fact of his having used his currents too weak. Then, again, he thought the doctor had made a mistake in ignoring the milliamperemeter as a plaything. Many women would bear intense pain and say nothing about it, and electricity might be thus administered in dangerous doses. It was impossible to estimate the particular resistance of the tissues in every case, and for these reasons the meter was always an important auxiliary.

The CHAIRMAN asked whether Dr. Goelet's experience of intra-uterine galvanism had demonstrated to him that an occluded tube had become patent again and was performing its function like the other one which was assumed to be healthy. Of course the fact of fecundation occurring did not imply that both tubes were functionally competent.

Dr. GOELET replied that he could only assume that complete recovery had ensued from the fact that all symptoms had been completely removed, that menstruation had become normal, and that there had been no reaccumulation in the affected tube.

## Book Notices.

*Ophthalmology and Ophthalmoscopy* for Practitioners and Students of Medicine. By DR. HERMANN SCHMIDT-RIMPLER, Professor of Ophthalmology and Director of the Ophthalmological Clinic in Marburg. Translated from the Third German Revised Edition. Edited by D. B. ST. JOHN ROOSA, M. D., LL. D., Professor of Diseases of the Eye and Ear in the New York Post-graduate Medical School, etc. One Hundred and Eighty-three Woodcuts and Three Colored Plates. New York: William Wood & Company, 1889. Pp. xv-3 to 571.

ONE of the most popular of German text-books on ophthalmology is here presented for the first time in an English dress in a handsomely printed volume. It is divided into four parts and twenty chapters. The first part treats of the general examination of the eye, of errors of refraction and accommodation, and of amblyopia and amaurosis. We think it unfortunate that the author has retained the terms amblyopia and amaurosis as descriptive of diseases, since they are merely symptoms and at the best but ill-defined. The second part treats of ophthalmoscopy and diseases of the optic nerve, the retina, the choroid, and the vitreous humor. The third part considers the subjects of glaucoma and diseases of the lens, conjunctiva, cornea, sclera, iris, and ciliary body, including ophthalmomomalacia and sympathetic ophthalmia. The fourth part treats of diseases of the ocular muscles, the orbit, the eyelids, and the lacrymal apparatus.

The illustrations are all good and sufficient for the purpose for which the book is intended. There is a very good index, and the book is a very favorable specimen of the printer's art. The translator, whose name is not mentioned, has done his work well, and the editor has made numerous additions throughout the entire volume, which enhance the value of the work.

*A System of Obstetrics*. By American Authors. Volume I. Edited by BARTON COOKE HIRST, M. D., Assistant Professor of Obstetrics in the University of Pennsylvania. Illustrated. Philadelphia: Lea Brothers & Co.

THE contributors to this volume are Dr. Samuel C. Binney, Dr. George J. Engelmann, Dr. Barton Cooke Hirst, Dr. William

Wright Jaggard, Dr. H. Newell Martin, Dr. Theophilus Parvin, Dr. R. A. F. Penrose, and Dr. J. C. Reeve. It is safe to affirm that this contribution to obstetric literature contains the last word of science upon the subject of which it treats. Each division is complete in itself, interesting as historical reading, admirable as instruction, and valuable in point of clearness and for direct conclusions that are easy to find when in hurried search of enlightenment and advice. The special divisions of the subject, in their regular order, contained in the present volume are the history of obstetrics; the physiology and histology of ovulation, menstruation, and fertilization; the development of the embryo; the foetus: development, anomalies, etc.; pregnancy: its physiology, pathology, differential diagnosis, and premature expulsion; the conduct of labor and management of the puerperal state; the mechanism of labor and the treatment of labor based on the mechanism; the use of anaesthetics in labor; and the anomalies of the forces in labor. There are three hundred and nine wood engravings and one colored plate—the areola in pregnancy (after Spiegelberg)—that add greatly to the attraction and usefulness of the book. The work gives promise of being a reference library in itself that every physician can secure without too great outlay of money, and with great satisfaction to himself.

*Lehrbuch der allgemeinen und speciellen pathologischen Anatomie für Aerzte und Studirende*. Von DR. ERNST ZIEGLER, Professor der pathologischen Anatomie und der allgemeinen Pathologie an der Universität Freiburg in Baden. Zwei Bände. Sechste verbesserte und theilweise neu bearbeitete Auflage. Erster Band. Allgemeine pathologische Anatomie und Pathogenese. Mit 343 theils schwarzen, theils farbigen Abbildungen und einer Tafel in Chromolithographie. Jena: Gustav Fischer, 1889. Pp. xiv-567.

An English edition of this excellent work was noticed by us a few years ago and approved of unqualifiedly. What the popularity of the work must be in Germany, where similar works of the highest merit abound, may be judged from the fact that it has so quickly reached a sixth edition. There is no science in which new facts accumulate with such rapidity as in pathological anatomy, and, we may add, this accumulation is now more greater than in Germany. The present edition has rigorously followed the development of the science. The pictures of the stained microscope preparations and bacterial cultures are especially beautiful and throw a light upon the subjects treated of which is afforded by no similar work with which we are acquainted. It is to be hoped that we may have an English reproduction of this edition.

*The Cerebral Palsies of Children*. A Clinical Study from the Infirmary for Nervous Diseases, Philadelphia. By WILLIAM OSLER, M. D., Fellow of the Royal College of Physicians, London; Professor of Clinical Medicine in the University of Pennsylvania, etc. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. 103. [Price, \$2.]

This book is based upon the records of 151 cases of cerebral palsy. Of these, 120 were those of children with hemiplegia, 20 with bilateral hemiplegia, and 11 with paraplegia. From a study of these and a careful digest of the best work upon the same subject in English, French, and German literature, the author deduces some valuable conclusions. He finds hemorrhage to be the most frequent cause of all congenital forms, whether diplegia or hemiplegia; and he discusses judiciously the conflicting theories as to the origin of the more common variety of cerebral palsy—viz., the hemiplegias occurring during the first few years of life. The paralysis disappeared under

treatment in only two of the 120 cases of hemiplegia. Massage with sweet oil and faradism he regards as of great value to prevent atrophy and improve the nutrition of the paralyzed parts. Dr. Osler's brochure is without doubt the most complete summary of existing knowledge upon this as yet not entirely understood subject.

#### BOOKS AND PAMPHLETS RECEIVED.

A Hand-book of Pathological Anatomy and Histology. With an Introductory Section on Post-mortem Examinations and the Methods of preserving and examining Diseased Tissues. By Frances Delafield, M. D., Professor of Pathology and Practical Medicine, College of Physicians and Surgeons, New York, and T. Mitchell Prudden, M. D., Director of the Laboratory of the Alumni Association of the College of Physicians and Surgeons, New York. Third Edition. Illustrated by Two Hundred and Twenty-four Wood Engravings printed in Black and Colors. New York: William Wood & Company, 1889. Pp. xv-609.

A Treatise on Materia Medica, Pharmacology, and Therapeutics. By John V. Shoemaker, A. M., M. D., Professor of Materia Medica, Pharmacology, and Therapeutics in the Medico-chirurgical College of Philadelphia, and John Aulde, M. D., Demonstrator of Clinical Medicine and of Physical Diagnosis in the Medico-chirurgical College of Philadelphia. In Two Volumes. Vol. I. Devoted to Pharmacy, General Pharmacology, and Therapeutics, and Remedial Agents not properly classed as Drugs. Philadelphia: F. A. Davis, 1889. Pp. xii-5 to 353. [Price, \$2.50.]

Contributions to the Surgical Treatment of Tumors of the Abdomen. Part II. Electricity in the Treatment of Uterine Tumors. By Thomas Keith, M. D., LL. D. Edin., and Skene Keith, F. R. C. S. Edin., Edinburgh: Oliver & Boyd, 1889. Pp. viii-255. [Price, six shillings and sixpence.]

Transactions of the American Otological Society, Twenty-second Annual Meeting, Pequot House, New London, Conn., July 16, 1889. Vol. iv, Part III.

A Hand-book of Diseases of Women. Including Diseases of the Bladder and Urethra. By F. Winckel, Professor of Gynaecology, and Director of the Royal University Clinic for Women, in Munich. Authorized Translation. Edited by Theophilus Parvin, M. D., Professor of Obstetrics and Diseases of Women and Children in Jefferson Medical College, Philadelphia. Second edition, revised and enlarged, with One Hundred and Fifty Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. xxiii-17 to 766.

Hand-book of Obstetrical Nursing, for Nurses, Students, and Mothers. Comprising the Course of Instruction in Obstetrical Nursing given to the Pupils of the Training School connected with the Woman's Hospital of Philadelphia. By Anna M. Fullerton, M. D., etc. Philadelphia: P. Blakiston, Son, & Co., 1890. Pp. viii-16 to 214. [Price, \$1.25.]

Outlines of the History of Medicine and the Medical Profession. By Joh. Hermann Baas, M. D. Translated, and in conjunction with the author revised and enlarged, by H. E. Handerson, M. A., M. D. New York: J. H. Vail & Co., 1889. Pp. 10-13 to 1172.

Concealed Pregnancy: its Relations to Abdominal Surgery. By Albert Vander Veer, M. D., Albany. [Reprinted from the "American Journal of Obstetrics and Diseases of Women and Children."]

The Treatment of Internal Derangements of the Knee Joint by Operation. By Herbert Wm. Allingham, F. R. C. S., Surgeon to the Great Northern Central Hospital, etc. London: J. & A. Churchill, 1889. Pp. viii-165.

Massage. Kort Framställning af Douglas Graham, Medicin Doktor, ledamont af Massachusetts Medieinska Sällskap. Bemyndigad öfversättning af Nils Posse, Sjukgymnast Föreständare för Gymnastikskolan i Boston, Nord-Amerika. Lund: C. W. K. Gleerups.

Severe Continuous Cephalgia as an Early Secondary in Syphilis. By William Browning, M. D. [Reprinted from the "Brooklyn Medical Journal."]

Case of Tuberculosis Papillomatosa Cutis, with Remarks on the Relation of Papilloma to Syphilis, Lupus, etc. Illustrated with Chromo-

lithographic Plate. By Prince A. Morrow, A. M., M. D. [Reprinted from the "Journal of Cutaneous and Genito-urinary Diseases."]

New York Society for the Relief of Widows and Orphans of Medical Men. Incorporated 1843. Constitution and By-laws, to which is annexed a Brief History of the Society, and a Complete List of the Officers, Members, and Benefactors.

Introductory Address delivered at the Opening of the Fifty-seventh Session of the Medical Faculty of McGill University, October 1, 1889. By R. L. MacDonnell, B. A., M. D. [Reprinted from the "Montreal Medical Journal."]

Sixty-sixth Annual Report of the Managers of the New York Asylum for Lying-in Women. Presented April 18, 1889.

Prospectus of the Brooklyn Dispensary for the Treatment of the Nose, Throat, and Lungs.

First Annual Report of the New Amsterdam Eye and Ear Hospital. For the Year ending May 14, 1889.

First Annual Report of the Health Department of the City of Mansfield, Ohio. For the Year commencing March 1, 1888, and ending February 28, 1889. By R. Harvey Reed, M. D., Health Officer.

Third Annual Report of the Training School for Nurses connected with the Post-graduate Medical School and Hospital. May 31, 1889.

The Therapeutic Value of Motion. By G. H. Patchen, M. D., of New York. [Reprinted from the "Medical Advance."]

#### New Inventions, etc.

##### A SINUS CURETTE.

BY H. BEECKMAN DELATOURE,

BROOKLYN.

A NUMBER of cases in which I desired to curette have come under my care, but none of the curettes at command were small enough. Cases in which a small curette is of use are a whitlow, for instance, in which after incision considerable broken-down tissue is found. The old way of applying a poultice after incision required weeks to obtain a cure, while now, after incision and curetting away the necrotic tissue and applying a wet dressing, the parts will promptly heal in less than a week. A sinus may remain open for some time after a drainage-tube has been removed, as the granulations which line it are slow to close in. In such a case as this, if the granulations are removed and external pressure is applied along the line of the sinus, immediate union of its walls will take place. There are also cases of necrosis of small areas having narrow sinuses leading to the surface. These sinuses are so small that they will little more than admit a probe, and yet a comparatively large wound would have to be made in order to remove this bone with an ordinary curette.

It was for a case like that just mentioned that I had made for me by Messrs. Tiemann & Co. the small curette which I have named a sinus curette.

It consists of a sharp spoon, fenestrated, a quarter of an inch long and three sixteenths of an inch wide, mounted on a metallic handle five inches and three quarters long. The peculiar shape of the spoon renders it possible to pass it through an opening which will hardly more than admit a probe. When I began to use this little instrument I was much surprised to find the amount of work that it would do and the number of cases in which it was of use. In the case for which it was made I succeeded in removing a considerable area of necrosed bone from the femur through the sinus that existed, and was much gratified at having the sinus heal immediately.

This little instrument has served me so well in many cases that I feel justified in bringing it before the profession, and hope that others may find in it as faithful a companion as I have.

## Miscellany.

**A Case of Diabetes benefited by Phosphorus.**—In the "British Medical Journal" for November 30th Dr. Balmanno Squire says: "As new therapeutic results are probably more often the result of chance than of design on the part of the investigator, I may perhaps be held excused in communicating to you what, so far as I know, is a new and somewhat important therapeutic fact, but which, whatever it may be worth, is as certainly not the result of any premeditated design on my part."

"A gentleman, aged sixty, was brought to me on October 9th by Dr. Williams Jones, of Manchester, who wished my advice as to his patient, who for a long time had been affected somewhat severely with eczema of his face, neck, and upper limbs, including his hands. Dr. Jones had previously consulted two or three other practitioners as to his patient's condition, and informed me that his patient, who had become much worn out from want of sleep, was now willing to do whatever might be required of him. Dr. Jones also informed me that his patient had for long been affected with diabetes, for which he had treated him.

"I suggested to Dr. Jones that, in addition to the local remedies which we agreed on, the patient should take phosphorus 'perles' for the improvement of the eczema. To this Dr. Jones saw no objection. I accordingly proposed to him that the patient should take one 'perle' three times a day for three days; and that, should no nausea result from their use by the end of that time, the dose should then be increased to two 'perles' three times a day. Owing to some difficulty in obtaining the 'perles,' the patient did not commence taking them until November 1st, and, after the expiration of three days, Dr. Jones put his patient on the double dose.

"To-day (November 11th) the patient visited me at Dr. Jones's request, and certainly as to his eczema he is nearly quite well, and he tells me that he now enjoys sound sleep at night. Thus much I was quite prepared to hear. But I was a little astonished when he informed me that these were by no means the only benefits that he had derived. He was also greatly better of his diabetes, very suddenly and very markedly so. He says that for the last four or five days he has been far better in this latter respect than he has been for many months. He had been used to being obliged to get out of bed four or five times in the night to pass water; but, for the last four or five days, he had not had any call of the kind at night. The quantity that he passed in the twenty-four hours had for long been a very considerable quantity, but it had suddenly diminished in amount very notably. The urine has until quite recently been very pale in color, but now it presents a fairly natural degree of color. He suffered from constant thirst, which he was compelled to assuage frequently. He is now no longer troubled with thirst. He traveled this time from Manchester to London without wanting anything to drink on the journey, and required to get out at Bedford only to pass water. He assured me that his first journey to me was by no means so free of incidents either as to incomings or outgoings of liquid. He stated that he felt now very much better in health altogether. I requested him to pass water just before he left, but he felt so little inclination that he doubted whether he could. However, he passed about six fluid ounces.

"Although I had no reason to doubt Dr. Jones's diagnosis, I thought I would, before writing this note, obtain independent confirmation of the fact that the patient's complaint was beyond doubt diabetes. I accordingly asked my neighbor, Dr. Goodhart, to examine the urine for me. Dr. Goodhart, after remarking that the color of the urine was somewhat exceptionally good for a diabetic, found that its specific gravity was 1.032, and that it contained plenty of sugar and no albumin. He has kindly permitted me to use his name for the purposes of this note so far as concerns these facts respecting the quality of the specimen of urine that I submitted to him.

"The quantity of phosphorus that the patient took may be estimated from the basis that each of the 'perles' contained one thirtieth of a grain of phosphorus dissolved in oil. So that, for the first three

days of his phosphorus treatment, he took a tenth of a grain a day, and for the remaining seven days he took a fifth of a grain daily. From such experience as I have in the administration of phosphorus internally I should be disposed to say that he was fairly under the influence of phosphorus; moreover, he has just begun to experience a slight but decided degree of nausea from its use.

"In what manner the phosphorus has acted in controlling the diabetes, as it seems to me it unquestionably has acted, I am not prepared to offer any kind of opinion. That the administration of phosphorus acts most decidedly on the liver is well known, because, in undue and over prolonged doses, phosphorus is capable of producing fatty degeneration of the liver. This circumstance would seem to afford the clew to its marked action in this case in controlling diabetes; but I am not prepared to assert that this is the correct explanation. It is possible that the effect of the phosphorus may be due to its action on the nervous system.

"In any case, the circumstance seems to me well worthy of record in the columns of the 'Journal,' because I venture to think that, when the question comes to be sifted by observers more competent than myself, it will be found that phosphorus exerts a very potent action in the control of diabetes."

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

REASONS WHY PHYSICIANS SHOULD  
SUBSCRIBE FOR THE

# New York Medical Journal,

EDITED BY FRANK P. FOSTER, M.D.,

*Published by D. APPLETON & CO., New York.*

---

**B**ECAUSE: It is the *LEADING JOURNAL* of America and contains more reading-matter than any other journal of its class.

**B**ECAUSE: It is the exponent of the most advanced scientific medical thought.

**B**ECAUSE: Its contributors are among the most learned medical men of this country.

**B**ECAUSE: Its "Original Articles" are the results of scientific observation and research, and are of infinite practical value to the general practitioner.

**B**ECAUSE: The "Reports on the Progress of Medicine," which are published from time to time, contain the most recent discoveries in the various departments of medicine, and are written by practitioners especially qualified for the purpose.

**B**ECAUSE. The column devoted in each number to "Therapeutical Notes" contains a résumé of the practical application of the most recent therapeutic novelties.

**B**ECAUSE: The Society Proceedings, of which each number contains one or more, are reports of the practical experience of prominent physicians who thus give to the profession the results of certain modes of treatment in given cases.

**B**ECAUSE: The Editorial Columns are controlled only by the desire to promote the welfare, honor, and advancement of the science of medicine, as viewed from a standpoint looking to the best interests of the profession.

**B**ECAUSE: Nothing is admitted to its columns that has not some bearing on medicine, or is not possessed of some practical value.

**B**ECAUSE: It is published solely in the interests of medicine, and for the upholding of the elevated position occupied by the profession of America.
