"The *os externum* was lacerated from her previous labor. The upper portion of the cervical canal was narrowed by dense cicatricial tissue, so that its diameter was about 2 centimetres. Antero-posterior diameter of pelvis was 10 centimetres; transverse diameter, 14 centimetres.

"The anatomical diagnosis is accordingly: *Rupture of the uterus, with old, firm cicatricial contraction of the cervix uteri.*"

The case is rare, inasmuch as the cicatricial contraction was situated at the internal os and the lower uterine segment. Dilatation by incision or other artificial means was impossible. When cicatrices are limited to the lower part of the canal, which is of more usual occurrence, the obstacle to the birth of the child is usually removed by the employment of the knife to sever the limiting bands.

Again, the case furnishes a new illustration of the fact that in spontaneous rupture the laceration is not of necessity confined to the thinned lower uterine segment, as has been maintained by some of the extreme partisans of Bandl's theory.

The early performance of the Cæsarean section or of the Porro operation would probably have saved the patient's life. At the late period of her admission to the hospital either operation would have partaken of the nature of a forlorn hope.

As a supplement to the foregoing history, I hope I shall not be trespassing too much on ground familiar to my audience if I briefly review the usual mechanism of uterine rupture and the means at our disposal of combating the mischief done. Spontaneous rupture during labor is not so rare an event that those engaged in busy practice can afford to be ignorant of the means of combating the tendency to a fatal result by all the resources of modern science.

To Bandl belongs the merit of showing that nearly all ruptures begin in the lower uterine segment. In normal labors during each pain the fundus and body of the uterus thicken while the lower segment is stretched and thinned by the ovum or the presenting part of the fetus. So long as no obstacle exists which hinders the descent of the ovum or the fetus, this process ends in the conversion of the uterus and vagina into a continuous canal. Ordinarily in advanced

\* Read at the fifth annual meeting of the Fifth District Branch of the New York State Medical Association, held in Brooklyn, May 28, 1889.

labor the lower circumference of the body is distinguished from the stretched lower segment by a thickened ridge termed the contraction ring, or the ring of Bandl. In easy labors this ring is often but slightly indicated and is found in the neighborhood of the pelvic brim.

When, however, the descent of the fetus is hindered by any cause, the resistance of the ligaments which hold the uterus in position is overcome by the continued retraction of the fundus and body, and as a consequence the contraction ring is withdrawn upward, the lower segment is thinned, and in extreme cases nearly the entire uterine contents may occupy the distended passive inferior segment. Under these circumstances the contraction ring is strongly marked and may be felt through the abdominal walls above the pubes, or even in the neighborhood of the umbilicus. This movement upward of the contraction ring is limited somewhat by the pelvic and round ligaments and by the direction of the abdominal pressure. As these restraining agents operate more efficiently in first than in subsequent labors, it is not difficult to comprehend the relative frequency of rupture in women who have borne many children. Bandl reports nine cases of rupture in multiparae to one in the primiparous woman. As a result of the continued retraction of the body of the uterus the lower segment may become so distended as to form little more than a membranous covering to the fetus, and the conditions favoring rupture are established. It has been maintained upon theoretical grounds that spontaneous rupture is arrested by the contraction ring. This is certainly the rule when there has been no active intervention. My own case shows, however, that the rule has its exceptions.

Undoubtedly the popularization of Bandl's teachings has contributed greatly toward the adoption of an intelligent prophylaxis in difficult labors. Thus the physician knows that a dangerous attenuation of the lower uterine segment is liable to result from the presence of a hydrocephalic head, from a neglected shoulder presentation, or where the descent of the child is hindered by pelvic contraction, by cicatricial tissue, or by tumors obstructing the parturient passage. The situation of the contraction ring, which, when well defined, can usually be felt through the abdominal walls, furnishes in many cases an index of the degree of the threatened danger. The risks are further increased in cross-births and in lateral and anterior displacements of the uterus, owing to the augmented pressure exerted under such conditions upon a limited portion of the already overdistended tissues.

If rupture occurs under these circumstances we can not wash our hands of responsibility. We know that the faulty uterine positions should have been early corrected by judicious bandaging, that the hydrocephalic head should have been reduced in size by puncture, and that in all forms of obstructed labor there is a time when patient waiting ceases to be a virtue and active intervention is demanded. This is not the place for the complete consideration of the resources of our obstetric art. But the new learning teaches us that when the uterine efforts have proved unavailing to fix the presenting part, and the increasing distance of the contraction ring from the pelvic brim points surely to a

dangerous thinning of the uterine muscle, the physician must decide promptly upon the indicated measures of relief. These in head presentations are version, craniotomy, and the Cæsarean section. In neglected shoulder presentations only cautious attempts at version are justifiable. If turning is attempted, the operator should never forget to support the head with one hand through the abdominal walls in such a way as to relieve the strain upon the overdistended tissues. In case of failure, the persistent use of rude force is criminal. The alternatives from which choice should be made are decapitation of the child and the Cæsarean section.

My object in dwelling upon these points is the fact that I do not believe that uterine rupture is by any means so rare as statistics would seem to indicate. Statistics do not take into account innumerable cases buried out of sight by ignorance or by silence.

While insisting, however, upon a rule of personal accountability as regards the obstetric attendant, it is necessary to recognize that to Bandl's scheme there are exceptions. Now and then cases are reported in which primary rupture has occurred in the fundus and in the body, and where the lower segment has given way without antecedent signs or warnings. Thus I once witnessed an instance of spontaneous rupture in a woman with an ample pelvis who had previously given birth with ease to nine children. The head of the child presented and no abnormal condition of the soft parts was recognizable. There was nothing to account for the occurrence excepting a supposed vulnerability of the uterine tissues.

Rupture may be complete or incomplete. In the latter the tear is confined to the muscular structures and the peritonæum remains intact. This is more likely to occur in lateral tears at the site of the folds of the broad ligaments, though, owing to the relatively loose attachment of the peritonæum at the lower segment, incomplete ruptures are not necessarily confined to these points. In most instances the haematomas resulting from the bleeding vessels dissects up the peritonæum for a certain distance beyond the tear.

In the complete form the peritonæum likewise gives way, but often to a less extent, and in these cases dissection of the peritonæum from the uterine muscle beyond the borders of the tear would seem in many instances to show that a certain interval had existed between the rupture of the muscular tissues and that of the peritonæum.

When the shock, the sudden stoppage of the uterine pains, the recession of the presenting part, the bloody discharge, and the lateral tilting of the fundus or its apparent disappearance in the case of the passage of the entire child into the abdominal cavity have led to a diagnosis of rupture, the first indication for treatment is the speedy removal of the child. In selecting the manœuvre by which this is to be accomplished—*i.e.*, whether by forceps, by version, by craniotomy, or by laparotomy—the important consideration to be kept in view is that it shall to the least extent possible increase the dimensions of the already existing rent.

In general terms it may be stated that with an undilated cervix, or in cases of extreme pelvic contraction, or after the passage of the head and arms through the rupture,

and in all cases where the child passes entirely into the abdominal cavity, laparotomy is the more conservative measure. Not only is there less shock, but the opening of the abdomen enables the operator to remove effused blood and amniotic fluid from the peritoneal cavity. Still, the not uncommon impression that the ruptured uterus furnishes a promising field for abdominal surgery does not take into account that in so many of the cases where laparotomy is clearly indicated the patient is practically moribund. Even our most enthusiastic salpingotomists are disposed to restrain their benevolent impulses in the presence of impending death.

The employment of the suture to close the uterine wound, in view of recent Cesarean successes, sounds reasonable, but it is to be borne in mind that with ragged borders infiltrated with blood, with the peritonæum stripped off, and sometimes with emphysema of the subperitoneal connective tissue, the conditions for union are in no wise comparable to those which exist in the Cesarean section. The Porro operation promises fairer results, though the deep situation of the tear makes it difficult to secure a healthy pedicle. Godson collected seven cases, all of which terminated fatally, but Slavjansky and Fontana have each more recently reported a recovery after the Porro operation.

When the abdomen is opened, even if hesitation is felt about the deep suture or complete extirpation, there should be none concerning the suturing of the peritoneal surfaces. The rupture is thus converted into an incomplete one with its more favorable prognosis.

When the child can be removed by the natural passages without increasing the extent of the rupture, and the latter is confined to the lower segment, laparotomy is of doubtful value. In many such cases recovery *quoad vitam* has been obtained by the employment of antiseptic irrigation and filling the gap with antiseptic gauze. Drainage at the same time should be secured by means of iodoform wicking, or the bent rubber tube passed for an inch or two beyond the torn borders. Drainage and packing are most effective when the tear is situated in the posterior wall. The plan of treatment recommended is, of course, only effective where no infection of the abdominal cavity has taken place at the time of rupture. The best results are obtained, therefore, in cases of incomplete rupture. At the same time that drainage is used, compression of the fundus and body should be employed by means of the hands through the abdominal walls, and, in case of hemorrhage, effective aid can be furnished by pressure made upon the aorta. It may be necessary to maintain manual compression for hours. Finally, a carefully graduated compress should be placed around the uterus to maintain firm contractions. For this purpose I prefer to employ the hydrostatic bag, which I now show. It is of rubber, of a disc shape, and furnished with a tube by which it is partially filled with water. In the condition under discussion and in all forms of post-partum hemorrhage I have found the bag most effective. It adjusts itself nicely to the contour of the contracted uterus, and sometimes has seemed to me to work as intelligently and as surely as the skilled hand of the operator.

I have stated that by drainage a fair number of recov-

eries have been reported so far as life was concerned. In a portion of them, in a recent discussion before the Vienna Obstetrical Society, it appears that there was not a complete *restitutio ad integrum*, an opening into an adjacent sac, either formed by the folds of broad ligament or by false membranes, persisting after removal of the dressings.

**CASE II.** *Patient with Kyphosis; Pregnancy complicated by Pendulous Abdomen; Cesarean Section, with Fatal Termination to Mother, Child living.*—Ellen M., aged twenty six, native of England, unmarried; father died of phthisis at the age of fifty-six; three brothers and five sisters living and in good health. Patient was a healthy child and had no sickness until she was six years old. At that time she fell down four stone steps, striking her back upon the corner of one of them. She could not raise herself and had to be carried to her bed. After three days she got up, but noticed pain on trying to straighten her back. Weeks afterward a swelling formed at the seat of injury. An abscess followed which discharged for about five years. It then healed, but subsequently broke out again, and has discharged intermittently up to a year ago. The consequent spinal deformity has increased continuously. There have likewise been psoas abscesses on both sides opening at the groin, and there are marks of old sinuses on the outer side of either thigh.

Patient was admitted to the hospital December 12, 1888. According to her recollection, she menstruated last in the early part of April. On examination, the patient was found to measure fifty-one inches. Owing to the extreme kyphosis, the three lower ribs overlapped the ilia. The space between the sternum and the symphysis was greatly diminished, so that the uterus in its development had been directed forward and outward. On admission, the fundus was four inches below the level of the pubic wall. For four months previous the patient had suffered constant pain in the back and on the left side; the bowels had been constipated, but no uneasiness had been experienced from pressure on the bladder.

The indication for Cesarean section resulted not so much from the pelvic contraction, though the outlet was greatly narrowed, as from the faulty position of the uterus, which directed the head backward and high up above the promontory. Rectification was rendered impossible by the nearness of the sternum to the symphysis. With the limited space at our disposal, with the elevation of the presenting part, and with the acute angle formed by the body of the uterus with the cervico-vaginal canal, it seemed impossible to devise any plan of extraction by the natural passage which would not have subjected the inter-vaginal tissues to the certainty of fatal laceration.

At about eleven o'clock in the night of December 13th labor pains began quite suddenly and severely, recurring by twelve o'clock at five minutes' intervals. At midnight a hypodermic injection of seven minims of Magendie's solution of morphine was given with the view of delaying labor until daylight. The patient fell asleep and rested until seven in the morning, when the pains recurred. I was then sent for. The patient was bathed, and the bowels, which had previously been regulated with care, were emptied by a large enema.

*December 14, 1888.—(Notes taken by Dr. D. H. McAlpin, Jr.) Operation by Cesarean section. Operator, Dr. Lusk. Assistants on the operation, Dr. Greene and Dr. White. Ether by Dr. Maury. Instruments passed by Dr. Williams. Ligatures held by Dr. Anderton. Baby cared for by Dr. C. A. Smith.*

9.57 A. M.—Hypodermically, Magendie's solution, m. viij; atropine, gr.  $\frac{1}{60}$ .

10.00.—Temperature, 98·6° F.; pulse, 142; respiration, 28.  
 10.05.—Ether started by Dr. Maury with Clover's apparatus; less than half a pound used during the operation.  
 10.09.—Chloroform, 3 ij, given.  
 10.12.—Incision from left of umbilicus down to symphysis pubis.  
 10.14.—Abdominal cavity opened.  
 10.16½.—Uterus drawn out of abdominal cavity.  
 10.17½.—Rubber ligature placed about uterus.  
 10.18.—Incision made into uterus.  
 10.19.—Left arm of baby presented; cried loudly; given to Dr. C. A. Smith.

Post-mortem appearance of the uterine wound.

10.19½.—Cord tied.  
 10.20.—Cord cut.  
 10.21½.—Placenta detached entire; a slight tear, less than an inch, at lower left side, starting from and at right angles to the vertical incision.  
 10.22.—Douche of Thiersch's solution used to cleanse the inner side of uterus, and passed through into vagina.  
 10.24.—Began suturing uterus; deep sutures of heavy silk, fourteen in all.  
 10.31.—Began tying sutures.  
 10.39.—Put in eighteen superficial sutures, five of which were of very fine silk.  
 10.52½.—Loosened ligature about neck of uterus.  
 10.53.—Hypodermic of ergotin, gr. ij.  
 10.56.—Ligature about uterus removed.

10.57½.—Returned uterus into abdominal cavity.  
 10.58.—Abdominal sutures of wire, twelve in all.  
 11.09.—Sponges removed from abdominal cavity.  
 11.17.—Finished tightening wire sutures. Operation ended.  
 11.34.—Ergotin, gr. j, whisky, fl. xx, hypodermically. Dressed and in bed.

1 P. M.—Temperature, 98·8°; pulse, 138; respiration, 19. The operation was purposely performed in a leisurely way. The time occupied from the first incision to the introduction of the last suture was an hour and five minutes. The slight lateral tear mentioned in the report occurred in the extraction of one of the shoulders. Owing to the small amount of abdominal space, the uterus, even after the removal of the child, subjected the abdominal stitches to a severe strain. As the sequel will show, it was a mistake in this instance not to perform the Porro operation.

For the first four days subsequent to the operation all went well. The temperature varied between 99° and 101·5°, but the higher temperature was of short duration, lasting usually for an hour or two at midnight. The pulse ranged from 110 to 120, and was of good quality. The stomach behaved well. The kidneys secreted freely. The external wound presented a most favorable appearance. Save for occasional attacks of flatulence, there was little discomfort experienced. No doubt was entertained of a favorable result, the unruly disposition of the patient alone furnishing ground for anxiety.

The fifth day (December 18th) began in the same promising manner, but in the early afternoon the patient became restless, tossed about in bed, and tore at her dressings. Remonstrances were unheeded, vomiting set in, tympanites developed, and the pulse became very rapid. In spite of every form of stimulation, collapse was well marked by nine o'clock, and death occurred at eleven. The only high temperature reached was at 7 P. M., when for a brief period it rose to 103·5°.

It was not easy to account for the cause of this sudden change. It was presumed by those of us who had watched the case that an insidious form of septic peritonitis had closed the scene; but at the autopsy, which was made on the 20th inst., there

was no serous or purulent exudation, and no trace of peritonitis except a slight redness at the line of the abdominal incision. The uterine wound had healed kindly, and the organ itself appeared healthy. The only disturbance evidenced in the process of repair was a slight superficial separation of the tissues at the site of the lateral tear mentioned in the history.

Of special organs, the intestines, the spleen, and the kidneys were healthy. The heart weighed eight ounces. On the right side the cavity was dilated and the walls were hypertrophied, and the left ventricle appeared contracted, whereas eccentric hypertrophy of the left ventricle is the rule in pregnancy. The aortic valves were normal; the mitral valves were somewhat thickened. The most sur-

prising result of the autopsy, however, was the size of the lungs. The diaphragm reached on the right side to the upper border of the third rib, on the left to that of the second rib. The right lung weighed six ounces, the left lung five ounces, while the combined weight in the healthy female is from thirty to forty ounces. The liver weighed three pounds and twelve ounces, was marked by the ribs, and showed evidences of fatty degeneration. At this stage it was concluded that death was the result of the patient's feeble resisting powers, due in part at least to the small size of the lungs, the unhealthy liver, and other consequences of extreme spinal deformity.

It was then decided to remove the pelvis. In attempting this, large abscesses were found, distending the sheaths of the psoas muscles, having their origin in various bone at the site of the angle in the vertebral column. How far this condition was responsible for the fatal termination is, of course, a matter of conjecture. But, when one considers the small amount of space originally existing in the abdominal cavity, it seems probable that the encroachment made upon it by the pus collections must have contributed largely to gas accumulations in the intestines, to discomfort to the patient, and to interference with the processes of digestion and absorption—functions of the utmost importance for securing convalescence. I can not but feel that, had Porro's operation been performed, the increased room thereby obtained would have been of signal advantage. Still, from the outset the unruly disposition of the patient was a heavy weight in the balance.

### DYSPHONIA SPASTICA.\*

BY FREDERICK I. KNIGHT, M. D.,  
BOSTON.

I WOULD like briefly to introduce this important subject, in the hope that, as so little has been published on it, I may perhaps be the means of drawing out some unpublished observations by members of this association, before whom the subject has not been presented in many years.

All of our members are probably familiar with the disturbance of the voice-production which has been variously named aphonia spastica, aphthongia laryngea spastica (Gottschheim), stammering of the vocal cords, spasms of the tensors, speaker's cramp, etc.

In this phenomenon there is evidently a spasmodic action of the muscles of phonation or respiration, or both, which gives rise in the majority of cases to a high-pitched, jerky, and feeble voice. There is sometimes a long intermission in the vocal sound, so that the term aphonia spastica might be appropriate, but in the cases which I have seen the term dysphonia spastica seems more suitable.

The fellows of the association who were present at the meeting in Boston in 1882 will remember a patient with this affection well marked, whom I presented to them. Since that time I have seen only four cases, which leads me to agree with Sir Morell Mackenzie, who considers the affection a very rare one, rather than with Mr. Lennox

Browne, who considers it "so far from being rare, in its milder forms one of almost every-day occurrence." We do sometimes see a condition of somewhat similar nature in cases of acute laryngitis, and perhaps such a condition might be easily overlooked when a patient was suffering from acute inflammation of the larynx, and every effort was being made to prevent him from using his voice, but I am sure that as a chronic condition the phenomenon can not be overlooked, and consequently, in my experience, I believe that it is rare.

Three of my cases occurred in men, and one in a young woman of twenty years. One of the men was a physician, one was in mercantile business, and one was superintendent of a factory, where he was obliged to talk to men in the midst of much noise. His mother, moreover, was deaf.

The woman, whom I have recently seen, is a teacher, and the trouble developed while she was forcing herself to talk with a hoarse cold. This is the lightest case I have ever seen, and one in which it might appear that the prognosis was better than usual, though the condition has already existed a year. There is no obstruction in the nasal passages, but, on the contrary, a tendency to an atrophic condition, and a slightly offensive secretion. Under the use of cleansing solutions for the nose, strychnine internally, and cold douches, the spastic symptoms have improved, but they return, especially on conversation with strangers. Massage of the larynx or compressing the wings of the thyroid improves the voice temporarily. There is nothing especially morbid on laryngoscopic examination, and I was not able in any of the cases to obtain a view of the spastic phenomenon. It seemed as if the simplicity of the required vocal effort prevented nervous excitement.

In the absence of post-mortem examinations it is impossible to say what the lesion is in these cases.

It seems natural in some, with Schech, to call the affection a co-ordinated neurosis of occupation, like writer's cramp, etc. Cases like that of Heymann \* suggest a central lesion, while such cases as E. Hoffman's † and Hering's ‡ suggest a probable reflex origin.

The lesion and mechanism are probably not always the same.

My own experience in these cases would lead me to regard the prognosis as very unfavorable, but of course would be favorable in reflex cases dependent on a cause capable of removal, as in Hoffman's patient, who was cured by the removal of the hypertrophied anterior ends of the middle turbinates.

I have nothing to add to the long list of therapeutic measures laid down by Schech and others—viz., absolute rest of the voice, galvanism of the throat and brain, vocal exercises, tonics, and cold douches on the head and neck, which latter remedy cured one of Schech's cases after all other treatment had failed.\*

I would like by this communication to draw out from

\* "Internationales Centralblatt für Laryngologie, etc., vol. iii, p. 260.

† "Monatsschrift für Ohrenheilkunde, etc., 1885, p. 428.

‡ "Internationales Centralblatt," vol. ii, p. 571.

\* "Monatsschrift für Ohrenheilkunde," 1885, p. 1.

the fellows of this association a report of every case of chronic aphonia or dysphonia spastica which has been cured or modified by treatment.

## REPORT OF TWO CASES OF BUCCAL TUBERCULOSIS.\*

BY C. E. BEAN, M.D.,  
ST. PAUL, MINN.

I AM aware that during the past two years a great deal has been written on this subject and quite a number of cases reported, but I wish to add these recorded cases, for only by additional notes and evidence can data satisfactory and conclusive be obtained.

One of these cases is of especial interest, not only from the extent of the ulceration, but from the fact that it was developed in a female, this being, so far as I can learn, only the third case of the kind on record.

**CASE I.**—Henry B., farmer, aged thirty-two, was seen in May, 1887, and gave the following history:

Up to four years before this time he was entirely healthy, with the exception of a slight cough. After working hard all of one afternoon, drawing water from a well with a bucket, he expectorated a slight amount of blood. This had continued at intervals ever since, though at no time was there any severe hemorrhage. Up to a year ago he had not lost any flesh. In the fall of 1886, whenever he smoked or chewed tobacco, his tongue would sting and burn and get very red. This troubled him to such a degree that he was forced to give up the use of tobacco altogether.

Four months ago (January, 1887) a sore appeared on the right side of the end of the tongue, commencing like a crack. Two months ago (March, 1887) it began to grow larger, and has gradually grown ever since. At this time the tongue began to swell, and is now (May, 1887) about twice its normal size, while an ulceration extends on the right side from the tip back as far as the middle, three sixteenths of an inch deep, with shelving edges. On the 4th of July, 1886, he caught a severe cold, and, following that, his voice was a trifle hoarse. In the middle of March, 1887, his throat began to get sore, and his voice grew gradually worse until, about ten days after, his voice had entirely disappeared.

Two years ago his weight was one hundred and fifty-five pounds; one year ago, one hundred and forty-five pounds; now only one hundred pounds. Unable to swallow any solid food, and only a small quantity of liquids.

*Examination of the Larynx* showed thickening and ulceration of the right free edge of the epiglottis and ulceration of both vocal bands their entire length.

*Examination of the Chest.*—Dullness on percussion over entire right lung, with moist râles. Bronchial breathing and dullness in apex of left lung.

**Family history:** Both parents living, and over seventy years of age. Father's sister died of phthisis. His three brothers and two sisters are healthy.

Temperature, 101.2° F.; pulse, 124; respirations, 34.

As the patient resided at a distance and it was plainly evident that he had only a few days to live, I sent him home and advised morphine hypodermically and cocaine locally to ease his intense suffering.

**CASE II.**—Mrs. S. was seen in August, 1887. Her history was as follows:

**Family history:** Mother died of consumption, aged forty-five, and a maternal aunt with the same disease, age unknown.

**Patient's history:** Up to three years before the time I saw her her health had been comparatively good. At that time, following a cold, she had protracted cough, with slight frothy expectoration. This continued for six months, when cough and expectoration almost entirely ceased, the cough being only in the morning and at night. About one year after the first symptoms she had, without any premonitory symptoms, a severe hemorrhage; slight hemorrhages followed, at intervals of from three to six months, up to the time I saw her. During the last two years the expectoration had been thick, firm, and yellowish-green in color.

Some time in the spring of 1887 (the patient thought in February or March) her tongue began to feel sore and stiff, with occasional severe pains, but mostly a dull aching.

About June there appeared, near the tip of the tongue on the right side, a small ulceration, which grew rapidly until, in August when I saw her, it had extended along the right side of the tongue, involving the lower portion of the tonsil and back wall of the pharynx on the corresponding side. The tongue was thickened, and the act of deglutition was accompanied by excruciating pain. The voice was thick and muffled, and it was only by an effort that any words could be articulated.

The ulceration was irregular in shape, with for the most part clean-cut edges. The floor of the ulceration was bathed in pus.

*Examination of the larynx* showed only a superficial inflammation.

*Examination of the lungs* showed extensive destruction of the right lung and consolidation of the upper lobe of the left lung. Temperature, 100°; pulse, 110; respirations, 28.

The following line of treatment was advised to the consulting physician:

Internally, cod-liver oil.

Locally, applications of oleate of cocaine (5 per cent.) made to the entire ulceration, and afterward lactic acid to be carefully applied.

This patient lived two months, but at no time was there any improvement in the appearance of the ulceration or relief from the pain.

Tuberculosis of the tongue is to be especially distinguished from carcinoma and syphilis. When it is secondary it is not a difficult question; but the development of it primarily has been so frequently demonstrated, although it is in a large proportion of cases secondary, as to render its existence no longer a question.

It is distinguished from carcinoma by the absence of the glandular enlargement and the sharp lancinating pains characteristic of the latter disease.

From syphilis, outside of a positive specific history, the internal administration of antisyphilitic remedies alone can settle the diagnosis.

**Treatment.**—In neither of the two cases reported was there any opportunity for personal attention to treatment; indeed, both cases were so far advanced that no amount of treatment could have been of any permanent benefit.

The three plans of treatment most advocated are curetting, with subsequent applications of the cautery, excision of the tongue, and lactic acid.

In a paper on this subject read before this association in 1886, Dr. Delavan reports a case cured by excision.

\* Read before the American Laryngological Association at its eleventh annual congress.

Lactic acid has been very much vaunted, and one or two cases are reported as having been cured by means of this remedy, well rubbed into the ulceration; but the numerous failures to even afford temporary relief seems to demonstrate the fact that it is no more to be depended upon when the disease is situated in the tongue than when it has been developed in the larynx; and the result of treatment in that location has been disappointing.

Thorough and deep curetting, with careful and repeated applications of the Paquelin or galvano-cautery, offers the most efficient plan of treatment yet suggested for the primary manifestation.

When it is secondary to lung complications we are as powerless to arrest its progress as we have ever been.

#### NOTE ON THE OCCASIONAL TOPICAL USE OF SOLUTIONS OF SILVER NITRATE\* IN THE TREATMENT OF CHRONIC LARYNGITIS.\*

By SOLOMON SOLIS-COHEN, M. D.,  
PHILADELPHIA.

THERE are many subjects of greater scientific interest than the treatment of chronic laryngitis, yet very few of more practical importance to a large number of our patients.

The general questions of therapeutics, systemic and topical, of this affection have been so ably and thoroughly discussed in text-books and special articles by so many distinguished members of this body, that further elaboration now would be superfluous; and I simply desire to briefly communicate the results of personal experience during the last three or four years with a single agent, for the purpose of eliciting an expression of opinion from the competent observers present as to the real value of that agent—once overused, now over-neglected.

There is no necessity to report cases in detail. They have not been due to nasal disease or obstruction, nor have they been those in which all topical treatment is unnecessary. Where indigestion, constitutional disease, or diathesis have been present, these have, of course, received due attention—hygienic, dietetic, and medicinal. It is thus simply of topical applications for the relief of local conditions that I speak. We have all encountered cases of chronic laryngitis, especially in singers, clergymen, lawyers, traveling salesmen, public speakers, etc., in which, after all discoverable sources of irritation, local or general, have been removed, and approved topical treatment suited to the individual case has been faithfully employed for a longer or shorter time, improvement would take place up to a certain point and there stop. Perhaps all visible evidence of disease, except an irregular pinkish striping of the vocal bands, would have disappeared; or perhaps there would be a uniform faint coloration, or may be only a loss of luster; but something there would be that persisted and that prevented the patient from resuming with comfort full use of the voice in singing or speaking, or perhaps even in ordinary conversation for social or business purposes.

It is in such conditions as this, the last obstinate remnants of the disease, that I have derived considerable satisfaction from the topical use by sponge, cotton-wad, or brush of weak solutions of silver nitrate, about ten grains to the ounce, applications being made every day for two or three days until some congestive reaction was produced; after that at longer intervals. In the course of treatment, too, in some cases, before reaching the last stage above described, I have found recovery apparently hastened by occasionally substituting stronger solutions of silver nitrate, forty to sixty grains to the ounce, for the iodized glycerin, tannin, tar, or other routine application. A visible increase in congestion immediately follows the use of the silver solution; but this passes off quickly, and at the next visit great improvement is usually manifested. These applications are made once in about two or three weeks, according to circumstances. By thus using solutions of silver nitrate, not as a routine measure, but occasionally in the course of other treatment, as a topical stimulant—the strength of the solution being in inverse ratio to the progress of the case toward recovery—I believe that in very many of the cases in which topical treatment is indicated recovery may be hastened; and in particular that the troublesome final stage may be managed with greater ease than by the use of any other agent with which I am acquainted.

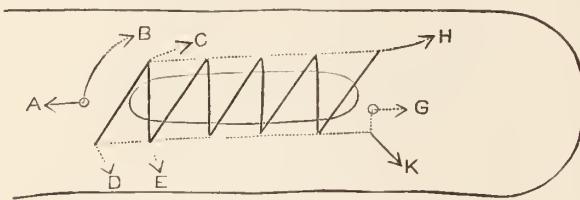

#### A CONTINUOUS SUTURE FOR THE INTESTINE AND OTHER ABDOMINAL VISCERA.

By CLARENCE L. LEWIS, JR., M. D.,  
HOUSE SURGEON, BELLEVUE HOSPITAL.

I HAVE noted that nearly if not all of the sutures employed to appose serous surfaces have the following objections brought against them—viz., first, that they are interrupted and do not hold the surfaces in close and even apposition; second, that all the tension of each stitch is placed upon a single thread; and third, but by no means the least, that the time required to place them jeopardizes the life of the patient. Meditating upon the possibility of obtaining a suture that would rectify these objections, and performing a few experiments, I have in the end secured a continuous silk suture that, in the opinion of many eminent surgeons, meets all the requirements. First, it is continuous and easy to execute, and holds the serous surfaces evenly in apposition; second, the tension, instead of being made by a single thread, is made by a side-stitch of an eighth to a quarter of an inch; and, third, it can be applied very rapidly. My only experiments have been upon the cadaver, with very happy results. This suture is especially adapted to wounds of the intestine and to complete resection of that viscus. The great difference between the sutures now used and the one I propose to describe is as follows: The stitches in my suture run along the sides of, as well as across, the wound. They are placed in position loosely until the suture is finished, and then the loops are caught and drawn taut. In its completed state the peritoneal surfaces, which are inverted, are supported by side pillows of silk, while the exterior shows cross retention threads. I use a small Hagedorn (curved) needle, threaded with small iron-dyed silk.

\* Read before the American Laryngological Association at its eleventh annual congress.

In a small wound of the intestine I first fix my suture with an ordinary Lembert stitche, and end it with the same stitche; but in a complete resection the suture finishes itself.

The drawing shows how simple the suture is. Commencing at the point A, we make an ordinary Lembert stitche. We next enter the needle at the point B, and, carrying it through the peritonaeum and into the muscular coat, bring it out at the point C. We next enter the needle at the point D, and in the same manner bring it out at the point E, opposite the point C. In like manner we proceed to the end, leaving small loops in each stitche. Our next move is to tighten the loops, beginning at the point D. When the loops have all been taken in, a Lembert stitche, G, is made to fix the end securely. These Lembert stitches are not required in the complete resection suture, as it is easy to see that the points B and K would be opposite, and could be readily tied with a square knot. Now, the question for consideration is, What faults *could* be found with this suture? I understand the word *could*, for I can think of but one—viz., Would there be any danger of strangulation of the tissues between the sub-peritoneal (dotted) lines and the edge of the wound? This is a question which I can not answer at present. But, even if it did occur, which is very improbable, the adhesion of the peritonaeum would prevent any infection, for, when the loops are drawn taut, the points B and D and the points E and C would become approximated, thus shutting that portion within the caliber of the intestine.

#### A CASE OF OVARIAN TUMOR IN A GIRL SEVEN YEARS OLD. OVARIOTOMY: RECOVERY.

BY W. D. HAMAKER, M. D.,

MEADVILLE, PA.,

LATE RESIDENT PHYSICIAN, UNIVERSITY AND PRESBYTERIAN HOSPITALS,  
PHILADELPHIA; MEMBER OF THE PATHOLOGICAL SOCIETY,  
PHILADELPHIA.

CASES of ovarian tumor before puberty are very rare. The youngest patient operated upon was that of Roemer, of Berlin, who removed successfully a congenital tumor from a child twenty months old, which proved to be a dermoid cyst as large as a child's head.\* Roemer collected a number of additional cases. Dr. Neville, of Dublin, operated on a child aged two years and eleven months; Buseh had a case at two years of age, and Aleott's patient was three years old. All of these cases were unsuccessful. Schwartz successfully removed a large proliferating tumor from a child, four years old, with prepubescent puberty. Barker had two cases, and Knowsley Thornton one case at seven years, while Spencey Wells, Cupples, and Chenoweth had each a case at

eight years.\* In addition to these cases collected by Roemer, Wegscheider reports a bilateral cystoma, in a girl twelve years old, which weighed about seven pounds, and Marjolin removed a multilocular tumor, weighing nineteen pounds, from a girl eleven years old. Gaillard Thomas removed, post mortem, a large tumor from a child aged three and a half years.† A second case, three years old, is reported, but the operator's name is not given.

Among one hundred and ninety-seven cases of dermoid cyst collected by Pauly, Lebert, and Olshausen, seven cases were in children under ten years of age.‡ A number of cases of sarcoma and carcinoma of the ovary, in those under twelve years, are reported by Olshausen and others. Lucas reported to the Clinical Society of London, in 1888, a case of round-celled sarcoma, which he had removed successfully in February, 1885, from a girl, seven years old, who had exhibited precocious puberty.¶

To these cases I wish to add a report of the case which recently occurred in my practice:

I was called to see Annie A., aged seven years, on October 22, 1888, and learned that her family history was good, no hereditary disease having existed, nor had there ever been a case of ovarian tumor in the family. There was no history of injury, nor had she shown any of the signs of puberty. She had been in good health until April, 1888, when she began to fail gradually in health, with pain in the left side and a slight tendency to bend forward in walking. During the spring and summer she continued to fail in health, and had considerable dyspnea. In August the parents first noticed abdominal enlargement, and also noticed the "blue veins" over the abdomen. During this time she had been treated for various diseases. When I first saw her she was anemic and very much emaciated. She was unable to lie down, on account of the dyspnea and pain just below the region of the liver. She was passing large quantities of limpid urine, which was low in specific gravity and without albumin.

At first, on account of extreme tenderness, the examination was very unsatisfactory. There appeared uniform enlargement of the abdomen, and the walls of the abdomen were quite tense. Fluctuation was made out, and dullness on percussion, except in the sides low down when she was lying on her back. I gave her an anodyne and a ferruginous tonic. Under these she was relieved of pain and seemed stronger in a few days. I aspirated her on November 4th, and drew off six pints of dark ovarian-like liquid, which, under the microscope, revealed the usual cells of ovarian fluid. After the aspiration a tumor of the size of a child's head could be made out, apparently growing from the left ovarian region. She was now quite comfortable, and in a few days was able to be about the house.

The operation of ovariotomy was now agreed to by the parents, and I placed her on a course of tonic treatment to prepare her for it. For two weeks she did very well, when the cyst began rapidly to fill again. The patient asked to have the operation postponed till after the holidays, and, although the tumor was enlarging very rapidly, this was agreed to, and the operation was set for January 3, 1889, when, at 11 A. M., I performed ovariotomy with strict antiseptic precautions. I was very kindly assisted by Dr. Eagleson, Dr. Cotton, Dr. Calvin,

\* "Brit. Med. Jour.," April 12, 1884.

† Olshausen, "Cyclo. of Obstet. and Gyn.," vol. viii, p. 80.

‡ *Ibid.*, p. 354.

¶ "International Jour. of Surgery," July, 1888.

and Dr. Carmichael. After etherization, a short incision was made from the umbilicus to a point an inch above the pubes. A few adhesions were found at the point of aspiration, and also the omentum was found adherent at several points. These were easily broken up and the contents of the cyst drawn off. The sac was now drawn from the opening, and, instead of arising from the *left* ovary, as it appeared after the former aspiration, it was found to be a cyst of the *right* ovary. There were one large cyst and several "daughter" cysts, and the tumor was attached by means of a long pedicle. The cyst had the glistening appearance of the ordinary ovarian tumor. The pedicle was ligated with strong silk, cut off, and dropped. No bleeding point required a ligature, and the cavity was quickly cleansed and the abdominal wound closed with silk sutures. A strip of lint well covered with carbolized vaseline was laid over the wound, and over this was laid salicylated cotton. Over this was placed a large pad of absorbent cotton and the bandage applied.

The patient quickly revived, and showed very few signs of shock. At 5 p. m. the temperature was normal and she vomited slightly. She required no catheterization, and, beyond the restless condition to be expected, there was nothing to note.

*January 4th.*—Morning temperature was 100.4° F., evening temperature 99.4°, pulse 132. During the day there was some pain and she was quite restless. Some bromide of potassium was given. A half-ounce of milk was allowed every two hours.

*5th.*—Temperature 99.4° in the morning, normal at night. Nervousness had disappeared, and she was doing very well. Milk increased to one ounce every two hours.

*6th.*—Milk increased to two ounces every two hours. At 10 p. m., after crying violently for something to eat, she fell asleep and had a profuse cold sweat with symptoms of beginning collapse. The temperature had been 100.4° in the morning, with the pulse at 108. In the evening after the sweat the temperature was 97° and the pulse 90. No pain or tenderness was noticed. Applied heat and gave some whisky and milk.

*7th.*—Doing well. Morning temperature 98.4°, pulse 90. Slight tenderness was felt over the umbilical region. Tongue clean; slight inclination to have bowels moved. Added beef tea to the diet.

*8th.*—Temperature normal, pulse 90 and strong. Dressed the wound and found no tympanites and very little tenderness. Ordered castor-oil and syr. rhei aromat.,  $\frac{1}{2}$  f 3 j.

*9th.*—Bowels moved well.

*10th.*—Doing well.

*13th.*—Removed the stitches.

*24th.*—Patient is in good condition and general health rapidly improving. No hardness or tenderness at any point. Allowed her to sit up.

From the last-mentioned date she rapidly improved and made a good recovery. At the present time (July 30th) she is in excellent health.

883 WATER STREET.

**Laryngeal Ulcers in Typhoid Fever.**—Dr. Antonoff publishes in the "Ejenedélnaya Klinicheskaya Gazeta" the result of a series of histological examinations of laryngeal ulcer occurring in typhoid fever. The earliest change, he says, is a hyaline degeneration of the membrana propria of the capillaries and smaller arteries, and in places of the connective tissue of the mucous membrane. The epithelium dies from coagulative necrosis. The reticulum formed becomes the seat of micrococc. There is no inflammatory infiltration in the broken-down tissue, but the process takes place on the border between healthy and morbid tissue. If the ulceration goes deeper, perichondritis with formation of pus, phlegmonous inflammation of the soft parts, and loosening of the fibers of the cartilage take place."—*Lancet*.

THE  
NEW YORK MEDICAL JOURNAL,  
*A Weekly Review of Medicine.*

Published by  
D. APPLETON & CO.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, SEPTEMBER 14, 1889.

CONVENTIONAL MOURNING OR HEALTH?

Whom shall it be? The time has come to choose. Unmitigated mourning must go. A movement has been started in England to put an end, if possible, to the present irrational mourning costumes that exact of women great personal inconvenience, physical injury, and disastrous expense. The conventional costume of a well-bred widow, for instance, possesses every known quality of unhygienic, non-aesthetic, and costly dress. Proper exercise while she is wearing it is out of the question. Seclusion is secured in ways less barbarous perhaps than inducing deformity of the feet, yet our occidental mourning customs effectually keep women within doors. The heart of the stoutest warrior might quail within him if a quiet stroll required the wearing of two crape veils, each six feet long originally and only slightly shortened, but not lessened in weight, by a hem half a yard deep—one veil to be worn over the face and the other to hang down the back! The widow's gown must be inconveniently long, the outside garment must cling, and both must be made of inelastic, non-inspiring material. Add to this that within, which passeth show, and the picture is pretty black. The husband who loses his wife escapes such outward trappings, not being forced to adopt any special habiliments that can incommodate or injure him. A simple band around the hat announces the fact of his changed circumstances and secures freedom from idle questions. Strange inconsistency of custom that thus discriminates between men and women, and always to the disadvantage of women in point of health!

In this new crusade of common sense Lady Harberton takes the lead, setting forth in a recent article the reasons why existing mourning costumes should be abandoned by all sensible women. The materials now in use are in themselves injurious, the dyes being often of a poisonous nature and frequently injuring the skin and ruining the complexion. What woman who indulges in conventional mourning escapes the staining process resulting from damp crape? Only the victim can know the energy and perseverance required to remove from brow and neck the literal clouds that gather from such a cause. The harm to the exterior of the body is easily perceived. Not less injurious is the irritation to the respiratory tract caused by minute loose particles of poisonous crape. To the pang of separation is added the thought that our loved ones are condemned to suffer physical discomfort for a year or two, and, possibly, disease for an indefinite period.

Lady Harberton suggests that persons should provide in their wills that no mourning should be worn for them. This might have a modifying effect upon things as they are. But,

of course, the whole matter, like every other social and domestic question, rests entirely with oppressed womankind. Women are not driven into mourning at the point of the bayonet. The Quakers get along very well without wearing it at all. The sincerity of their grief is not questioned because they remain clad in every-day attire. If precedent is needed, it is pleasant to know that it already exists, and to realize the fact that scores of calm-browed, earnest-hearted nineteenth-century women have not needed mourning as a protection or a means of expression in the hour of affliction. Grief would seem to be a personal affair, sacred to the individual, needing no outward sign of its having taken the world into its confidence, and having thus cast something of a shade over the joy of living—said joy not being an inexhaustible mine in any community. Rather is the stock in perpetual need of increase.

The moral influence of mourning is even more to be deplored than its physical effects. Gloomy garments, darkened rooms, all the subdued life of the house of mourning, depress the powers, lower vitality, and absorb an undue quantity of domestic ozone. Such unwise fashions tend to stultify the wonderfully recuperative powers of time and nature. Hugging grief to keep it warm is a poor business, and so is the worship of sorrow. Speed the day when it shall be considered unbecoming to wipe our eyes upon the public or to dust our neighbors' shelves with any personal woe! All that Diogenes asked of Alexander was that the king should stand out of his sunshine. And we all have a right to demand of society that it take its mourning out of humanity's sunshine.

#### THE CAUSE OF SLEEP.

M. BROWN-SÉGUARD, as will be seen by an abstract in Dr. Rabinovitch's report on physiology, published in this number of the Journal, combats the theory that attributes the induction of sleep to a change in the state of the intracranial circulation leading to cerebral anaemia. He rests this contention mainly on his having frequently observed a hyperæmic condition of the base of the brain, and especially of the medulla oblongata and the spinal cord, during sleep, and on the regular recurrence of sleep in certain animals that have had the cerebrum removed. In place of the theory of cerebral anaemia he sets up that of peripheral irritation—somewhere and of some sort—exercising an inhibitory action on mental activity, on the action of certain muscles, and perhaps to some extent on the circulation and respiration. As regards their proximate cause, he places both natural and hypnotic sleep on the same footing.

It is to be noted that he admits that contraction of the blood-vessels of the retina and of the cerebral lobes, implying anaemia of the brain, is one of the phenomena of incipient sleep, although he looks upon it—for what reason we are not told—as one of the details that "confirm the existence of irritations." A diminished supply of blood to the brain may, therefore, have something to do with the induction of sleep, even in the light of the considerations brought forward by M. Brown-Séguard. Moreover, it is reasonable to assume that one

of his arguments—that of the regular recurrence of sleep in animals deprived of the cerebral hemispheres—proves too much for the theory of inhibition of mental activity, unless it can be shown that mental activity has its seat in some other organ than the brain. Besides, it may well be doubted whether the abolition of mental action is all that goes to make up sleep, even with the addition of more or less inhibition of the cardiac and pulmonary functions, or whether mental processes are altogether in abeyance during sleep, leaving dreams to be accounted for as proceeding from some other part of the economy than the head. In addition, we may ask what the periodically recurring peripheral irritation is, and where it is located, that normally starts the nocturnal inhibition that leads to sleep. Evidently "there are more things in heaven and earth than are dreamed of in our philosophy," and M. Brown-Séguard, granting his demolition of the theory of cerebral anaemia, has not replaced it with one that is beyond cavil.

#### MINOR PARAGRAPHS.

##### THE SPREAD OF TUBERCULOSIS AND ACTINOMYCOSIS IN ANIMALS AND MAN.

THE "British Medical Journal" contains an analysis of a report of the Royal Agricultural Department for 1888, dealing largely with four diseases—tuberculosis, actinomycosis, anthrax, and rabies—which have a direct relation to preventive medicine and human pathology. The report refers to a lack of power to confiscate certain kinds of diseased cattle, and recommends that authority be given to seize, in fairs, in markets, and in transit, all animals that come under the denomination of "mincers" or "wasters"—so called because they are bought up by the beef-sausage makers and because they are in the last stage of emaciation from tuberculosis. The report gives the latest available information as to the production of actinomycosis in man: 1. The evidence that it is readily transmitted from the food-animals to man has not been adduced. 2. Animals have the disease mostly in the tongue, at points which have been abraded by certain kinds of fodder. 3. Barley is the fodder which makes these abrasions with special frequency; and is, also, most abundantly infested with the ray-fungus. 4. That barley can produce the disease in man seems to be shown by one case, quoted from Soltmann by the authors of the report above referred to. A boy, aged eleven years, accidentally swallowed an awn of barley, and an intrathoracic abscess resulted, in the pus of which the ray-fungus ultimately appeared. The awn also was discovered at the time of the first evacuation of pus. Professor Crookshank is the author of that part of the report which treats of the actinomycotic disease in animals and man. He has written one of the fullest and best accounts of the disease that have yet been published. His article is copiously illustrated with microscopic and other lithographs, and it covers nearly eighty pages in the volume, which contains in all 336 pages. The amount of space accorded to this subject is an evidence of the growing importance accorded to it.

##### THE HOT-AIR TREATMENT OF CONSUMPTION.

The latest contribution on this subject is by Assistant Surgeon J. J. Kinyoun, of the Marine-Hospital Service ("Weekly Abstract of Sanitary Reports," Sept. 6, 1889), who took patients that presented about the same physical signs, the diagnosis having been verified in each by examination of the

sputum. Each sitting lasted an hour, the temperature of the inspired air varying from  $120^{\circ}$  to  $230^{\circ}$  C., though that of the expired air was only between  $65^{\circ}$  and  $80^{\circ}$  C.; there was not more than one degree difference in the rectal temperature taken at the beginning and at the end of the sitting. Sometimes there was a decrease of from five to ten beats in the pulse, and rarely there was an increase by as much as twenty beats. The respiration was sometimes quickened, sometimes retarded, never more than five respirations; sometimes there was no change. There was slight improvement in the patients, but in all of them it seemed due to increased chest expansion. A test experiment was made with a tuberculous patient that inspired cold air; the rectal temperature, pulse, and respiration curves in the chart accompanying his history are closely comparable to those in the charts of the patients that used Weigert's apparatus, and, like them, he improved while indulging in the pulmonary gymnastics. In the last analysis of all the reported cases treated by this method, the beneficial results seem consequent upon the increased expansion of the lungs; and all the reporters agree that the air when it reaches the lungs is so moderately hot that at best the germicidal effect is limited to the bacilli in the bronchi.

#### THE NEW VOLUME OF THE "INDEX-CATALOGUE."

THE tenth volume of this great work takes the vocabulary from "O" to "Pfutsch." It brings the number of author-titles of volumes to 54,298, and of pamphlets to 93,002, and the number of subject-titles of books to 107,419, and of journal articles to 336,772. It continues the work with the same scrupulous carefulness that has been apparent in all the preceding volumes. A noteworthy article is the one headed "Periodicals," with references also to "Bibliography" and its subheadings, to "Journals," and to "Journalism." It is a list of the periodicals more or less complete files of which are contained in the Library of the Surgeon-General's Office, and includes 211 pages. The exact titles are given, with their changes from time to time, the names of the editors, and the places and forms of publication. Such a list is of incalculable value, especially to those engaged in editorial work.

#### THE HUDSON DISPENSARY.

This institution, which was started four years ago, has recently issued its first "Announcement and Report," by which it appears that its physicians are called upon nearly five hundred times a month, a fact which, as the report states, "sufficiently attests the necessity to which it ministers." The dispensary is situated at No. 425 West Forty-second Street. A pleasant feature of its organization is the fact that the gentlemen of the attending medical staff constitute the board of managers also.

#### TYPHOID FEVER IN BROOKLYN.

THE meetings of the Medical Society of the County of Kings will begin again on the evening of the 17th inst., with a report of the Section in Medicine. Typhoid fever has been set down as the leading subject for discussion at two or more of the early meetings. The subject of autumnal typhoid fever in Brooklyn has come up from time to time before the society, but has not hitherto been systematically debated.

#### THE STATE BOARD OF HEALTH ON CIGARETTES.

THE board's analyst, Professor Willis G. Tucker, of the Albany Medical College, has lately rendered an exceedingly sensible report on cigarettes. He shows the utter fallacy and ab-

surdity of current allegations to the effect that the tobacco or the paper of which the best-known brands are made is adulterated with any poisonous or injurious substance whatever; but he justly alludes to the facility afforded by cigarettes of using too much tobacco and of inhaling the smoke, and deplores their unrestricted sale to mere boys.

#### ALOPECIA AREATA TRAUMATICA.

At the recent meeting of the Missouri State Medical Society, Dr. Dumesnil recounted a case of alopecia areata in which there was a history of traumatism. The patient, about a year before, at the age of fifteen years, was hit upon the head by a falling shingle, a small scalp wound being produced. This healed promptly, but about a month later the hair began to fall out in spots and has continued to do so until the alopecia threatens to become complete.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 10, 1889:

DISEASES.	Week ending Sept. 3.		Week ending Sept. 10.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	112	19	53	7
Scarlet fever.....	21	2	24	3
Cerebro-spinal meningitis.....	3	2	0	0
Measles.....	21	1	7	1
Diphtheria.....	66	22	62	12

The American Pædiatric Society will hold its annual meeting in Washington, at the Army Medical Museum Building, on the 20th and 21st inst., one afternoon session being held at the Johns Hopkins Hospital, Baltimore. Besides an address by the president, Dr. A. Jacobi, of New York, papers are announced as follows: "Notes on a Case of Ataxia in a Child of Ten Years," by Dr. A. D. Blackador, of Montreal; "A Study of some of the Bacteria found in the Dejecta of Infants afflicted with Summer Diarrhoea" (second communication), by Dr. W. D. Booker, of Baltimore; "Noisy Respiration," by Dr. Dillon Brown, of New York; "Prolapsus Recti due to a large Stone in the Bladder in a Girl Three Years Old," "Two Cases of Nystagmus associated with Choreatic Movements of the Head in Rhachitic Babies," "Septic Diphtheria with Unusual Sequelæ," and "Personal Prophylaxis in Diphtheria," by Dr. A. Caillé, of New York; "Subcutaneous Emphysema in Children," "The Necessity of Prolonged Rest after some Attacks of Diphtheria," and "Two Cases of Carpo-pedal Contraction," by Dr. Charles Warrington Earle, of Chicago; "The Treatment of Scarlet Fever and its Complications," by Dr. J. Henry Fruitnight, of New York; "Spurious Meningocele" and "Double Empyema," by Dr. Francis Huber, of New York; "Aneurysm in Early Life," by Dr. A. Jacobi, of New York; "A Contribution to the Summer Diarrhoas of Infancy," by Dr. John A. Jeffries, of Boston (by invitation); "Tuberculosis of the Testis in Childhood," by Dr. H. Koplik, of New York; "Cases of Spastic Paraplegia," by Dr. Thomas S. Latimer, of Baltimore; "Scarlet Fever," by Dr. L. N. Love, of St. Louis; "The Artificial Feeding of Infants," by Dr. Arthur V. Meigs, of Philadelphia; "A Case of Diaphragmatic Hernia, with Operation," and "The Apparent Physical Contraction involved in the Reintlation of a Collapsed Lung while an Opening remains in the Pleural Sac," by Dr. J. O'Dwyer, of New York; "A Case of Simple Muscular Atrophy of the Facio-scapulo-humeral Type" and "Cerebral Sclerosis

in Children," by Dr. William Osler, of Baltimore; "Diphtheria," by Dr. A. Seibert, of New York; and "Some Practical Points in the Diagnosis and Treatment of Malarial Disease in Children," by Dr. H. N. Vineberg, of New York. Papers of which the titles are not given are announced to be read by Dr. W. T. Northrup and Dr. J. L. Smith, of New York, and Dr. V. W. Vaughan, of Ann Arbor.

**An Army Medical Board** will be convened in New York on October 1st, for the examination of such persons as may be properly invited to present themselves before it as candidates for appointment in the Medical Corps of the army. Application for an invitation should be addressed to the Secretary of War, stating date and place of birth and place and State of permanent residence, accompanied by certificates, based on personal acquaintance, from at least two persons of repute, as to citizenship, character, and moral habits. Testimonials as to professional standing, from the professors of the medical college from which the applicant graduated, are also desirable. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a regular medical college, evidence of which, his diploma, must be submitted to the board. There are now nine vacancies in the grade of assistant surgeon. Further information regarding the examinations and their nature may be obtained by addressing the Surgeon-General, U. S. Army, Washington, D. C.

**The Medico-legal Society** will hold its next meeting at the Hotel Buckingham, on Wednesday evening, the 18th inst. Dr. C. A. F. Lindorme, of Florida, will read a paper on "The Hygiene of Internments"; Dr. Joseph Jones, of New Orleans, will read a paper on "The Classification of the Varieties of Insanity"; and the president, Mr. Clark Bell, will give a *résumé* of a recent trip to Europe.

**Change of Address.**—Dr. R. R. Martino, Brooklyn, to No. 530 Macon Street.

#### Society Meetings for the Coming Week:

**MONDAY, September 16th:** New York Academy of Medicine (Section in Ophthalmology and Otology); Medico-chirurgical Society of German Physicians; Hartford, Conn., City Medical Association; Chicago Medical Society.

**TUESDAY, September 17th:** American Gynaecological Society (Boston—first day); American Association of Obstetricians and Gynaecologists (Cincinnati—first day); American Dermatological Association (Boston—first day); New York Academy of Medicine (Section in Theory and Practice of Medicine); Medical Societies of the Counties of Kings and Westchester, N. Y.; Ogdensburg Medical Association; Connecticut River Valley Medical Association (Bellows Falls, Vt.); Baltimore Academy of Medicine.

**WEDNESDAY, September 18th:** Association of American Physicians (Washington—first day); American Gynaecological Society (second day); American Association of Obstetricians and Gynaecologists (second day); American Dermatological Association (second day); Harlem Medical Association of the City of New York; Northwestern Medical and Surgical Society of New York (private); Medical Society of the County of Allegany (quarterly), N. Y.; New Jersey Academy of Medicine (Newark).

**THURSDAY, September 19th:** Association of American Physicians (second day); American Gynaecological Society (third day); American Association of Obstetricians and Gynaecologists (third day); American Dermatological Association (third day); New York Academy of Medicine; New Bedford, Mass., Society for Medical Improvement.

**FRIDAY, September 20th:** Association of American Physicians

(third day); Chicago Gynaecological Society; Baltimore Clinical Society.

**SATURDAY, September 21st:** Clinical Society of the New York Post-graduate Medical School and Hospital.

#### OBITUARY NOTES.

**David Tilden Brown, M. D.**, formerly of New York, died at his home in Batavia, Ill., on the 4th inst., in the sixtieth year of his age. The deceased, who was a graduate of the College of Physicians and Surgeons, was for many years the superintendent of the Bloomingdale Asylum. About fifteen years ago, on account of ill-health, he resigned his position and went abroad. On his return, he made his home in Batavia, where he devoted his declining years to the pursuit of agriculture. He is remembered by the New York profession as an alienist of high attainments and as a man of extraordinary nobility and gentleness of character—qualities that endeared him to those who had friends in Bloomingdale and to those of the inmates themselves who were not too demented to recognize them.

**Henry J. Menninger, M. D.**, died at his home in Brooklyn, on the 8th inst. He was a native of Germany, but came to this country while young, and was educated in New York. He graduated in 1863 at the University Medical College. He at once entered the medical corps of the army and served until 1868. From 1865 to 1868 he was surgeon-in-chief to the Marine Hospital at Newbern, N. C. He left North Carolina about 1874 and settled in Brooklyn. He was active in politics and was chosen coroner, a position for which he was admirably fitted.

#### Proceedings of Societies.

##### NEW YORK ACADEMY OF MEDICINE.

*Meeting of May 11, 1889.*

Dr. A. H. SMITH in the Chair.

**The Therapeutic Value of Oxygen Inhalation, with Experiments on Animals under High Pressure.**—Dr. W. G. THOMPSON, in a paper with this title, dealt with the question of the actual effects of an oxygen atmosphere under various pressures, from the standpoint of scientifically conducted experimentation, and exhibited his animals and apparatus used in this work. He alluded to the great variety of opinions now current as to the beneficial effects of breathing extra amounts of pure oxygen. Some regularly gave it when dealing with any one of a number of common symptoms or conditions, such as anaemia, dyspnoea, albuminuria, vital depression, etc., and quite commonly oxygen was administered without any definite aim. He should, therefore, aim to present a clearer estimate of the real value of the agent.

By causing the inhalation of oxygen at a pressure of fifteen additional pounds to the square inch the amount of oxygen which was carried in loose combination in the blood-plasma could be slightly increased possibly, but it had not appeared experimentally that an increased oxidation was thus caused, or that any measurable increase of the amount of oxygen so carried took place. Under ten atmospheres of pure oxygen something over three per cent. of the natural volume of oxygen in the plasma was taken up, but even here the effects were vague, and probably a person was not conscious of them, such various symptoms had been reported by different patients. The tem-

perature was not elevated. Very high pressures, and especially any sudden variations in pressure, up or down, caused convulsions, heart failure, or circulatory disturbances. The same could not be produced by common air under the same pressures. In other words, more air-pressure than oxygen-pressure could be withstood, perhaps because in the former case the vitiated air made its exit more readily. In either case the patient would suffer more or less from the retention of nitrogenous waste matters (perhaps having convulsions), since there was little gaseous diffusion possible in the lung when the atmospheric pressure was changed much; and the carbon dioxide itself did not escape from the deeper air-vesicles. Hence the blood did not take up oxygen, and the carbon dioxide and other waste products accumulated. As had been said, this process went on more rapidly under a high pressure of oxygen than under that of ordinary air. Finally, the high pressure caused an increased solution of carbon dioxide in the blood.

He would next consider the effects of the inhalation of oxygen under pressure where the respiration was already abnormal. The speaker here passed in review the various causes of dyspnoea, including neurotic dyspnoea. His experiments had shown that pure oxygen under pressure would relieve dyspnoea due to foul air, as common air under pressure would not. When in any way the respiratory passages were narrowed to below their normal caliber and dyspnoea resulted, both air and oxygen acted to relieve it, but he was convinced that if given under high pressures the result was impaired. Congestion of the lung from the same cause he had found to be greatly relieved by oxygen inhalations. Dyspnoea due to diminished lung space for aeration of the blood was also greatly relieved by oxygen, if under pressures between four and ten pounds, but was made worse by high pressures (such as of thirty pounds). His conclusion was that oxygen under moderate pressures helped certain forms of dyspnoea. A moderately increased pressure of common air would lower the temperature of animals suffering from septicæmia; he therefore was quite ready to believe that a moderate degree of extra pressure in oxygen given by inhalation was of real advantage.

Now, as to the general therapeutic uses of the agent. Its actual employment in this city had grown to very considerable proportions, from two hundred thousand to three hundred thousand gallons being consumed every year. Not only was it used largely in poisoning by gases, drowning accidents, and various forms of dyspnoea, but also in anaemia and other altered or impure states of the blood. He was convinced that in anaemia, chlorosis, and other such conditions oxygen had but slight advantages over fresh air under slight pressure. It invariably failed to relieve the symptoms of blood poisoning or to remove cyanosis. Subjective dyspnoea, however, was commonly relieved. In innumerable instances it had failed to give any improvement of condition in diphtheria. In a case of poisoning by illuminating gas where he had seen oxygen tried it had neither helped the cyanosis nor saved life. In his own experience he had found little encouragement for using it in affections of the circulation due to defective heart action. But with a diminished respiratory surface, such as occurred in pneumonia, or where the entrance of air was impeded, as in asthma accompanied by much bronchial secretion, he had got very good results; also where from any reason expansion of the thorax was poorly carried on or painful. Uraemic dyspnoea was often relieved; here was a prompt and easy means of aid in one of the worst forms of suffering known, although without effect on the outcome of the disease.

Dr. J. W. ROOSEVELT took various exceptions to the theoretical conclusions of the author's, and in particular doubted that in increased pressure there was any regularly present

advantage. As regarded the therapeutical value of the agent, he thought the active inhalations had much to do with the benefit resulting to the patient. In treating anaemia he had at different times tried iron alone, oxygen alone, and iron and oxygen together; the best results had come from the combination. He thought the mode of action which made this benefit possible might resemble that which came into play where diminution of lung surface was at the bottom of the trouble, and that in anaemia also the haemoglobin might be not always or nearly saturated. Such must be the case whenever cyanosis was relieved by oxygen, as occasionally it was. It was rational to suppose that oxygen inhalations had a practical value in anaemia when we considered that there was a diminution in the amount of haemoglobin, and that oxygen gas would increase the amount of oxygen carried into the circulation—as he believed it did—to an extent which was but slight, he would admit, and yet important in its results.

Dr. GEORGE L. PEABODY remarked that it was very difficult to determine the effect of a single remedial agent or agency in chronic diseases, and especially where it was only one of several remedies being used. If the disorder was one having a tendency toward recovery, the problem was still more difficult. The value of oxygen must be considered as vague and unsettled still. The history of its entrance into modern therapeutics was of itself suggestive of uncertainty. Substances rich in oxygen had once been given by the mouth with the expectation of oxygen being liberated in the stomach (where their only possible action could be that of a caustic) and so reaching the general economy. Next came the idea of giving oxygen by the lungs, under pressure, so as to cause the plasma to absorb extra amounts of it. The fundamental fact remained that haemoglobin could be trusted to satisfy its affinity for oxygen in common air. The amount of haemoglobin in the blood was therefore of far more importance to the tissues, provided the air-passages were not obstructed. From a clinical standpoint also he doubted that any aid worth mentioning was obtained from the use of oxygen, as such, in a vast majority of the cases in which it was now administered. The pulmonary gymnastics incidentally involved in the taking of oxygen explained to him largely any good results which might be noticed.

Where secretions were thrown out in such amount on the sides of the air-passages as to give the same condition in the lung as if the air inhaled were unduly attenuated (as in severe catarrhs, emphysema, pleurisy, or diphtheria), it might have a definite usefulness. In asphyxia from chlorine or illuminating gas its use might be considered; but he could testify that it had failed to give any aid in many cases of this sort where he had tried it. Finally, patients suffering from anaemia and chlorosis were likely to recover anyhow, both with and without the many remedies so constantly appealed to. He thought the aid to be had from oxygen in this result was unproved and physiologically improbable.

Dr. BEVERLEY ROBINSON differed decidedly with Dr. Peabody as to the utility of oxygen in the treatment of disease, having seen many veritable instances where absolute relief had followed its use. In anaemia, after trying vainly all the other remedies, he had met with unmistakable successes by using pure oxygen (and its purity was very important too). In the albuminuria of atrophic nephritis he had found oxygen inhalations of decided value, not in diminishing the amount of albumin, but in aiding the general nutrition. Whatever else it might or might not do, it helped digestion and assimilation, and certainly it had a very wide utility here. In phthisis it was good practice to use it, not only because it forced the patient to expand his lungs, but also because it acted as an antiseptic agent—did no harm, and might do some good; and finally it

improved the nutrition—always a good thing to accomplish. Oxygen should therefore be added to whatever other agencies we could bring to bear. Where we could not send phthisical patients out of the city, oxygen should be given. In view of certain clinical facts, it was rational to suppose that it might act as a stimulant to the formation of haemoglobin where this was deficient. Purely experimental results in the use of oxygen were not the absolute tests for medical men; the effects on patients were. It was unfortunate that oxygen was expensive still, and that we were not always sure of its being pure. It was often necessary to give it for a long period of time. Finally, the old writers were not far from the truth in their statement that "quiet, peace, happiness, and euthanasia" could be secured by the use of oxygen at the end of phthisis or cardiac diseases.

Dr. W. MENDELSON said he must take sides clinically with Dr. Peabody. In anaemia occurring in old men he had seen some remarkable results follow the inhalation of ten gallons of oxygen every day, but he believed that here the exercise involved, and the influence on the mind, had much to do with the benefits resulting. He had frequently seen dyspnoea relieved, and that too where the patient presently died; to relieve the distress of the last moments was certainly a good object to accomplish.

The CHAIRMAN remarked that the developments of the evening's discussion showed him that the results of his own work of twenty years ago still held good. There was one fact not yet touched on, in connection with the fact that under ordinary circumstances the blood was not entirely saturated with oxygen, namely, that the point of absolute saturation corresponded in the working economy of the body with the extreme of physiological demand for oxygen, such as might arise in a boat-race. This maximum demand was not made when quiet respiration was going on under an ordinary degree of bodily activity. So we had a rather wide margin between ordinary and extreme oxygenation of the blood and the conditions making either necessary; that is, we had a capacity for appropriating an additional supply of oxygen whenever the tissues made the demand.

If a pathological condition presented where enough oxygen was not being supplied to the blood, but would be if there was more expansion of the chest and a greater rapidity of respiration, and where the patient was unable to do the required amount of breathing himself, there oxygen gas might be supplied with benefit. He would thus also define the limit of the therapeutic value of oxygen, including within it, of course, cases where the access of air to the lung was impeded by obstructed passages. From an entirely clinical standpoint he had seen the most striking benefit follow the administration of oxygen gas to patients having suffocative bronchitis or poisoned by opium.

As regarded opium narcosis, he had once supposed that in that condition, owing to the slowing of respiration, not enough oxygen could be drawn into the lung to satisfy the haemoglobin of the blood, so that the condition was largely one of poisoning from lack of oxygen. But subsequently he had fallen on cases of opium poisoning where the rate and depth of respiration were unchanged and yet the narcosis was profound, and where, nevertheless, the administration of oxygen had given prompt relief. He had seen eight or nine such instances. He must suppose that the blood did not here find itself able to take up oxygen from ordinary air with anything like the ease that it could from an atmosphere of pure oxygen.

In considering the questions connected with inhalation of oxygen under pressure, there were many factors to be regarded. The sudden lowering of atmospheric pressure at the end of each inhalation of a gas under pressure explained many of the effects; we then had either changes in the distribution of the blood in

the lung and elsewhere, or a retention of certain gases in the blood.

Dr. THOMPSON objected to the chairman's inference as to partial and complete saturation of the blood with oxygen under ordinary and under extraordinary bodily exertion. Blood taken from an animal when in a state of repose was found to be saturated with oxygen; it would take up no more if placed in a chamber of pure oxygen.

In the case of the boat's crew in a boat-race, there we had an increase of respiration and heart-action and body metabolism simultaneously, but it had not been shown that the absorption of oxygen by the blood was increased in the proportions of volumes; the quickening of the circulation easily provided for an increased supply of oxygen to the tissues.

The CHAIRMAN added that in his experiments made years ago he had kept animals in a pure oxygen atmosphere for periods of four days at a time, and on taking them out had found no changes either in weight, appetite, circulation, or general nervous state which could point to any differences in the vital effects of pure oxygen and those of ordinary air.

##### SECTION IN ORTHOPEDIC SURGERY.

*Meeting of April 19, 1889.*

Dr. A. B. JUDSON in the Chair.

**Psoas Abscess following Pott's Disease.**—Dr. V. P. GIBNEY presented a patient, a girl fourteen years old, on whom he had operated for double psoas abscess following Pott's disease of nine years' duration. The carious vertebrae were evidently consolidated when, in last November, large abscesses were discovered, and the patient was brought under treatment. On the right side the tumor was incised in Scarpa's space, a long forceps was passed under Poupart's ligament through the iliac fossa and into the lumbar region, and a counter-opening was made on the forceps along the border of the erector spinae muscle. Pieces of bone escaped with the pus. The cavity was curetted and the bone scraped gently. With antiseptic dressing and injections of carbolic-acid solution (1 to 40), and a one-percent. creolin solution, both wounds closed in a month. The left side was then operated on by simple incision and drainage. Large quantities of bone detritus were scooped out with the finger. A sinus still remained on the left side, from which a piece of bone was occasionally discharged.

The patient was exhibited as showing the advantage of Owen's method over attacking simply the sac and not the whole suppurating tract. The speaker believed it would have been better to treat both sides according to Owen's method; but in general he doubted the propriety of doing this operation during exfoliation, which would render a subsequent operation necessary. It was also important that the patient should be in pretty good condition.

Dr. R. H. SAYRE had used injections of peroxide of hydrogen in large abscess cavities, with better results than he had seen from carbolic, bichloride, or boro-salicylic solutions.

Dr. GIBNEY said a similar experience had been reported by Dr. Vance.

The CHAIRMAN thought an objection to operating in these cases was that for the natural incarceration of the pus and detritus we substituted an artificial opening, requiring antisepsis to hasten cicatrization. If these accumulations were doing no harm, it was better to leave them for removal by natural processes; and, if in due time they perforated the skin, the general and local conditions were ready to promote evacuation and speedy cicatrization.

Dr. J. A. WYETH said that an operation was indicated when large abscesses were situated on exposed parts of the body, and liable to injury and subsequent septic complications. He recalled the case of a woman who, thirteen years after being considered cured of Pott's disease, slipped and fell on a large gluteal abscess. The accident speedily gave rise to symptoms of sepsis with high febrile movements, and several operations under ether were necessary for the removal of bone detritus, which was spread through the gluteal muscles. The patient ran great risks, but finally recovered. He had had other similar cases. A psoas abscess behind the peritoneum causing no trouble should be left alone, but one pointing in the thigh, back, or other exposed situation should be operated upon, as the danger of the operation was almost nil.

Dr. N. M. SHAFFER was reminded of the history of a patient with Pott's disease and an abscess occupying the gluteal region and the anterior part of the thigh. The child fell, striking the gluteal tumor. The immediate symptoms were alarming, but, without the adoption of any special treatment, the accident resulted in the entire disappearance of the abscess. If there were any means of determining with certainty when an abscess from Pott's disease contained bony detritus, it would be preferable to operate; but while spondylitis was still active it was better to postpone an operation as long as possible. He recalled a case of Pott's disease and hip-joint disease, which he had been watching for several years, where spicula of bone as large as the end of the finger were expelled in a sudden and violent attack of coughing. The bone came undoubtedly from the cancellous structure of the sixth or seventh cervical vertebra. The patient was relieved at once, and physical examination showed that very little trouble had been caused by the entrance of the bone through the lung tissue into the bronchial tubes.

**Knock-knee; Club-foot; Deformity following Hip Disease.**—In a paper on "Osteotomy" Dr. WYETH related two cases in which he had corrected in-knee and out-knee in the same patient by double osteotomies. The patients were three and a half and four years old, respectively. Both were discharged entirely relieved. Strict antisepsis was followed and the limbs were dressed in plaster of Paris in a position of over-correction. He preferred MacCormac's incision on the outer side and just above the capsule, since the saphena vein and anastomotica magna artery were not endangered, as in MacEwen's operation on the inner aspect of the thigh. He also briefly related three cases in which patients, aged thirteen, eighteen, and twenty-six years, respectively, had been relieved of the deformity following hip disease and restored to good power of locomotion by operations on the femur. The method pursued was by Gant's osteotomy below the lesser trochanter. The after-treatment had been with Buck's extension and Hamilton's long splint. In one of the patients there had been double hip disease. Two months after the left femur had been operated on, the right one was operated on; and four months after the date of the first operation the patient was discharged cured, with good power of locomotion.

He also related two cases in which congenital talipes equino-varus of the most exaggerated type had been corrected with good recovery, and with the feet in excellent shape. Tenotomy of the tendo Achillis, tibialis anticus, and tibialis posticus was first done—the first two subcutaneously, and the last by open incision, the tendon being dissociated from that of the flexor digitorum and divided on an aneurysm needle. The operation was completed by an osteotomy as follows: An incision was made on the outer side of the dorsum, exactly over the point of greatest convexity; the tissues were lifted from the tarsus with an elevator, and a conical section, including portions of the calcaneum, astragalus, cuboid, and scaphoid, was removed. The

rule should be to remove all parts which prevented replacement of the foot. The foot being brought into its normal position by eversion and rotation, aseptic dressing and plaster of Paris completed the treatment, the result of which had been excellent.

Dr. GIBNEY said that the anatomical point raised in the paper concerning supracondyloid osteotomies certainly commended the operation of MacCormac. Although in-knee and out-knee in the same subject were rare, he had seen many instances of multiple deformity among Bohemians and Italians. He had recently done a sextuple osteotomy at one sitting, and was treating an ununited fracture of the right tibia, all the others having united.

The CHAIRMAN thought that in congenital talipes the reduction of the deformity by mechanical or operative means was easy; but that was a small part of the necessary treatment. So long as the patient was growing, he must be under occasional observation, and, if necessary, made to wear for a few months, at intervals of two or three years, a brace fitted to the needs at the time, in order to prevent threatened relapses. In the deformities of the knee there was a special reason for preferring mechanical means of correction, because there was the advantage of the leverage found in the tibia and femur, while in club-foot there was only the tibia on one side and, on the other, the short and many-jointed foot.

Dr. H. L. TAYLOR said that late observation of the results of treatment was of special importance in orthopaedic practice. If surgeons and orthopaedists would report the condition of patients five, ten, or more years after their dismissal, a more intelligent choice of methods could be made.

Dr. SHAFFER said that his experience with mechanical appliances in the treatment of talipes had led him to think that many severe operations were performed on patients who could be better treated by traction. He recalled a case in which there was confirmed equino-varus, although three or four tenotomies and five or six osteotomies had been performed. He had applied the "external lateral stretcher," and the patient was now walking on the flat of the foot. He referred to the interesting question whether osteotomy was advisable when there was some motion in the hip joint. In a patient on whom Dr. W. T. Bull had operated, some motion was found after etherization. The reduction of the deformity by osteotomy had been followed by persistent traction with the hip-splint, and good position and slight motion had both been retained.

Dr. GIBNEY believed that the presence of motion was not a contra-indication to the operation. About six months before, he had performed Gant's operation for a right-angled deformity. The flexion had been reduced from 90° to 15°, and the limb was retained at 15° of flexion by a traction apparatus for three or four months, when it was removed and the patient allowed to walk about with a high shoe. After about six weeks the flexion had increased to 25° or 30°. Traction was reapplied, and the limb was again being brought down. He recognized the necessity of protective apparatus in order to retain or increase the result secured by operation.

Dr. WYETH had operated in several cases where there was motion, and had refused to do it in others. In a patient whom he had seen with Dr. L. A. Sayre there had been considerable motion, and he had done a tenotomy for temporary relief postponing osteotomy.

Dr. R. H. SAYRE said that, in the case referred to, improvement had followed the tenotomy, but an apparatus was necessary to prevent a return of the deformity. He thought that in some cases sufficient reduction of the flexion might be brought about by section of the psoas and iliacus muscles. This had been done in one case in which, although the operation was

subcutaneous, injury of the vessels had been avoided. By open section this danger would be avoided.

Dr. J. D. WILSON expressed surprise at the frequent mention of elevations of temperature in the history of Dr. Wyeth's cases, which had been treated antiseptically. Had our teachings been too absolute, or did such temperatures really indicate imperfect antisepsis?

Dr. WYETH replied that "the temperature of reaction," occasionally as high as 102°, occurred in the first twenty-four hours, but it usually fell to normal in forty-eight hours. Traumatism, ether, shock, and the use of sublimate combined to produce this reaction, which might still be called an aseptic temperature.

He closed the discussion by saying that the simplicity and safety of osteotomy had been shown by the cases he had reported. While no case of equino-varus treated during the first two years of life should require tarsotomy, neglected cases would present themselves where nothing but tarsotomy would give relief. The operation might give considerable foreshortening to the foot, but one could certainly correct the deformity, however great, by removing enough bone; and, if this was properly done, he believed it to be real conservatism.

#### JEFFERSON COUNTY, ALABAMA, MEDICAL SOCIETY.

*Meeting held at Birmingham, August, 1889.*

W. E. B. DAVIS, M. D., in the Chair.

#### Ileo-colostomy in which Davis's Catgut Mats were used for Approximation.—Dr. JOHN D. S. DAVIS reported the history of a case.

On July 16, 1889, at 8 p. m., his brother, Dr. W. E. B. Davis, had been called by Dr. Charles and Dr. C. T. Drennen to operate on W. G., a negro, aged forty-two years, a furnace-tender, for intestinal obstruction. He had found the patient *in extremis*; temperature 101° F., pulse 135. He had made a diagnosis of perityphilitic abscess, suppurative peritonitis, and faecal obstruction in the ileum in the region of the ileo-caecal valve, and had expressed the opinion that the man would die in a few hours, regardless of any operation. He had opened the abdomen from the symphysis to midway between the umbilicus and the ensiform appendix, and had found a perityphilitic abscess; general peritonitis, due to rupture of the abscess sac; compound flexion of the ileum bound by strong adhesions in the region of the ileo-caecal valve; faecal impaction, accompanied by great distension of the intestine above the seat of obstruction. The abdominal cavity and abscess sac were thoroughly cleansed by irrigations of hot water. The ileum was opened near the point of obstruction and emptied of nearly one gallon of impacted faeces, liquids, etc. A second opening was made at the junction of the jejunum with the ileum to allow the escape of a large quantity of gas in the upper part of the bowel. These openings were closed by Czerny-Lembert sutures. At this point in the operation the patient had seemed to be holding out well; and, to avoid the necessity of resorting to the formation of an artificial anus, he had been requested to do an anastomosis by means of his approximation catgut mats, with the view of establishing the continuity of the intestines. The ileum above the seat of obstruction was brought in communication with the ascending colon below the point of obstruction by making one incision an inch and a half in length in both intestines at a point opposite the mesenteric attachments, and the visceral wounds were carefully united by means of approximation catgut mats. A catgut mat, to which were fastened four braided silk threads, was introduced through each opening into the intestines. The lateral sutures were passed through the margins of the wound

to prevent ectropion of the sides of the incisions. After the mats and sutures were in place, the wounds were brought in contact and the four sutures tied, which accurately coaptated the serous surfaces of both bowels over an area corresponding to the size of the mats. This procedure occupied only three minutes. No outside safety sutures were applied, as the approximation was perfect and the coaptation sutures were well protected between the approximated serous surfaces.

A glass drainage-tube was fixed in the lower portion of the wound and the peritoneum closed by a continuous catgut suture. The abdominal wall was closed by interrupted silk sutures and an antiseptic dressing applied. The time occupied in the whole operation was sixty-five minutes. The patient rallied well, was comfortable, and gave favorable signs of recovery for fourteen hours. Three hours after the operation had been completed the patient had a small faecal operation, when a large quantity of gas had passed *per rectum*.

The temperature, ten hours after the operation, was 100° F., and the pulse 120. Fourteen hours after the operation, while unattended by the nurse, the patient attempted to get up by himself and died suddenly from exhaustion.

*Necropsy Two Hours after Death.*—Abdominal wound united. Omentum adherent to the wound at the points of operation and incisions. The anastomosis was perfect and the new opening was sufficiently large to nearly equal in size the lumen of the ileum. Adhesions between the two serous surfaces of the bowel were firm, and extended a little beyond the line of approximation, as could be seen from the specimen removed at the autopsy.

While this had been a desperate case for any operative interference, the speaker was sure that the patient's life had been comfortably prolonged ten or twelve hours by the opening, emptying, and washing out the abdominal cavity.

He expressed his regrets that Dr. Drennen had not seen the patient early enough to be able to give him the benefit of the anastomosis at a time more favorable to recovery. Even at the late hour in his illness at which the operation had been performed, he did not think a better, safer, or easier means for restoring the intestinal continuity could have been had. The specimen which the speaker showed clearly illustrated the possibility of the future popularity of intestinal anastomosis.

He was not at all doubtful of the great advantage it possessed, when obstruction existed, over the tedious, difficult, and often fatal operation of circular enterorrhaphy. The mechanical principle was clear, the method was practicable, and the application had been clearly demonstrated. Resections with circular enterorrhaphy, lateral apposition with suturing, and plastic operations, though of little value, had had their day, the objection to them being a dangerous consumption of time, long exposure to infection, frequent leakage, and abscesses. While the application of the principle to man had yet been limited, the method offered advantages many times as great as those of the old operations as to mortality, and could be done in one sixth of the time.

Intestinal anastomosis undoubtedly appealed to the practical surgeon, and would find greater favor every day; and it was no jejune proposition that its appeal to favor rested on the technique of the operative procedure rather than upon the basis of inductive logic that had that mixture of a small amount of truth with a large amount of error which gave so many popular procedures their temporary plausibility and mischievous tendency.

The speaker gave a description of how to make his catgut mats,\* and demonstrated on the dog how easily they could be

\* "Virginia Medical Monthly," May, 1889, pp. 166 and 167; "Alabama Medical and Surgical Age," May, 1889.

applied. He exhibited a dog weighing twenty-five pounds on which he had done three laparotomies—one for omental grafting and two for anastomosis. He also stated that the catgut mats, if not already on hand, could be made of any desirable size by the most ignorant nurse in an hour.

The CHAIRMAN agreed with the author of the paper that his catgut mats were superior to Senn's decalcified bone plates and Abbe's catgut rings. He thought the experimentations of the author had proved conclusively that the mats possessed all the advantages stated for them. Referring to the case reported, he said that this was the second case in which he had opened the abdomen three days after symptoms of rupture of a perityphilitic abscess with general suppurative peritonitis. While these had been hopeless cases, the operation had given great relief in both instances, and certainly had not shortened the lives of the patients. He had operated in both cases in order to give the patient the benefit of a complete diagnosis, and with the hope that he might find a condition less serious than he had diagnosed. He said that the lesson taught in the report of these late operations, with fatal results, was the importance of early diagnosis and prompt operative procedure. He thought if the abdomen could be opened within the first twenty-four hours the chances for recovery were favorable. He emphasized the importance of a thorough study of perityphilitis by the general practitioner, that the surgeon might be consulted in time to give the patient the benefit of early operations. He favored opening the abdomen, even after the third day, in cases of suppurative peritonitis, in order to wash out the cavity and to afford the patient relief; and, too, from the fact that a diagnosis could be made, and perhaps a condition found capable of relief, whether the hypodermic needle found pus or not.

Dr. A. L. MONROE, of Louisville, said he thought Dr. Davis's catgut mats the best device he had seen for intestinal anastomosis.

Dr. J. C. ABERNATHY asked Dr. Davis if he used drainage in such cases as he had reported.

Dr. DAVIS said, as to drainage after intestinal anastomosis, that he was guided as in all other abdominal operations. He never put a drainage-tube in when he was able to cleanse the abdominal cavity thoroughly. When conditions existed with the abdominal viscera that rendered drainage necessary, he put in a blind glass drainage-tube, with numerous lateral perforations to allow of the escape of any collected abdominal fluids. Through it the abdominal cavity might be flushed with sterilized water, and the water withdrawn by gravity without danger of getting air into the cavity. In general suppurative peritonitis of three days' duration the serous surfaces of the bowel and peritoneal cavity were largely deprived of the endothelial covering, and the washing out of the abdominal cavity was followed by a copious exudation of plastic lymph, which, like a cement substance, mechanically agglutinated the numerous coaptated folds of the bowel throughout. These multiple adhesions, which bound the bowel in so many flexions, could possibly be prevented by the early administration of cathartics, which tended to relieve the paresis and increase the peristaltic movements. And in cases where he thought it impossible, after operation, to restore the peristaltic movement sufficiently to prevent adhesions, he would not hesitate to operate, that the sufferer might have the benefit of the doubt, and also for the purpose of rendering his dying hours comfortable.

**Ligatures.**—Dr. A. T. HENLEY presented two double silk ligatures with the following history: Mrs. T. had suffered for two or three years with ovarian disease. Dr. T. Gaillard Thomas had performed a laparotomy on her on October 10, 1888, removing both ovaries and tubes. The recovery had been

uneventful, except that two fistulae had formed in the abdominal wound and had continued to discharge pus of a healthy character. She had returned to Birmingham on December 1st. During the spring months she had suffered considerable pain in both inguinal regions, with very marked tenderness. Probes could not be introduced more than an inch. In May this pain had been very severe. There had been no perceptible swelling.

About the 1st of July a portion of the ligature had made its appearance at the opening of the lower fistula, but it could not be removed without more force than had been thought advisable to use. On the 23d of July both ligatures had been discharged upon the dressing, and the fistulae both closed in a few days, leaving her without an ache or pain of any kind and apparently in perfect health. One of the ligatures was in perfect condition; the other had been partially absorbed. These ligatures came from the pedicles. In a letter from Dr. Thomas, written in May, he had stated that the pedicle ligatures were causing the trouble, and predicted that they would be discharged.

Dr. J. D. S. DAVIS said that he believed the want of success with abdominal silk ligatures was due to insufficient sterilization; that silk thread contained more or less oil from the hands of the workmen, and must therefore be thoroughly freed from all fatty matter before it was placed in the antiseptic sublimate solution, because watery solutions would not act on the thread if the oil was present. He kept all ligatures in chloroform or ether for twelve hours before using them; then shook them well, and immersed them in ninety-five-per-cent. alcohol, where they were left for twelve hours; and then transferred them, while still moist, to a 1-to-1,000 watery sublimate solution, in which they might be allowed to remain for twenty-four hours. After taking them from the bichloride solution, he allowed them to dry, and then rolled them in sterilized linen compresses and placed them in a suitable glass bottle, or ninety-five-per-cent. alcohol, to keep. He maintained that the main object was to free the silk from all fat and oil before sterilization, and that when ligatures for the abdominal cavity were thus rendered aseptic they were not apt to produce suppuration or secondary abscesses; otherwise, primary abscesses would necessarily be the result.

The CHAIRMAN considered the silk ligatures a frequent cause of pelvic abscess. He reported a case in which he had removed the ovaries and tubes nine months before, and stated that the patient had recently had an abscess due to the ligatures, which had opened into the vagina. He also referred to a case operated on three weeks ago, in which the ligatures had caused an abscess which had opened through the rectum, after which the patient had done well. While he recognized that silk was more liable to be followed by this complication, yet he considered it decidedly the safest ligature to use. He agreed with Dr. Goodell that catgut would soon bring one to grief in the loss of a patient from haemorrhage.

## Reports on the Progress of Medicine.

### PHYSIOLOGY.

By LOUISE G. RABINOVITCH, M. D.

**The Quantitative and Qualitative Interchanges of Nitrogen and Phosphorus in the Body, under the Influence of the Mind.**—A. E. Steherbak ("Vratch," No. 4, 1889) has experimented on his own person, and has obtained the following results: Under the influence of active mental work there is a decreased assimilation and increased elimination of nitrogen and phosphorus, the source of elimination being

the same ingredients of the tissues. With regard to the variation of the qualitative changes, the energy of the process of oxidation is below normal; this was learned from the fact of the occurrence of an increased amount of deficiency oxygenated products in the urine. The earthy phosphates in the urine predominate over the alkaline.

From a series of comparative analyses with respect to the amount of phosphorus contained in the diurnal and nocturnal urine, the results were unsatisfactory. The increase of eliminated phosphorus in the diurnal urine is neither much marked nor constant; the difference in the alkaline and earthy phosphates in the urine is more conspicuous; the latter phosphates, as a rule, preponderate in the daytime.

The diverging results of different authors who investigated the variation of the interchanges of phosphorus in the tissues under the influence of mental work is to be ascribed, according to the author, to the fact that the final results of these interchanges, in connection with mental work, must vary with: 1. The relation of the amount of the combinations of phosphorus undergoing decomposition in the brain to that of phosphoric acid sent to the brain. 2. The length of time during which the brain rests and is enabled to regain its loss.

**On the Relation of the Spleen to the Hæmoglobin in the Blood.**—Schwartz pointed out recently in his thesis the new property of protoplasm and the splenic cells, which consists in first destroying and subsequently regenerating hæmoglobin, regeneration being in proportion greater than the quantity previously destroyed.

This led Professor Ph. Krugner ("Vratch," No. 3, 1889) to study the comparative analysis of arterial blood and that of the splenic vein with respect to the contained hæmoglobin and their solid extracts. The hæmoglobin was determined by Hüfner's spectrophotometer. In four cats the blood from the splenic vein contained on an average 9·5 per cent. of hæmoglobin and 19·01 per cent. of solid extracts, while blood from the carotid artery of the same animals contained hæmoglobin 9·28 per cent., and solid extracts 18·73 per cent.

The higher per cent. of hæmoglobin and solid extracts in the blood of the splenic vein can not depend, according to the author, upon the absorption of liquid from the same by the lymph vessels, since they are scarce in the spleen, and the lymph in the spleen is richer in solid extracts than that from any other region of the body. The inference is that this increase of hæmoglobin and solid extracts in the splenic vein is brought about by their generation in the spleen. According to Koultehitsky, the histological structure of the spleen permits of such supposition.

**The Influence of Massage of the Abdomen on Blood-pressure and Respiration.**—To decide the question as to the mode of distribution of the blood in the cephalic and podalic extremities of the body under the influence of massage of the abdomen, R. O. Glovetsky ("Vratch," No. 3, 1889) has used the plathysmograph for the purpose, and found the size of the upper and lower extremities to diminish during massage; after suspension of the same the size returns to the normal; the upper extremities, however, frequently exhibit gradual increase in size, that of the lower not uncommonly being decreased at the same time. From experiments on men and animals, the blood-pressure is seen to be increased during and some time after the massage; in animals this is the case even after section of the splanchnic and sympathetic nerves. By means of the manometer the intracranial blood-pressure was shown to be increased too.

The number of cardiac pulsations first increases during the process of massage, but becomes gradually slower, and at the same time fuller toward the end of the process, and especially is that true of the subsequent period. No satisfactory results were obtained as regards the respiration in men; in animals there was a decided increase of the respiratory activity. In cases of asphyxia the use of massage efficaciously influenced the cardiac action.

**Researches on the Pathology of Diabetes** (Presented by Brown-Séquard).—M. S. Arthaud and M. L. Bettle ("Comp. rend. de l'acad. des sci.," No. 4, 1889) conclude from their recent experiments that:

1. An artificial double and simultaneous neuritis of both vagi is followed by death of the animal within a few days, the symptoms being analogous to those characterizing section of the same nerves. For experimental purposes death can be delayed by gradual interstitial injections into the nerves of inert powder or other irritating substances.

Following the first injection there is polyuria with slight albuminuria; after the second, gastric symptoms supervene (vomiting), accompanied by extreme thirst and emaciation, which is explained by the inanition. The amount of urea excreted is diminished, and sugar appears (0·14 grammes of sugar to the animal kilogramme in the twenty-four hours). Death ensues about the second month after the second operation; the anatomical alterations consist especially in congestive and inflammatory lesions of the lungs and the abdominal viscera.

2. One nerve being artificially injured, the degree of resistance to death is greatly in proportion to the intensity of the neuritis. In both the dog and the rabbit emaciation sets in with polyuria and azoturia in the beginning, and an intermittent glycosuria persists during the entire period of experimentation. The post-mortem shows the existence of renal, hepatic, cardiac, and intestinal lesions, the lungs being almost normal, the kidneys are congested, and histologically there is a sclerosis of arterial origin of different degrees. There is hepatic congestion with a granular condition of the hepatic cells; the heart is the seat of interstitial endocarditis; the mucous lining of the alimentary tract is the seat of a peculiar degeneration, resembling that described by Cau-tain as being found in diabetes.

3. To decide whether these phenomena were brought about by centripetal or centrifugal action of the nerve, the central end of the vagus was irritated after resection; the operation was followed by polyuria and glycosuria, but these symptoms soon disappeared, and within a few weeks the animal recovered perfectly.

4. Peripheral irritation of the vagus was constantly followed by gradual aggravation of symptoms, and death within from four to six months.

5. The inference is that centrifugal irritation of the vagus in animals is apt to induce the different clinical varieties of diabetes as met with in men, according to the individual predisposition.

Analysis permits of the statement that this artificial disease differs in no respect from the varieties of spontaneous diabetes in men, for which the author adopts the neuropathic theory.

**The Mechanism of Death in Rabbits subjected to Transfusion of Dog's Blood** (Presented by M. Charcot).—Like Héricourt and Riehet, G. Hayem ("Comp. rend. de l'acad. des sci.," No. 8, 1889) has observed the fact of the quick succumbance of rabbits when subject to transfusion of dog's blood, whether the entire defibrinated blood or serum is used. The order of toxicity is, beginning with the highest, first defibrinated, then entire blood, and last serum; 5 to 7 c. c. of defibrinated blood to the animal kilogramme suffice to bring about a quick death. In one or two minutes after transfusion, symptoms of asphyxia develop; dyspnoea, followed by cyanosis, and terminal asphyxie convulsions, with dilatation of the pupils, occurring within the following five to fifteen minutes. In case of an insufficient dose, the symptoms are simply those of dyspnoea. After a while some of the animals pass red urine, containing red blood-cells and dissolved hæmoglobin; others are affected by polyuria, the urine containing for one or two days biliary pigments and urobilin, or urobilin alone. Post-mortem immediately after death reveals, in all cases, distension of the right heart cavities with coagulated blood, which extends into the pulmonary arteries and their first large branches. In some cases thrombi are found in the eava or portal veins. The lungs, being bloodless, are sometimes the seat of infarctions, and the left heart is empty.

The constancy of these results leads to the conclusion that the death by asphyxia here is due to arrest of the right heart circulation. The animals die as if their pulmonary arteries had been ligated. As observed previously by Landois, the pathology of the process is explained by the solubility of the red cells of the rabbit in the blood or serum of the dog: microscopic examinations prove this to be the fact; the dissolved hæmoglobin is in direct proportion to the amount of transfused blood. Allusion is made to the possibility of the red cells containing impure albuminoids capable of coagulating circulating blood.

Two forms of coagulation might be produced, according to the specimen of blood used; it might be either embolic or thrombotic, the latter causing instantaneous death. Whatever form of coagulation results, it is stated, it is possibly due to the contact of two living organisms closely resembling each other, and this is of interest in the study of the pathology of thrombus and embolism formation.

**On the Quantity and the Activity of Reduction of Oxyhæmoglobin in Diabetic Patients.**—Dr. A. Henocque ("Arch. de phys. norm. et pathol.", 1, 2, 1889) has kept under observation ten diabetic patients for several years, and made eighty analyses of the urine and seventy-two of the blood. He has found it impossible to establish a line of relation between the amount of oxyhæmoglobin and the degree of glycosuria; the process seemed too complete to rely upon the daily examinations of the amount of sugar and the corresponding activity of haemoglobin reduction.

After the hourly examinations for three consecutive days of the correlation of these two processes, the conclusion arrived at was that in most of the cases the maximum of sugar production occurred between 10 a. m. and 1 p. m., or else 4, 6, or 8 p. m. The activity of reduction is augmented at the same time. In the evening, and particularly during the night, the glycosuria is diminished, and is accompanied by a corresponding decrease of the activity of oxyhæmoglobin reduction. The author expects to show in future the concomitant relation of the excretion of urea, glucose, and phosphoric acid.

**Clinical and Experimental Researches on the Decussation of the Conductors of Voluntary Movements.**—The current knowledge of cerebral physiology implies that both physiologists and clinicians accept the view that a transverse section through the entire width of the base of one hemisphere should be followed by paralysis, for the reason of interruption of communication between the muscles and the seat of volition, the arguments for this being: 1. The experiments of Fritsch and Hitzig, Ferrier, and others. 2. The clinical facts of crossed paralyses following unilateral cerebral lesions, or direct paralyses following unilateral spinal lesions. 3. The facts of descending degenerations of the motor tracts commencing at the base of the brain and descending through the cord. Brown-Séquard ("Arch. de phys. norm. et pathol.", Nos. 1-2, 1889) opposes the localization theory on the ground of clinical observation and his personal experiments.

Stimulation of different parts of one half of the cerebral base was followed in most of his cases by movements of the limbs on the corresponding side. He denies decidedly the localization theory and substitutes for it a theory of reflex action.

In opposition to the cases which encourage physicians to favor the localization theory, the author reports cases being in perfect contradiction with those generally known. With reference to secondary degenerations, the author expects to show in future that such lesions may exist without exhibiting any pathological phenomena, and so prove the incorrectness of spinal localization. The cases collected by M. Brown-Séquard support his views decidedly, and enable him, without stating the details here, to formulate in general that these cases prove the possibility of the existence of a lesion, or of destruction of the medulla limited to its motor portion, or of this and its neighboring parts, without a resulting paralysis of the limbs. On the other hand, paralyses were observed to follow lesions of parts that are not considered as motor areas, the motor areas having been unaffected.

Though, it is stated, observations have been made that confirm the current theory of cerebral and spinal localization, and the crossed function of each hemisphere, yet there are evidences that leave no doubt as to the fact that injuries of one side of either the areas considered as motor, or of those that are not recognized as such, might be followed by palsy on the corresponding side of the body. The cases collected are: 1. Dr. A. T. H. Waters, "Trans. of the Medico-chirurg. Soc.", London, vol. xlvi, 1863, p. 115. 2. Dr. Dompeling, "Nederlandsch Arch. voor Genees- en Naturkunde," vol. iv, 1869, pp. 179-190. 3. Dr. S. O. Habershon, "Guy's Hospital Reports," 3d ser., vol. xxiv, 1879, p. 130. 4. M. Pénard, "Bull. de la soc. anat.", 1846, p. 389. 5. M. Hallopeau, "Thèse de concours d'agrégation," Paris, 1875, p. 987. 6. Dr. R. Mayne, "Dublin Hosp. Gaz.", 25 May, 1861. 7. J. P. Gama, "Traité des plaies de tête et de l'encéphalite," Paris, 1830, p. 264. 8. M. Luneau, "Comp. rend. de la soc. de biol.", 1870, p. 133. 9. Jobert, "Études sur le système nerveux," Paris, 1838, p. 446-453. 10. Dr. E. R. Hun, "Transactions of the American Neurol. Assoc.", vol. ii, 1877, p. 206. 11. M. Couty, "Gaz. hebdom. de méd.", 1877, p. 110. 12. M. Picot, "Oblitération de l'artère vertébrale dans le crâne," Bordeaux, 1881, pp. 12-19. 13. Reported by Professor Boettcher, "Arch. of Oph-

thalm. and Otology," by Professors Knapp and Moos, New York, vol. iii, 1873, p. 135. 14. M. J. M. Snook, "Trans. of the State Med. Soc. of Michigan," Lansing, vol. vi, 1874, p. 228. 15. MM. Cossy and Lorreye, "Bull. de la soc. anat.", 1874, p. 83. 16. Parent-Duchatlet and Martinet, "Recherches sur l'inflammation de l'arach.", Paris, 1821, p. 47. 17. Published by M. Duranti, "Gaz. hebdom. de méd. et de chirurg.", Paris, 1862, p. 39. Other references are alluded to which show that the anterior pyramids corresponding to the palsied side of the body were found injured.

On the grounds mentioned the author concludes that: 1. Parts of the cerebrum which are not supposed to be motor are apt, by being injured, to induce paralysis. 2. Destructive lesions, sometimes very considerable, of the supposed motor areas in the medulla and pons Varolii are not always followed by paralysis of the limbs. 3. Very slight often, but most frequently very pronounced, if not complete, paralysis may follow a lesion on the corresponding side of the medulla, regardless of the seat of the lesion, which may be either in the posterior or lateral parts of the medulla, in the interior of this nervous center, or in the anterior pyramids. 4. It is impossible to admit that those direct paralyses were due essentially to some other lesions than those in the medulla, as reported. It would be wrong to suppose that in the reported cases of direct paralyses there was no decussation of the pyramids.

The author is aware of three instances of direct paralyses where anatomical examinations were made, and the decussation of the anterior pyramids was found perfect. (Dr. E. H. Dickinson, "The Liverpool and Manchester Medical and Surg. Reports," Liverpool, p. 141, 1878; M. Blaise, "Bull. de la soc. anat.", p. 387, 1882; MM. Fére and Arnould, "C. R. de la soc. de biol.", 1887, p. 220.) As far as the author is aware, of the reported cases with bulbar lesions, the number of direct is greater than that of crossed paralyses. This argument, it is stated, is the more valuable in face of the fact that the proportion of direct to crossed paralyses in cases of lesions of the cerebral cortex is one to one thousand, while the proportion of the same in bulbar affections is far greater.

The author intends to show hereafter that bulbar or local lesions of other encephalic parts are not the essential cause of paralysis; that palsy is not dependent upon the loss of function of the injured motor area so called; that it is due to an influence exerted by irritation of the nerve cells and fibers surrounding the palsied parts; and that the irritation is propagated to a distance, and affects, in different parts of nerve distribution, the nerve elements fulfilling the motor function in the organ, this function disappearing by inhibitory act. The article is concluded by the statements that: 1. It is not the case that the fibers of the anterior pyramids decussate at the inferior part of the medulla, and that they are the principal paths for transmission of voluntary movements. 2. It is incorrect to suppose the medulla to be the principal seat of decussation of the conductors of voluntary movements. 3. Decussation of conductors of voluntary as well as of reflex movements of the limbs exist through the entire length of the cerebro-spinal center. 4. Paralyses following unilateral lesions of either the medulla or any other cerebral part, in man and in animals, are not dependent upon destruction of the local centers or of a group of conductors of voluntary movements.

**On the Methods of resuscitating Still-born Children.**—The first step in Schultze's method is considered of great value for the reason that it commences by an expiratory act, and thus permits foreign matter or bodies to clear the air-passages and escape through the mouth. Schroeder remarks, in his work on obstetrics, that it is doubtful whether it is possible by this method to clear the air-passages from foreign bodies as thoroughly as by means of a catheter. M. D. Nikitin ("Jour. akousherstva e jenskih boleznei," No. 1, 1889) states that the moment the foreign matters reach the posterior nares and mouth they must be removed artificially by the catheter, or the air-passages will become blocked up again at the first inspiratory act obtained by this method. Schnitzle himself, as stated by Hofmann ("Lehrbuch der ges. Med.", 4te Auflage), announces that his method has no success in prematurely born infants, for the reason of the softness of the chest-walls. And, as reported by different authorities, the main objection to the method is that ten to fifteen swingings of the child's body do not suffice to succeed in resuscitating it; it is necessary to perform thirty to fifty

swingings in order to secure perfect breathing, and this heroic treatment implies great injury to the child. Dr. Winter ("Vierteljahrsschrift für d. ges. Med." 1887, Bd. xlvi, II. 1, S. 81) reports three post-mortems after such treatment; in one there was found an extensive extravasation of blood into the abdominal cavity; in the second, rupture of the liver and fracture of three ribs; in the third, rupture of the liver and bone injuries.

Though these cases might be considered as exceptional ones, yet they are easily understood. Dr. Nikitin states, with F. H. Champneys, that traumatism is very apt to occur in the asphyxiated infant, which is perfectly inert, with a weakened condition of the ligamentous apparatus, and especially being deprived of the flexibility proper to the living infant. According to Nikitin, Schultz's method is not to be abandoned entirely; he suggests taking advantage of the first step in this operation, which procures the first expiratory effort and so expels foreign bodies from the air-passages; he then uses the catheter to free the latter radically from the mucus, liquids, etc.; should the introduction of the catheter be attended by difficulties, he advocates repeating the same manoeuvre for procuring expiration, and, if not successful, replacing this by Marshall Hall's method for the same purpose, using the catheter again for the removal of mucus, and immediately after this proceeding to insufflation through the catheter, or directly by the mouth of the operator.

The method of insufflation is too much neglected, the author thinks, the objections being, first, that the air fills up the stomach and alimentary tract rather than the lungs; and, secondly, that after forced insufflation the pulmonary alveoli are very apt to rupture. With the assistance of known authorities he experimented on dead subjects, and his opinion is that: 1. The introduction of air is performed with comparative ease. 2. Even with forced insufflation, the air enters more into the lungs than into the stomach, and it never reaches beyond the pylorus. 3. In completely filled lungs not once has artificial emphysema been found to exist.

The precautions that he observes are to avoid occlusion of the larynx by introducing the little finger into the child's mouth and lifting the root of the tongue somewhat forward. The external nares are closed with the fingers of one hand during insufflation, and immediately after this the mouth is occluded by the other hand for several seconds, to prevent the escape of insufflated air. He introduces the tube or catheter to the root of the tongue only; occlusion of the larynx by the tongue is avoided at the same time; the introduction of the catheter into the larynx or trachea he considers as being not only unnecessary for success, but even harmful, for it is under these very conditions that emphysema is induced, and very frequently the visceral pleura is ruptured by the great tension of air. It is advocated to avoid such accidents by insufflation, either directly by the mouth or by means of a catheter, into the mouth of the child. He finds no objections to the filling of the stomach with air by that means, for the air tension in the lungs is counterbalanced by that in the stomach, and artificial emphysema is thus avoided.

Other objections to the insufflation method are that the exhaled air of the operator is too poor in oxygen, and contains an excess of carbon dioxide; that foreign bodies present in the larynx are apt to be driven further into the lungs, which might result in pneumonia. Dr. Nikitin averts the first objection by alluding to Pflüger's statement ("Arch. für Physiologie," 1868, Bd. i, S. 61; also Schwarz, "Die vorzeitigen Athenebewegungen," Leipzig, 1858) that the consumption of oxygen in the newly-born is so small that there is hardly any difference noticed between the arterial and venous blood of the umbilical vessels; and, according to Paul Bert ("Leçons sur la physiologie comparée de la respiration," Paris, 1870), the muscular tissues of newly-born animals absorb less oxygen than those of adults in the proportion of 29 to 47; so that there is still a sufficient amount of oxygen in the exhaled air for the newly born.

With regard to the excess of carbon dioxide, which is four per cent. according to P. Bert, respiration is interfered with in animals when the amount of carbon dioxide amounts to twenty-four per cent. under pressure of 760 mm.

Further advance of foreign bodies into the lungs can be avoided, it is stated, by carefully cleansing the child's mouth with the little finger,

or by introducing the catheter into the larynx and aspirating. The author speaks highly of the use of insufflation, especially when simple means fail to bring about respiration; should even amniotic liquid blood, and mucus be driven into the lungs, the mucous lining of the respiratory tract might absorb these substances, or they may be thrown off by the first expiratory effort (Schroeder).

The use of ether for inhalations or local applications to the nostrils (Harris Jones, "New York Medical Journal," August 21, 1886) Dr. Nikitin does not consider preferable to that of spirit of ammonia. He thinks that subcutaneous ethereal injections (Grose, of England) must be of value in the enfeebled circulation of the asphyxiated infant, but that experimentally this has not been sufficiently worked out.

Faradization of the phrenic nerve is advocated by Pernice, and is often of good service, but it has the objection of the foreign matter remaining in the respiratory tract, the essential inconvenience, however, being the absence of the battery when needed.

**On the Currents of Activity in the Frog's Brain.**—B. F. Verigo ("Vratch," No. 2, 1889) makes this communication. Professor J. M. Setchenoff had studied the nerve currents in the medulla of the frog, and noticed that they were periodical, which he ascribed to periodical excitations of the medullary centers.

The reporter has studied the nerve currents in the cerebro-spinal axis, connecting by a galvanometer two points in the spinal cord—one in the thoracic region, the other in the lumbar enlargement. He has obtained a deviation of the galvanometric arrow which, he thinks, indicated the occurrence of a current at each reflected impulse of the limbs; the direction of the current was such as always to present the electro-negative area in the lumbar enlargement.

Since during reflex movements the lumbar region must be in a condition of higher excitation than other parts of the central nervous system, the inference is drawn that the electro-negative tension is conveeted with areas of most activity. On this basis the galvanometer was proposed by Professor Farhanoff to be used in the study of brain localization. Verigo obtained constant swingings of the galvanometric arrow while experimenting on one hemisphere of a frog; the anterior part of the hemisphere, however, was found decidedly electro-negative to the posterior at each movement of the limb. Professor Farhanoff remarked that this spoke in favor of the anterior cerebral half of the hemisphere performing the function of voluntary movements.

**On the Absorption of Necrosed Hepatic Tissue by the Hepatophagous or Giant Cells.**—Professor W. W. Podwotsky ("Vratch," No. 3, 1889) relates the following facts with the view of throwing some light on the pathogenesis of the giant cells: An injection of from 2·5 to 3 c.c. of alcohol, of a 35 to 40 per cent. solution, into one of the branches of the portal vein immediately traversing the hepatic parenchyma is followed by gradual formation of groups of giant cells in the mortified hepatic area supplied by this branch. The giant cells are most abundant at the line of demarkation between the normal and dead hepatic tissue, being in intimate contact with the dead hepatic cells; on the seventh or eighth day the number of giant cells is enormously increased, and they lodge not only in the line of demarkation, but too in the very focus of necrosis, individual areas collecting in groups around the dead hepatic cells. In proportion to the increased amount of giant cells in the peripheral layers of the deadened focus the line of demarkation becomes wider, looks more irritated, and contains less traces of hepatic parenchyma. The size of the giant cells differs, each containing from three to four up to fifty and more nuclei in the enormously increased protoplasm, which may extend over an area of several dozens of hepatic cells.

Even with a low power the giant cells are seen under the microscope to have a more or less regular semilunar shape, in the concavity of which lodge somewhat round or polygonal masses; other cells are simply very large, containing in their interior similar opaque masses, which seem to be surrounded by a limiting zone. Frequently one giant cell holds in its interior several such opaque masses of different sizes, and some of them attain a large size, seeming to be composed of several polygonal masses. On the seventh or eighth day after injection the portal branches of the necrosed areas are bloodless and obliterated by connective tissue.

The relation of the giant cells to the masses they contain and the adjacent necrosed hepatic area is made very clear by using double-staining agents, such as borax-carmine followed by picro-Victoria-blue. The stained specimens thus obtained permit of the inference that the masses inclosed by the giant cells and the necrosed hepatic cells are virtually identical.

Microscopic examinations with a high power confirm the idea that these masses are disintegrated hepatic cells; the degree of disintegration can be studied in the line of demarkation and in the giant cells. With the advance of disintegration and decrease in size of the masses of hepatic cells the giant-cell protoplasm is constantly increasing.

The anatomical changes taking place in the line of demarkation of the normal and pathological hepatic cells are formulated as being: 1. Formation of giant cells around the necrosed hepatic cells. 2. Subsequent disappearance of these pathological cells in the giant cells and under their influence, the giant cells assimilating the organic matter resulting from cell disintegration.

The author thinks this to be the first description of the process of assimilation of the necrosed hepatic cells by the giant cells, generated through the circulatory medium, in the necrosed hepatic parenchyma. He compares the giant cells to I. I. Metchnikoff's phagocytes, and names the former hepatophagues, or absorbers of hepatic tissue. He suggests, too, the term "necrophagues," since it is applicable to cells eating away dead from living tissue, and by doing so, it is supposed, there will be avoided the confusion with the term "phagocytes," which eat away living (bacteria) and dead tissue indifferently; for the cells destroying living tissue the term "biophagues" is suggested.

In accord with Virchow, Ziegler, Wegner, Levschin, and others, the author thinks the giant cells to be derived from connective tissue and endothelial cells; he has not found any facts speaking in favor of their origin being from the leucocytes.

Concluding, the author remarks that the giant-cell genesis seems purposeless in the beginning of the process which is going on under the influence of foreign bodies in living tissue, and that the physical and chemical properties of the foreign bodies play an important rôle in the formation of giant cells; that irritations of a given character and intensity are apt to start this process of atypical protoplasm formation, a type of which are the giant cells.

According to Marchand the contact of iodoform with granulation tissue prevents giant-cell formation. The author has pointed out elsewhere in his work on partial hepatic necrosis influenced by the presence of ammonium and phosphorus in the blood, that no giant cells were to be found around such necrosed areas, and this leads him to believe that irritation caused by alcohol must be different from that stated above; that the same phenomenon is observed in the action of different bacteria, some of them being, and others not, capable of encouraging giant-cell formation.

**On the Variation of Glycogen Production in Icterus.**—MM. Dastre and Arthur ("Progrès méd.," No. 14, 1889) have studied the subject, and the statements are made that there are difficulties in the way of determining this variation; that in experimenting it is necessary that one of the principal hepatic ducts should be ligated in such a way as not to interfere with the function of the others. Partial icterus is so induced, and it is possible at the same time to compare the pathological and physiological portions of the same liver. In this way it was determined that the amount of glycogen in the icterous portion of the liver diminished invariably, and this was confirmed by the different known reactions. The authors remark that noticeable digestive disturbances must follow in such cases.

**On the Alteration of the Red Blood-corpuscles subsequent to Eclamptic Fits.**—M. Fétré ("Gaz. liebd. de méd. et de chir.," No. 12, 1889) has observed decided alteration of the red cells after epileptic fits; on examining the blood one hour and a half after the fit, the cells are found to be spherical; the next day they assume their normal aspect, their globulin having increased at the same time. This fact is analogous, the authors think, to what occurs after haemorrhage, menstruation, or any serious disease.

**On the Hepatic Lesions in Eclampsia.**—M. Pilliet ("Progrès méd.," No. 14, 1889) reports that such lesions are found very frequently on microscopic examinations; they are seated in the portal spaces, and

consist in a stagnation of blood with destruction of hepatic tissue. In the varieties of eclampsia that terminate in icterus, which are met with frequently in maternity hospitals, the same lesions are found, being very extensive, and sometimes confluent; in the latter cases the parenchymatous disintegration of the liver resembles that found in fatty icterus.

**On the Measurement of the Blood-Cells—a Globulimetric Scale.**—M. L. Malassez ("Jour. des soc. sci.," No. 3, 1889) suggests that the easiest method for practical measurements of the blood-cells is: 1. To take an impression of a certain magnitude of a nice preparation of blood by means of the camera lucida. 2. To measure the corresponding designs of the cells, and then calculate the normal diameters. The first part of the process can be performed more or less accurately by taking certain precautions, as was pointed out by the author in June, 1878. The results are more satisfactory when photographs of the blood-cells are used for the purpose. The second has the objection that the blood-cells are not always perfectly circular; this being the case, it is necessary to measure more than one of their diameters to obtain the average; this requires much time and is not exempt from error.

It is four years that the author has been trying to simplify the latter operation, to render it more precise and rapid; he has invented now for the purpose a graduated scale, which he chooses to call a globulimetric scale.

It is a flat, transparent ruler, with finely engraved circles disposed in order of their increasing diameters.

The most convenient arrangement, the author thinks, is to have the diameters of the crossing circles disposed in two lines differing from each other in one fourth of a millimetre, the disposition being as represented:

... (6)	(6.50)	(7) ...
(6.25)	(6.75)	(7.25) ...

The scale is made of glass or any other material. The instrument is used by placing it over the photograph of the blood-cell. The size of the engraved circle on the scale corresponding to the photograph of the blood-cell being known, and also knowing how much the diameter of the photograph is magnified, the natural size of the blood-cell is easily deduced.

He further states that the results obtained are pretty constant, and it is rare that a blood-cell does not correspond to any of the engraved circles of the scale. Should errors still exist, they amount only to half the difference between two successive sizes, or half of one fourth of a millimetre when the photograph is magnified a thousand times. He measures usually a hundred blood-cells and takes the average. Mention is made of the importance of being enabled by this instrument to get, without loss of time, the proportionate differences of the cell diameters.

For demonstrative purposes he suggests the graphic method, which may be expressed either in curves or in columns of different heights and widths, the latter indicating the difference of diameters and the former that of the number. The globulimetric scale can be used, it is suggested, for exact measurements of all microscopic bodies having a circular or spherical shape; satisfactory results are obtained too by measuring different diameters of bodies of more complex forms.

**On Pulmonary Ventilation and Thoracic Amplification under the Influence of Gaseous Lavation.**—M. Brown-Séquard has demonstrated experimentally ("Académie des sci.," Feb. 11, 1889) the existence of a respiratory poison, which is eliminated in healthy persons, and is capable of poisoning rapidly, if injected hypodermically, or even if simply inhaled. For this reason improvement in the pulmonary ventilation is practically beneficial to phthisical patients; it is admitted that the diminution of this poison is in direct ratio to the pulmonary ventilation.

Dr. L. Bergeon ("Lyon méd.," No. 13, 1889) proposes to ventilate the lungs themselves in phthisical patients, instead of ventilating the rooms.

According to Cl. Bernard, Demarquay, and the experiments of Bergeon himself, carbon dioxide introduced into the rectum is rapidly eliminated by the lungs, and the pulmonary ventilation is considerably augmented at the same time. If this gas contains no impurities it is rapidly absorbed by the intestinal venous system, and carried to the lungs, through which it filters, charged with débris of organic matter.

The statement is made that it is well to administer this gas in the form of natural mineral waters; that certain patients do not tolerate sulphureted waters. The author has used arsenical waters of complex mineralization. He is convinced that the bacilli of tuberculosis have been observed to grow irregular under such treatment, and to disappear gradually. He ascribes these results not to the direct action of the gaseous lavations, but to the improvement of pulmonary ventilation, which increases the filtration of organic impurities, increases the organic respiratory energy, the vital overactivity, and causes a greater capacity of resistance; all these conditions bring about the pulmonary self-disinfection. Allusion is made to the fact that insufficient thoracic dimensions predispose to pulmonary phthisis, and that under the influence of gaseous lavations the thoracic circumference is decidedly increased.

Dr. Bergeon presented a phthisical patient who had been submitted to this method of treatment. In November, 1888, the thoracic circumference was seventy-five centimetres, the intermamillary space eighteen centimetres. After two months' treatment the measurements were found, respectively, seventy-six and nineteen centimetres. In March, 1889, they were seventy-nine centimetres for the thoracic circumference, and twenty-one centimetres for the intermamillary space. The patient was improving considerably during the period of treatment. Other cases are reported with equally successful results.

It is remarked that thoracic amplification is not manifested under the treatment in confirmed phthisis, especially at the period of the existence of pulmonary cavities; but the amount of tissue remaining sound improves in nutrition and compresses the walls of the cavities, and the stethoscopic indications of the same disappear. The cavity remains practically as such, but, from close opposition of the limiting walls, air no longer cuters it.

**Tracings of Excitations obtained by stimulating an Anæsthetic Region in Hysterical Persons.**—M. Alfred Binet ("Jour. des soc. sc.," No. 5, 1889) states that faradaic or mechanical excitations applied to anæsthetic regions in hysterical persons diffuse readily all over the body, and that myographic tracings of these excitations can be obtained from any part of the body. Sometimes it is necessary to reapply the stimulus a number of times, but the tracing can finally be got. The length and duration of the contraction are dependent upon the intensity and duration of the excitation. A stimulus of the same intensity applied to a normal and to an anæsthetic area diffuses more markedly in the latter; the results are more conspicuous by using the Du Bois-Reymond apparatus.

The observations, being in accordance with those of Charcot, Richer, Fétré, and a number of other physiologists, show that, though the hysterical person is unconscious of the excitation of the anæsthetic region, yet the stimulus is felt all over his organism and acts on all his muscles. With a certain amount of care it can be found that the tracings indicate precise rhythmical reactions, and not an irregular diffusion of the stimulus. This proves that the psycho-motor centers perceive the number and form of the insensible excitations. These motor phenomena seem to the author to have connection with the phenomena of visual perception in hysterical anesthesia ("C. R. de l' Acad. des sc.," December, 1888). He has shown that in some hysterical subjects excitation of an anæsthetic region determines definite visual impressions which are in relation with the number and form of excitations, and alleges now that, even in case all precautions are taken to prevent the patients being conscious of the stimulus applied, the same results hold good.

He supposes that the phenomenon of visual perception is a variety of motor reaction provoked by excitation of the insensible region, the only difference being that in one case the excitation is appreciated by the visual and in the other by the psycho-motor centers. The identity of causation of the motor and visual perceptions in such cases M. Binet bases upon the fact that the time of visual impression, as indicated by the subject, coincides with the myographic tracings brought about by the same stimulus.

M. Ch. Fétré ("Note sur quelques effets des excitations périphériques chez les hystériques," "Jour. des soc. sc.," No. 5, 1889), while not denying the possibility of visual impressions being induced by cutaneous excitations, accepts the statements with reserve.

**On the Influence of Anæsthetics on the Force of the Respiratory Movements** (Presented by M. Verneuil).—Hutchinson and Krahmer have shown experimentally that men and animals can not overcome, in either the inspiratory or the expiratory act, the pressure of a column of liquid offering a certain resistance. MM. P. Langlois and Ch. Richet ("Comp. rend. de l' Acad. des sc.," No. 13, 1889) have verified the statement, and found that, as a general rule, it is impossible to expire or inspire through a column of mercury of 100 mm.

They made a tracheotomized dog respire through a Müller's plug, modified somewhat by themselves, the branches of the plug containing columns of mercury of different heights. Under such conditions a dog could breathe for a few moments through a column 60 mm. high, but it soon got asphyxiated. To maintain rhythmical respiration and avoid asphyxia, the column must not exceed 25 to 35 mm.; this would allow respiration for several hours; though breathing is laborious, no asphyxia threatens.

Should the animal be anæsthetized by ether, chloroform, or chloral, a feeble pressure suffices to interfere with respiration; a pressure of 10 mm. asphyxiates a dog profoundly anæsthetized, but produces no interference in the normal animal. It is the expiratory effort that is mostly interfered with; under the pressure of a column of mercury of 15, 20, and sometimes 25 mm., inspiration is still performed during anæsthetization, whereas the pressure of a 10-mm. column of mercury actually interferes with the expiratory act, and asphyxia takes place.

The experiments are in accordance with the physiological phenomena of respiration; the inspiratory movements are always active, but the expiratory are purely passive in the normal state, being due to pulmonary elasticity, without the intervention of muscular action; they are active only when they are voluntary or reflex. Both voluntary and reflex actions being abolished by anæsthetization, the active part in expiration is of necessity wanting; the pulmonary elasticity is then not sufficient alone to overcome the pressure of a column of 10 mm. Under the same conditions of anæsthesia the inspiratory act is maintained, for, though being an active phenomenon, it is neither voluntary nor reflex; it is automatic, brought about by bulbar incitations, which, though enfeebled, are not abolished by the anæsthetic.

With regard to the use of anæsthetics in surgery, this shows that it is of great importance to keep the respiratory tract perfectly free from mucus during this process, for an obstacle to respiration imperceptible in a normal animal is very apt to asphyxiate an anæsthetized subject. The author thinks that surgeons pay special attention to the inspiratory act, when it is of most importance to provide for the performance of expiration; the most frequent obstacle is usually the base of the tongue.

**Researches showing that the Toxicity of the Expired Air is not Dependent upon the Presence of Carbon Dioxide.**—In three communications made previously ("Acad. des sc.," Nov. 28, 1887; Jan. 9 and 16, 1888) the effort was made to show the relation between pulmonary tuberculosis, the expired air of men and domestic mammalia, and the toxic power of one or more substances derived from the lungs. New researches on the subject lead MM. Brown-Séquard and d'Arsonval ("Jour. des soc. sc.," No. 8, 1889) to think that the simple or multiple poison escaping with the expired air, even in small doses, is capable of killing without being injected directly into the blood-vessels. Injected subcutaneously, this poison was seen to kill seventeen out of eighteen animals. In two thirds of these animals death supervened within from twelve to twenty-four hours after the injection. The majority of the animals were injected with less than 32 c. c. of the toxic liquid. The smallest of them weighed 1,750, and the largest 2,350 grammes. The poison is capable of killing even if injected into either the stomach or the rectum, though two only out of seven rabbits died that had received from 24 to 36 c. c. of the liquid by the stomach. Cl. Bernard and P. Bert have shown that large quantities of water can be injected with impunity into the lungs of mammalia. According to Brown-Séquard and d'Arsonval, an injection of even such a small quantity as 8 to 12 c. c. of water obtained from condensed expired vapors brings about death, which is preceded in the majority of cases by inflammatory products in the lungs. Such are the results, the authors think, from the effect of confined air. They do not accept the toxicity of the pulmonary liquid as due to the presence of micro-organisms, since the toxic action remains the same after the

liquid has been brought to a temperature of 100° C., and exposure to the external air avoided. They used for the researches an apparatus that served to determine the vicious effects of the expired air, and convinced themselves that the carbon dioxide of this air did not share in the toxicity.

An incomplete description of the apparatus is given, and it is concluded from the experiments, in which some of the animals were made to breathe the air expired by the others, that death under such conditions takes place in a way similar to that occurring after subcutaneous or intravascular injections of the pulmonary liquid. The respiration is lowered, the action of the heart accelerated; the temperature falls, at first gradually and toward the end suddenly; soon diarrhoea supervenes, and lasts till the close of the animal's life. Death takes place without agony, or at least without convulsions. The cadaveric attitude shows that there has been no struggling before death, the animal reposing on its bent limbs, abdomen, and thorax as if it were asleep. The post-mortem reveals that the animal died of arrest of exchanges between the tissues and blood. The right ventricle contains reddish instead of dark blood. The aorta and vena cava contain more blood than in cases of ordinary death; the color is brighter than that found after death following agony. The bladder and rectum are full; the lungs are of faint red color, scattered with ecchymotic spots and foci of inflammation, as is found in animals killed by an injection of the pulmonary liquid into the bronchi; a similar emphysema is found too. The liver, kidneys, and other abdominal viscera are congested. Frequently intestinal haemorrhages are found, and sometimes pericardial also.

The authors conclude, on the basis of the analogy of the post-mortem appearances in the cases of death from respiring confined air and those of death caused by injections of the pulmonary liquid, that the cause of death in both cases is identical, though they do not deny the possibility of admixture of some additional poison in the experimental cases of inhalation of vitiated air.

#### Researches on the Action of the Poison of the Salamandra Maculosa.

—M. Abel Dutarte ("Comp. rend. de l'acad. des sci." No. 13, 1889) communicates the results of his observations on the action of this poison on the different organic functions of the frog.

As has been pointed out by others, the action of the poison on frogs is characterized by a violent convulsive period, with general tetanic attacks, which are followed by a period of paralysis, suspension of respiration, and complete muscular relaxation. According to the amount of poison, the paralytic period may be followed by death with suspension of the heart's action in diastole, or by return to life preceded by a convulsive attack. Thus far the author admits the results, but, in addition, he has found that death finally supervened in frogs that were considered by others as convalescent from the poisonous effects.

At the autopsy, in such cases, all the organs of animal life were found completely anaemic, and often it was impossible to collect a few drops of blood from the heart.

The author thinks M. Calmels is wrong in supposing the action of the poison of the scorpion to be similar to that of the salamander, for, according to M. Joyeux-Laffine, the former poison acts neither on the muscles nor on the blood. According to the author's researches, the action of the poison manifests itself on the nervous centers; convulsions ensue by direct excitation of the bulbar or medullary centers; the brain has no action in this phenomenon; the sensibility, though enfeebled, persists longer than the motor function. The motor nerves are poisoned and the poisonous action on the nerves is complicated by similar action on the muscular fibers themselves. Muscular contractility is abolished very rapidly, even on the occurrence of the first convolution; the results were confirmed by tracings obtained from the gastrocnemii of the poisoned frogs, as compared with the limbs isolated by a strong ligature excluding the sciatic nerve. No histological changes of the muscular fibers were found. The respiration remains normal for from five to ten minutes after the injection of the poison; then tracings show a deep inspiration followed by from five to six feebler ones in the succeeding few minutes. The respiratory movements soon become more vigorous and numerous, continuing so until the first tetanic attack, when there occurs respiratory suspension with lowering of the buccal floor. Between the convulsive attacks the respiration may be re-established for

a few seconds. In the beginning of the paralytic stage there is decided and final arrest of respiration, which lasts during the entire period of immobility. Cardiac tracings show that the number of beats varies little during the period of poisoning, but the different parts of the cardiac curves show progressive enfeeblement with the progress of the paralysis; a period of repose appears between the auricular and the ventricular systole, the reverse of what occurs in normal cold-blooded vertebrates. This poison acts directly upon the blood-corpuscles by dissolving them. Under the microscope segmentation of the blood-cells is observed to occur; when they are treated with a solution of the poison, the degree of their solubility is in proportion to the strength of the poisonous solution. Specimens of blood taken at different periods of poisoning from the beginning show first that, after a few hours' intoxication, the blood-globules are granular and the nucleus soon disappears; that after a more advanced period a larger number of globules are deformed and decomposed. Those remaining intact preserve the property of staining readily with eosine, which indicates the persistence of haemoglobin, but most of the globules and plasma disappear.

**On the Influence of Cortical Lesions on Vision.**—M. Lannegrace ("Arch. de méd. expér. et d'anat. pathol." No. 1, 1889) enumerates the best-known works on the subject, and the diversity of opinions on the same. His own methods of inducing the cerebral lesion and of testing for the lesion and the nature of it are carefully described. From his two years' experiments on dogs and monkeys he arrives at the following conclusions: 1. That visual disturbances can be induced not only by occipital lesions, but also by injuries of the frontal, temporal, and parietal regions. In accord with Goltz, Loeb, Luciani, Tamburini, and Bianchi, he finds that a lesion of the most anterior portion of the frontal lobe, or that in front of the motor zone, fails to induce visual trouble. 2. Not always does visual trouble ensue after injury of the regions named; it is frequently impossible to detect any visual defect, whichever region has suffered injury. The inference is either that there is no specialized area whose existence is necessary for the visual exercise, or that the induced visual imperfection, in some cases, is too feeble to be appreciated by the methods available. 3. The intensity of the visual trouble, induced apparently by identical lesions, varies greatly; the same is true of the degree of the induced sensory and motor disturbances. 4. The intensity of the visual trouble depends upon the seat of injury. All conditions being equal, the most marked disturbances follow occipital lesions. 5. The intensity of the visual disturbance depends upon the extent of the lesion, augmenting considerably on the repetition of the injury. A lesion of one centimetre in diameter is always followed by visual disturbances; and, in case of negative results, a second lesion, either at the place of the preceding one or in its neighborhood, regardless of its diameter, is always followed by visual defect of great intensity. 6. Visual imperfections subsequent to the first lesion are always transitory, lasting from several days to several weeks. The compensation takes place either in the remaining cortical substance of the same hemisphere or in the corresponding portions of the opposite hemisphere. 7. Successive unilateral lesions render the visual trouble not only more intense, but more permanent and persistent. It is permissible to suppose that different cerebral portions compensate in a certain measure for the injured area, when such compensation is needed. 8. After the disappearance of visual disturbances induced by one or more unilateral mutilations, a symmetrical or non-symmetrical lesion on the opposite side not only gives rise to visual disturbances proper to such a lesion, but also makes the previous lesion reappear and renders it more persistent. This leads one to suppose that either one hemisphere compensates for its fellow (and evidently injury to the compensating hemisphere must of necessity result in the conditions stated), or, if gradual recovery after the first lesion is due to the remaining uninjured cortical portion, its function is abolished by inhibition after injury to the opposite hemisphere. The inference is that the function of one cerebral hemisphere depends upon the integrity of the opposite one. 9. Very extensive bilateral lesions have never induced permanent blindness, even when the occipital regions were mutilated; all these lesions involved the surface of the cerebral convexity.

With reference to the nature of visual disturbances the statements are made that: 1. The nature of disturbances following cortical lesions varies; there may be homonymous hemianopia or crossed amblyopia. 2.

There may be pure homonymous hemiopia; crossed amblyopia is almost always associated with some degree of hemiopia, and is very rarely pure amblyopia. 3. The nature of the ensuing blindness is dependent upon the seat of the lesion; homonymous hemiopia follows lesions of any region; anterior lesions only are complicated by crossed amblyopia. It is proper to suppose the cerebral surface to possess a very extensive hemiopic zone, having the main focus in the occipital region, and a limited amblyopic zone anterior to the preceding one. 4. In visual disturbances of cortical origin tolerable perception of impressions seems always to exist in the center of the retina. 5. In accordance with Goltz and Loeb, the author finds that there is no correspondence between given cortical and retinal areas. This he does not state as an absolute rule. With regard to ocular, motor, sensory, and nutritive disturbances induced by cortical lesions, the statement is made that the internal and external muscular mechanism of the eye remains intact, whatever the seat of the lesion is.

**Normal and Hypnotic Sleep the Results of Inhibition of Mental Activity.**—In previous researches Brown-Séquard ("Arch. de phys. norm. et pathol.", Nos. 1, 2, 1889) has demonstrated that hypnotic sleep was the result of an inhibitory effect, and that, in organic or traumatic lesions of the encephalon, the temporary loss of consciousness is due to the same intellectual inhibition. The following reasoning is given for attributing normal sleep to an inhibitory effect: Durham and Hammond's theory that sleep is dependent upon vascular contraction taking place in the cerebral lobes can not be accepted, since rabbits and guinea-pigs, after section of both great sympathetics of the neck, sleep the same as if they had normal cerebral circulation. The same results are obtained from experiments on cats and dogs, after extirpation of the superior cervical ganglia on one side, and section of the vago-sympathetic on the other. This opposes directly the theory of vaso-contraction during sleep, for, whether there is intense hyperæmia or anæmia, sleep is not interfered with. That the loss of consciousness during sleep, as well as during numerous other accidental or pathological conditions, is due to inhibition of the cerebral faculties is confirmed by the facts that (1) loss of consciousness from puncture of the medulla and similar conditions is decidedly due to an inhibitory act; (2) with regard to what is known of the conditions that precede or accompany sleep, it suffices to conclude that, as in any inhibition, at the onset and during sleep there exist irritations in the organism at a distance from the organ subjected to loss of activity. The following details confirm the existence of irritations: *a*, The so-called need of sleep is characterized by certain sensations, and particularly by a sense of heaviness in the eyes; *b*, persistent constriction of the pupils; *c*, contraction of the orbicularis palpebrarum; *d*, contraction of the rectus internus and superior; *e*, contraction of the blood-vessels of the retina and cerebral lobes. Aside from inhibition of the psychical faculties, there is inhibition of certain muscles, and perhaps some cardiae and respiratory inhibition. These different inhibitory acts during cessation of intellectual activity imply the existence of irritation somewhere or at different points.

The induction of sleep in man by compressing the carotid and cervical vago-sympathetic (Fleming and Augustus Waller) proves that sleep is apt to be induced by peripheral irritation. To this may be added the fact of the somnolent influence of certain gastric irritations. As regards the location of the irritation inducing sleep, it is not correct to suppose its existence in the brain, for pigeons sleep and awake periodically after as well as before ablation of the cerebrum. The reflex contractions and paralytic irritations associated with sleep, if considered as originating from the same point, are to be located in the excitable parts of the cerebral base rather than in the cerebral lobes. (The author has often witnessed the hyperæmic condition of the base of the brain, and especially of the medulla and spinal cord, during sleep.)

As an argument additional to these statements, it is alleged that, in artificial epilepsy of guinea-pigs, it is possible to induce loss of consciousness and cessation of convulsions by peripheral irritation; loss of cerebral activity may take place, too, by inhibition through the influence of irritation, even when very slight, especially if the seat is in Flourens's *nervus vitalis*.

There can be no doubt after these statements, the author thinks, that there exist irritations at different points present during sleep, and

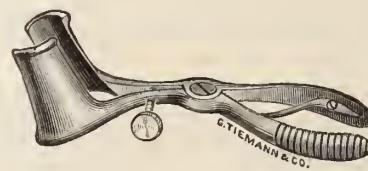

beginning before sleep sets in. He is convinced that the facts are sufficiently conspicuous to lead to the belief that the principal phenomenon of ordinary sleep—*i. e.*, loss of consciousness—is the effect of an inhibitory act.

## New Inventions, etc.

### AN IMPROVED NASAL SPECULUM.

BY CARL E. BLACK, M. D.,  
JACKSONVILLE, ILL.

RECENT advances in the diagnosis and treatment of nasal troubles have made it necessary that every practitioner shall be provided with a nasal speculum. Many forms are now in use, yet there is room for improvement, or, perhaps more properly, for simplification. It is desirable to have an instrument that may be adapted to the greatest number of cases in the hands of both the general practitioner and of the specialist. After having used Simrock's speculum for some time with satisfaction, in a limited number of cases, the writer was led to devise the speculum represented in the following cut:

It retains all the advantages of the Simrock and at the same time may be adapted to a much larger range of cases. The blades are short enough not to impinge painfully against the bony parts, and yet are long enough to give a complete dilatation of the nostril. The ends of the blades are of such a shape as to be easily self-retaining when once put into place and the nostril dilated. The handle is put on at such an angle as to lie against the face, and is entirely out of the way of the operator. This handle is also useful in manipulating the speculum so as to bring the various parts of the anterior nasal cavity into view.

The blades are three quarters of an inch long, and when closed are similar in shape to the undilated nostril. The thumb-screw takes the place of the spring which is used in so many specula, and which is too strong for some cases and too weak for others. It is rarely necessary to insert a speculum more than half an inch, and a quarter of an inch is usually far enough, as great dilatation is needless and it is painful to the patient. All parts of the anterior nasal cavity can be brought into view by moving the head of the patient, or by changing the direction of the blades of the speculum.

This instrument was devised while I was at work in the clinic of Professor Schroetter, in Vienna, and was made in that city. It is now made from the same model by Tiemann & Co., of New York. Several instruments of this new pattern are in use at the Massachusetts Eye and Ear Infirmary, and by many private practitioners.

## Miscellany.

**The Paris Universal Exhibition.**—The special correspondent of the "Lancet" thus continues his account of the session of the International Congress of Hygiene: On the 8th inst. the English delegates gathered in Section 5, in the hope that the question of quarantine would be reopened. Dr. Proust, however, was absent, and, as he was the author of the report on the subject, it was thought advisable to await his arrival. The Section therefore proceeded to discuss the subject of vaccination. Dr. Villemain related that in the department of France where he lived

vaccination was performed only once a year, and those who were not present on that occasion could not be vaccinated. A Mexican delegate spoke in favor of compulsory vaccination, and Dr. Treile lamented that, even in an intelligent center like Paris, the population displayed the greatest indifference to the subject. He described how at Fribourg small-pox had reappeared since the abolition of compulsory vaccination in that town. An American delegate said that from time to time he instituted a house-to-house visitation, so as to know if all the inhabitants had been vaccinated. Dr. Arnoult, military inspector, claimed that to the army belonged the honor of having given the example to the French nation of the advantages that accrue from vaccination and revaccination. But their difficulty was to contend against the non-vaccinated civil population. In the Second Army Corps some soldiers under his care contracted small-pox at the Amiens Hospital. To avoid resistance he had sought to popularize vaccination from the calf. Dr. Proust, who by this time had arrived, said that the German army was only really exempt from small-pox when the civil population had been vaccinated and revaccinated. He preferred vaccination from the calf to the use of lymph from even the healthiest-looking children. Dr. Félix said that in Roumania vaccination, but not revaccination, was obligatory. They had not succeeded, even with the aid of the law, in vaccinating everybody till vaccination from the calf was introduced; then the popular resistance ceased. Dr. Janssen said that in Belgium vaccination was not obligatory by law, but was insisted upon in every school, in every public service and institution, and was so admirably organized that there were very few Belgians who were not properly vaccinated. The subject was then allowed to drop.

Mr. Adolphe Smith, on behalf of the English delegates, now rose to inquire whether the Inspector-General of the French Sanitary Services, Dr. Proust, understood that the Section had not adopted the fourth clause of the conclusions of the report on sanitary works in seaport towns. The first three clauses had been carried unanimously, but, as nothing had been said about quarantine, Mr. Smith, in common with several others, imagined that the vote did not apply to the fourth clause. The English delegates, especially at this late hour, were not in the least desirous of opening up the question of quarantine, and if Dr. Proust would concur in the opinion that the fourth clause had not been put to the meeting the subject need not be further discussed.

Dr. Proust, however, did not agree to this. He was under the impression, on the contrary, that the fourth clause had been adopted; but, if there were any objection to this clause, he was quite willing that the matter should be investigated. Dr. V. Vignard, formerly director of the sanitary service of the Lower Danube, rose and fully indorsed what Mr. Adolphe Smith had said. He had also voted for the first three clauses, which alone had been discussed, and not for the fourth, to which he was absolutely opposed. A conversation thereupon arose between Dr. Proust and Dr. Vignard, which continued till they were called to order and each party asked to make a statement. Dr. Vignard consequently delivered an energetic speech. The resolution stated "that it was only when the ports presented a soil unsuitable for the penetration of morbid exotic germs that the last quarantine checks could be abolished"; but what criteria were they to show that the soil could not harbor germs? A port was never quite purified. People talked of the "rendering healthy" (*the assainissement*) of England as if it was something similar to the washing of a plate—an operation which, when once performed, was evident to all eyes. But there were English delegates present who could testify that this was not the case. In spite of the great works accomplished in England, much remained to be done, and even in London there were many plague spots. He complained that he did not know what was going on in the sanitary services of France, and required a large publicity and public control with regard to the quarantine observations imposed by the French port authorities. He had noted with pain and surprise a remark in Dr. Brouardel's opening speech, to the effect that the treason of one guardian of a lazaret had cost Spain in 1884-85 no less than 200,000 lives. What was this system which by the momentary neglect of one out of many thousand guardians could bring about the loss of 200,000 lives? He agreed with quarantine as defined by Fodéré in 1815. It meant a rope. The difficulty was to prove its utility or its inutility; for if we pointed to failure in one country, others would point to success in other countries.

History, however, was against quarantine; for in the fifteenth century it had been properly and rigorously applied. In those days it was said that for a quarantine three things were necessary—money, force, and the hangman. A quarantine enforced, as in the past, by sentences of death was logical; but as we were not prepared, and as it was absolutely unpractical, to return to these barbarous practices, it was illogical, vexatious, and useless to maintain the fiction of quarantine. It was not till the Government of England had officially proclaimed that quarantines were useless that real sanitary improvements were accomplished. The great fear entertained in England of cholera facilitated the execution of sanitary works. What was the use of asking municipalities to vote large sums for sanitary works if they were told at the same time that they would be protected by the imposition of quarantines which would cost them nothing?

Dr. Proust, in reply, protested that he had no desire to revive the old quarantine methods. They were willing to give every facility to companies whose ships were well managed. As for publishing the details of what was done, that would be very uninteresting reading, but whenever anything of interest happened it was at once communicated to the press. The term quarantine was subject to misinterpretation; the abolition of this word had been proposed at the Rome conference. We need only take precautions against the cholera, the plague, and the yellow fever. These diseases came from such a distance that precautions were possible. First, all consuls in the different distant ports could telegraph information; then the journey took from fifteen to twenty days, which was in itself a period of observation; and, finally, the greater part of the ships had to pass through the Suez Canal, where timely information could be obtained and, if necessary, the ships detained before they entered the Mediterranean. This detention was proposed at the Rome conference, and approved by the twenty-two or twenty-three nationalities officially represented. England and India alone voted against the proposal. If a ship had a disinfecting stove on board, a good doctor, and no dangerous case had recently occurred, then they would give free pratique. But if there had been cases of cholera on board two or three days previously, then the ship should be detained. Practically, he had found on inquiry that such detention would have the effect of stopping four or five English ships for four or five days each year. There was a great difference between this and the quarantines described and denounced by Dr. Vignard. Besides, England had herself just sent the ship Neva into quarantine for sixteen days at Southampton. (This assertion greatly surprised the English delegation, who had certainly not heard of the circumstance.) Dr. Proust went on to give further explanation, which tended to reduce the meaning of the word "quarantine" to method of observation and of disinfection, very different from what is generally understood by the term. Dr. Treile approved of quarantines, and maintained that they had saved Algeria from cholera in 1884.

Mr. Adolphe Smith arose to explain that the point at issue was the actual wording of the resolution. Dr. Proust might attenuate the meaning of the word quarantine in a very satisfactory manner, but this would have no effect whatever with the outside public. Hundreds of newspapers would publish the text of the resolution, but would not know, or would not have space to mention, the explanations given in the Section. The point was not what Dr. Proust might mean, but what the resolution meant; and the resolution undoubtedly meant that quarantine might be imposed even in the most salubrious of ports, for there was no port in the world which could be described as absolutely incapable of harboring imported germs of disease. Dr. Proust and several French delegates protested that they did not interpret the resolution in such a literal sense; but Mr. Smith, supported by the English delegates, persisted that this was the view the outside public, unenlightened by the discussions of the Section, would take of the matter, and that therefore he should be obliged to press the question to a division. Dr. Proust now, however, offered to withdraw the word "quarantine," and put "restrictive measures" in its stead. This, when taken in conjunction with the general tone of the discussion, was considered satisfactory, and it leaves for future congresses to discuss what restrictive measures may be imposed as a substitute for the old-fashioned quarantines. An amicable compromise being thus effected, the Section adjourned without a division. The following is the text of the original resolution and the

amendment proposed, and accepted by Dr. Proust and the entire Section: "C'est seulement alors que les ports présentent un terrain réfractaire à la pénétration des germes morbides exotiques on pourra supprimer complètement les dernières entraves quarantaines." Altered to "les dernières mesures restrictives."

On Friday morning the members of the International Congress of Hygiene went to the Exhibition and examined the sanitary apparatus displayed there. In the afternoon, in Section 5, M. Maignen read a lengthy paper on water filtration. He suggested, as a test, that water should be mixed with a known microbe, and a guinea-pig or rabbit inoculated with the water. Another rabbit should be inoculated with the same water after filtration. If the former died, and the other did not, this might be taken as a proof that the filter was good. Dr. Macé had made experiments with the germ of anthrax in this manner, and found it did not pass through the "filtre rapide." The filter was equally efficacious in preventing the passage of metallic poisons, copper, lead, etc., in solution. Some little discussion ensued, during which preference for the porcelain filter was expressed by some of the speakers, though it works much more slowly. M. Maignen was thanked for his interesting communication, and the president of the Section concluded by saying that filters were always excellent at first; the difficulty was to discover how long they would last.

Dr. Girard (Rheims) opened a discussion on the supervision of meat, urging that diseased meat should be cremated; that this was the best means of preventing its being surreptitiously sold. He further urged that the rules for supervision should be the same in rural as in town districts. This proposal was adopted by the Section.

After a few words about syrup of glucose, Dr. A. J. Martin's report on river pollution was taken into consideration. There has been a great amount of legislation on this question in France. There were ordinances issued in August, 1669; in February, 1773; in June, 1777; and July, 1782. All these had the force of law, and all declared that refuse, filth, manure, etc., should not be thrown into rivers. These old laws were recently invoked (July 24, 1875) by a ministerial decision. Then there is the law of October 10, 1810, on manufactories, etc. The law of April 15, 1859, inflicts a fine of from 30 francs to 300 francs and imprisonment of from one to three months on those who throw into rivers chemicals that kill the fish. A ministerial circular, dated July 31, 1882, forbids pits or porous wells, by which subsoil waters can be polluted with the residue of factories. Nevertheless, all these enactments require to be codified, and, above all, more strictly applied. Consequently, Dr. Martin concluded that industrial residue of a dangerous nature should not be allowed to flow into a river or an underground watercourse. This can only be allowed when the residue has been so treated as to deprive it of all toxic, putrid, dangerous, or any other sort of matter that can alter the natural quality of the river water. The purification of industrial waters or residue must be rendered compulsory and executed according to approved methods. The purification by irrigation is the most perfect means of treating the waste water from mills, etc., containing organic matter. This must sometimes be preceded by chemical and mechanical processes, to render such waters fit for agricultural purposes. These conclusions were adopted, but a very lengthy discussion ensued as to who should be responsible for the application of such a law. If a manufacturer refused to purify his residue, should the state do the work for him and charge him with the cost? If so, what method would the state apply? Perhaps some antiquated expensive method—in a word, the state might blunder and put the manufacturer to unnecessary expense. As it was, many manufacturers had actually made money in seeking to prevent water pollution, for this had led to the discovery of advantageous methods of utilizing waste. M. L. Faucher, civil engineer, member of the Central Council of Hygiene in the department of the Nord, related that river pollution had produced typhoid epidemics in his district. Each manufacturer, however, denied that the waste was the cause, because they only partially polluted the rivers. It was as if one man had a pistol, another some powder, and a third a bullet, and each declared he could not possibly do any harm. Yet it was only necessary for the three to come together to be able to kill some one. This is exactly what happened in the river with the waste from factories, and now that it had been stopped in his district, typhoid fever had been stamped out. It

was ultimately decided that the authorities ought to carry out the necessary works if the manufacturers persistently refused to do so themselves.

In Section 4, on Saturday morning, Madame Tkatcheff read a most interesting and carefully prepared paper on the condition of the working classes in Russia. Irrespective of Siberia and Poland, she said, there were about 932,000 operatives employed in the mills and factories of Russia. The way a considerable proportion of these workers were recruited had a great influence on public health. Many of them were agriculturists who, being unable to earn enough to live, came to the industrial centers and worked in factories from September to February. They had no homes in those industrial centers, but slept very often in the factory itself, in the midst of the machinery, or in a sort of dormitory provided for them just above the works, and separated from the works only by a rude wooden floor, through which all the bad odors passed. Here the workers lay down on wooden shelves. They slept in their clothes, and at best had a little sacking. The shelves were placed one above the other, so that sometimes there was only a hundred cubic feet of space per person. All the inspectors appointed by the Government to inquire into these questions had complained of the dirt, overcrowding, and the promiscuity, for men and women often slept in the same dormitory. The hours of work varied from twelve to fourteen, and the food was altogether insufficient. The clothing was also of the poorest description. It was rare that a man could afford to wear leather boots, but contented himself with wrapping his feet in paper and rags and thrusting them in woolen shoes. Shirts were considered a vain luxury, and but for the sheep's skins, worn with the wool inside, the people would die of cold. This sort of life soon destroyed all sense of self-respect, and fearful immorality was the result. The migrations of villagers into towns for a short time each year had brought back syphilis to the villages, and there were some villages in Russia where every single inhabitant was syphilitic. In some departments ten per cent. of the recruits were syphilitic. There was but one redeeming feature: the Russian, however poor, always insisted on having a bath. He would as soon go without his food as go without his weekly bath. There were no statistics to show what was the mortality of the Russian working-class population, but the general mortality was sufficiently significant; it was 17 per 1,000 in Sweden, 24 per 1,000 in France, and 36·8 per 1,000 in Russia. Out of 1,000 deaths, the proportion of infants under one year was 113 in Norway, 190 in England, 216 in France, and 313 in Russia. The mortality among adults was equally high in Russia, and, taking the deaths occurring at ages varying from thirty to sixty years, the comparison was as the figures 11 for Norway, 13 for France, and 19·4 for Russia. Up to the year 1882 children five years old worked in factories. These children were sometimes syphilitic as well as the victims of alcoholism. There were no regulations to prevent the explosions of boilers, nothing to hinder accidents with machinery. Women had to suckle their babies in the passages of the factories; and as for benefit societies or anything of that description, it would be a mockery to speak of saving to people who are driven by starvation to put up with so fearful an existence. In the match trade 75 per cent. of the workers were children, and they employed white phosphorus. Yet there were men and women in Russia well acquainted with the progress accomplished in Europe, and some attempt had been made to imitate the good example. In 1882 a law was enacted forbidding the employment of children under twelve years of age, and limiting their work up to the age of fifteen to eight hours—that is, four hours, then an interval of three hours' schooling, and then four hours' more work. The law also forbids the employment of children in thirty-six different and dangerous industries, and this is three more than is the rule in most European states. Another law enacted in 1885 forbids night work for women and children, in weaving and spinning mills, but this law is as yet only applied in three centers. There is also organized, under the Ministry of Finance a system of factory inspection. Russia for this purpose is divided into fifty-nine industrial departments; and, as each head inspector receives 5,000 roubles and the sub-inspectors 3,000 roubles, it is anticipated that they will be able to render good service, and that it will not be easy to bribe them to neglect their duties. There is also a law to the effect that where there are more than a hundred persons employed in a factory

medical attendance should be provided; but it is physically impossible to apply this law, for there are only 18,000 doctors in the whole of Russia. Consequently, many factories have no medical attendant, and the lack of proper care in sickness is another cause of the high rate of mortality.

Madame Tkatcheff's paper, of which this is but a brief and incomplete summary, produced a deep effect. After a few questions had been put, Mr. Adolphe Smith rose and urged the Section not to rest satisfied with congratulating Madame Tkatcheff. She had given them a graphic and appalling picture of widespread suffering and human degradation. It was no use holding congresses if they did not exercise their undoubted influence to put an end to such abominations. He would suggest that the Russian delegation might prepare a report on the effect of the recent Russian legislation, and on the actual condition of the working classes in that country. This report could be presented to the London Congress, and followed by a resolution worded in the manner which the Russian delegates might think would have the best effect in Russia. Such a resolution, put to the entire London Congress, and adopted unanimously, as there was every reason to hope it would be, could not but have effect. There was no government so deaf as not to hear the voice of a congress representing the best elements of sanitary progress in modern civilization. In any case, it was impossible to sit still and make no effort to remedy a state of affairs which was a disgrace to our common humanity. The use of international congresses was precisely to bring international pressure to bear where there was a weak point in the armor with which Civilization clothed herself to war against disease and premature death. He therefore moved the following resolution: "That this Section invites the Russian delegates to submit to the International Congress of Hygiene, in London, in 1891, a report on the results of the new laws for the protection of labor, and a resolution for the amelioration of the material condition of the working classes in Russia."

This speech and proposal were warmly cheered, and the resolution was unanimously carried.

Dr. Dargelos read a paper on a method for rendering felt hat manufactory less unwholesome. M. Fisher brought forward some proposals for disinfecting night-soil on its passage to the sewers, and M. Maiguenan an invention for purifying sewer water and extracting therefrom the solid residue, the ammonia, etc. The Section, on the strength of these two papers, was asked to vote a resolution regretting that the proposed credit of 200,000 francs for experiments in this direction had been struck out of the French budget. Mr. Smith objected on the ground that the French budget did not concern an international congress, but only the principle at stake, and he thought we should all agree that all the governments, and not one single government, should be more liberal in such matters. The utilization of sewage was a problem that might necessitate expensive experiments, and the States of Europe and America should, by small subventions, encourage such experimental research. A resolution in this wider sense was thereupon unanimously adopted, and the Section adjourned.

On Friday afternoon some Sections met at two o'clock, but at four o'clock all the Sections met together in the grand amphitheatre for the final sitting. Dr. Brouardel, as president of the Congress, explained that the Sections had passed a number of resolutions, that the subjects to be discussed in each Section had been fully announced beforehand, and therefore each member of the Congress had enjoyed the opportunity either of supporting or combating any one of the proposals brought forward. Under these circumstances they might conclude that what the Sections had done had been well done, and now he would ask the Congress to approve by vote, and if possible without discussion, the decisions of the Sections. Dr. Martin then commenced to read upward of fifty resolutions. Dr. Brouardel soon discovered that a large number of these resolutions dwelt exclusively with French questions, and therefore did not put them to the Congress, but referred them back to the French committee. Most of the other resolutions of a general character were confirmed by a show of hands, though now and then there were a few opposing votes, and often a great number of abstentions. The fact was that many of the subjects were entirely new to a large number of the members, who had not been able to attend more than one Section at a time. Still, it was too late for discussion, and many

things were allowed to pass which will require revision. Many of the resolutions thus confirmed have already been given in describing the work of the Sections. To these I might add a resolution, very warmly applauded, demanding that an address be forwarded to M. de Freycinet, Minister of War, congratulating him on his recent measures on sanitation in the army. Other resolutions demanded a permanent inquiry into the cause of excessive infant mortality, a stricter control over midwives, the teaching of hygiene in schools, the publication of methods of water analysis, the creation of bureaus of hygiene and municipal laboratories in all centers of population, new laws enabling municipalities to compel householders to adopt the town water-supply, the abolition of all laws preventing cremation, the encouragement of cremation on battle-fields, the better inspection of pharmacies, etc.

The reading of these resolutions having taken up considerable time, the concluding ceremony had to be proceeded with very promptly, and Dr. Brouardel spoke for only a few moments. He announced that the next Congress would be held in London during the first week of August, 1891. The work of organization had already commenced, and the subjects to be discussed would probably be known in about six months' time. He thanked his colleagues from abroad for the excellent support they had given the Congress, and hoped the harmony which had prevailed during the week among the members of the Congress would continue to reign among the nations represented.

Dr. Roth, on behalf of the foreign delegates, wished to thank the president and the organizing committee for all they had done.

Senator Dr. Pacchietti, in an enthusiastic speech, reproved the president for qualifying him as a foreigner. "The president," he exclaimed, "salutes the foreigners, but there are none in France. We are all at home in France. Here we meet each other, we live close to each other, we learn to love each other, we talk on the same subjects, we pass the same resolutions; we are not foreigners, we are brothers."

Mr. Shirley Murphy, in the name of the English delegation, rose to thank the French organizers of the Congress for the admirable reception they had prepared. He hoped to demonstrate the gratitude felt by the care they would take in providing hospitable entertainment in London. The cause they had at heart merited the support of all civilized nations. He only regretted that London was not a beautiful city like Paris, and that London did not possess a Brouardel. Nevertheless, he cordially urged all present to accept the invitation and meet again in England, and therefore he did not say *adieu*, but *au revoir*.

Mr. Shirley Murphy was loudly cheered, and the Congress was declared closed, amid cries of "*à Londres!*"

Though the official work of the Congress was thus brought to an end, some two hundred members met again on the following Sunday morning, and, led by M. Bechmann, engineer-in-chief of Paris, visited the palatial sewers that run from the Place de la Madeleine to the Châtelet. In barges and in a sort of tramway they traveled through underground Paris. The sewers were illuminated by many lamps and also by electricity. The barges were supplied with cushioned seats, the ladies came in elegant toilets, and, so that they should not soil their dresses, the steps down into the sewers were carpeted. As an engineering feat these palatial sewers, as they have been so justly described, are certainly most remarkable, and well worth a visit. From the Châtelet the members of the Congress were conveyed in comfortable brakes to the sewage farm of Gennevillier. At Clichy they stopped to see the pumping machines, which lift a third of the sewage and send it over the river in an iron pipe to Gennevillier, where it is used to irrigate 750 hectares of market gardens. The remainder will in course of time be sent to Archères and to Méry. In the meanwhile, two thirds of the Paris sewage still fall into the Seine at Asnières, and the members of the Congress were able to witness how it fouls the waters of the river. They then went over the sewage farm, admired the vegetables, ate some of the fruit, and drank the beautiful clear water derived from the sewage of Paris. It contained, they were assured, a smaller number of microbes than the best spring water, the Vannes water, supplied to the town of Paris. The Congress now proceeded to enjoy the excellent luncheon provided by the town of Paris at a restaurant in the little village of Gennevillier. The toasts were preceded by speeches of a particularly earnest and hearty character. Dr. Martin, as president, proposed that a crown composed of flowers from the sewage farm of Gennevillier

villier should be deposited by the Congress on the grave of M. Alfred Durand-Claye, the author of the scheme of which they had admired the result. He recalled that when, in 1878, Durand-Claye had visited Gennevillier, he had been mobbed by the inhabitants; now he was the hero of the place.

M. Emile Trélat, who could scarce control his emotion, drank to the memory of his old friend. Durand-Claye had been an eminent engineer; he had distinguished himself at college, everywhere; but what made him really great was the whole-hearted manner with which he had given himself up to his work. Around them at Gennevillier, every sod of earth, every flower, breathed his name. A man with two hearts—a heart in France and a heart in his native Italy—Pacchioti, had proposed that a monument should be raised in honor of Durand-Claye. As a Frenchman, he could but blush that a Frenchman had not first made the suggestion; but while blushing, he gladly followed the example set by his excellent Italian friend. M. Deligny, Municipal Councilor, who had worked fifteen years with M. Durand-Claye, spoke a few affectionate words in his memory; and then the Mayor of Gennevillier, in the name of the inhabitants, desired to associate himself with the project, and promised a free grant of land for the monument.

M. Bechmann, M. Durand-Claye's successor, and Dr. Henriot, mayor of Rheims, having spoken, there were loud cries for Dr. Bourneville, who in the National Assembly had carried the bill which legalized these irrigation works, and whose admirable report on "l'Utilisation agricole des eaux d'égout de Paris" should be studied by all who are interested in the subject. Dr. Bourneville, in his speech, paid a handsome tribute to the various international congresses of hygiene. It was their debates, their decisions, which had strengthened his hands and enabled him to obtain the sanction of the French Assembly. M. Durand-Claye had collected a splendid library on sanitary questions, and proposed to leave it to the museum of hygiene which he hoped the municipality of Paris would soon be able to create, and he called upon M. Deligny to press the matter forward.

M. Bonkowsky Bey, chemist to His Majesty the Sultan, in a few well-turned sentences proposed that the name of the ten agriculturists who first consented to utilize the Paris sewage-water at Gennevillier should have their names engraved on Durand-Claye's monument. Delegates from Mexico, Brazil, and Egypt having also expressed their sympathy, Mr. Adolphe Smith was again selected as spokesman on behalf of England and America. In the name of these nations he desired to participate in the centenary celebrations of 1789, a date to be ever associated with the spread throughout the world of those principles of freedom which were the basis of true scientific research and knowledge. As representing the most liberal nations of the civilized world, he hoped America and England would always remain united with France in their forward march. He claimed for these countries the full right to participate in the honors to be rendered to the memory of Durand-Claye. He challenged the French right to monopolize this memory. Durand-Claye was a glorious example of the international character of sanitary science. He had never paused at a frontier line, but studied hygiene with equal assiduity in England, Holland, Belgium, even in Germany, availing himself of all the good ideas he could find in all countries. That library which he had so generously left to the town would be found to be an international library; and Paris was an international town, and hygienists of all countries meant to avail themselves of Durand-Claye's experience, and while inspiring themselves by his great works, claimed their right to contribute to the homage that would so justly be rendered to his memory. This speech was enthusiastically received. Dr. John H. Rauch, medical officer of health of Chicago, confirmed briefly in English the sentiments expressed, and promised to raise a subscription for the monument in America. Several hundred francs were at once collected among the guests, who, though they had started at nine in the morning, did not get back to Paris till five in the afternoon. Still the Congress was not quite over, for the next evening a hundred members, principally the foreign delegates, were entertained at a brilliant reception given in their honor at the Ministry of the Interior, by the minister, M. Constant.

Thus at last was this most animated and successful Congress terminated. I have given a very imperfect, incomplete account of the proceedings, but perhaps have said enough to show the interest and im-

portance of such congresses. Several subjects, notably the ventilation and heating of houses, so originally and ably treated by M. Emile Trélat and M. Somasco, I must leave for a separate study, and will attempt to describe the theories enunciated when dealing with the exhibits on these questions. But for a full account of the Congress it is best to wait till the official report, which will constitute a large and handsome volume, is published. This will probably be done at an early date, and will be sent gratuitously to all the members of the Congress. Those who were not members will probably be able to obtain the report by applying to the secretary-general of the Société de médecine publique et hygiène professionnelle, 28, rue Serpente, Paris.

#### ANSWERS TO CORRESPONDENTS.

**No. 287.**—The meetings are held in Newark. The secretary is Dr. A. Mereer, No. 31 Washington Street, Newark.

**No. 288.**—Since the year 1876.

**No. 289.**—We shall soon publish an article on the subject.

**No. 290.**—The author presented his observations as of physiological interest, and did not advocate their therapeutical application.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

**All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.**

**Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.**

**Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.**

**All communications intended for the editor should be addressed to him in care of the publishers.**

**All communications relating to the business of the journal should be addressed to the publishers.**

## Original Communications.

### A COMPARISON BETWEEN MERCURIAL AND AVITREOUS THERMOMETERS.\*

By MORITZ IMMISCH,  
LONDON, ENGLAND.

MEDICAL thermometry has not received the attention it deserves, and, though no doubt fully understood and appreciated by the few, it is totally neglected as a branch science of the medical profession by the many. Its immense importance in diagnosis and treatment is acknowledged by all, but, in order that the tell-tale thermometer should be a valuable guide to the medical man, it is important that the tale it tells should be rightly interpreted. Unless this is done it were better indeed not to depend upon thermometers at all. A thermometer presumably gives the temperature of the blood, and its readings are often taken as blood heat, whereas in reality it is not, and can not be anything of the kind. It gives simply the temperature of the part it has been applied to when the reading is taken. It depends entirely upon surrounding circumstances and accompanying conditions what relation the observed temperature bears to the actual temperature of the blood, which is really the point in question. The ability to correctly estimate these conditions at their proper value is only acquired by practice; but as a guide to every one who desires to become proficient in the use of thermometers it should always be borne in mind that the part to which the thermometer is applied is a radiating body constantly parting with its own heat to the surrounding atmosphere and other bodies in its vicinity not only by radiation proper but also by convection and evaporation. It is true that the circulating blood rapidly supplies fresh heat, but what is measured by the thermometer is not the blood heat, but the resultant of three things—namely, the real blood heat, the cooling process which is constantly active to lower the temperature, and the rate at which fresh heat is supplied. Anything which favors radiation, convection, or evaporation must necessarily have a marked influence upon that resultant in one direction and the actual blood heat in the other direction. The rate of heat-supply acts in one direction or the other, according to whether it is above or below the normal. As an illustration of the difficulties surrounding this question the following experiment might be tried: Place a dozen correct thermometers in different parts of a furnished room, and in an hour or two you will probably not find two thermometers reading alike. All that is necessary for this experiment to succeed is that the air in the room should be warmer than the inclosing walls. The air of the room may safely be taken to be of the same temperature throughout. In consequence of the very small capacity which air has for heat, the mobility of its particles, the ease with which air of different temperatures intermingles, all justify the assumption that the air surrounding these thermometers is really of the

same temperature, and yet we find this difference in their readings, which may amount to two degrees or more. The observed variation is owing to the differing absorptive powers of the substances which happen to be in their proximity. That the observed differences are really owing to this can be easily proved by coating the bulbs of the thermometers with varnish, gum, or lamp-black, by which means the radiation is greatly increased and the difference in the readings becomes more marked.

Now, the human body is another such heat center continually parting with its own heat to the surrounding air and other bodies in its vicinity. The presence of moisture on the surface of the body, a draughty room, a damp bed, a cold wall, whether the surrounding air is cold or warm—all these circumstances have a marked influence on the reading of the thermometer.

Take two equally perfect thermometers both reading alike, one in each hand; leave them there inclosed and stand sideways in proximity to a wall, and in ten minutes you will be able to tell whether the wall is cold or not. Although the blood itself is of the same temperature in both hands, the hand which is toward the wall, if the latter happens to be cold, parts with its heat at a greater rate than its fellow and the thermometer reads lower in consequence. Take a thermometer in your mouth in a cold room and you can not get it up to the normal point, although, doubtless, your blood is 98.4° F. Stand in a draughty place and the difference is greater, because the head itself got chilled by radiation and the breathing of cold air. It even makes a slight difference whether the head is bald or protected by a mass of hair. Each of the influences tending to lower the temperature in itself may not be very important, but when all combine, each adding its own effect, the difference may amount to one degree or more. Without taking these circumstances into consideration and simply going by what the thermometer tells you would be very improper, and in that sense thermometry would be worse than useless.

There are certain properties which are common to all thermometers and which must not be lost sight of by any one who wants to use them professionally. Every thoughtful observer will have noticed that the time required for a thermometer to rise from one degree to another is very much shorter when the difference between the temperature which the thermometer may happen to possess and that temperature which it is intended to measure is great. As this difference of temperature lessens, the time required to move one degree becomes greater and greater. Take the temperature to be measured 105°. In that case it takes quite as long for the thermometer to accomplish the last half degree as it required to move from 90° to 104°.

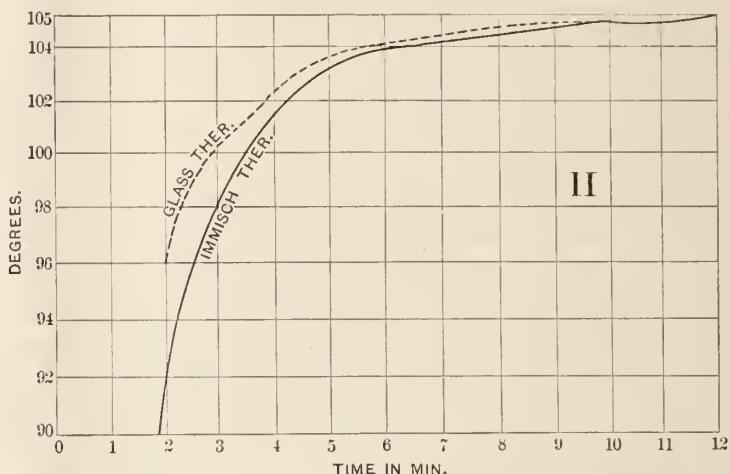

From a great many observations which I have made with different thermometers, all of which observations tally sufficiently close, I have prepared a series of diagrams. One of my objects was to compare thermometers of totally different make, and I used an "Immisch" thermometer alongside an ordinary clinical glass thermometer. The latter was not a self-registering one; both were verified at

\* Prepared to be read before the British Medical Association at its annual meeting.

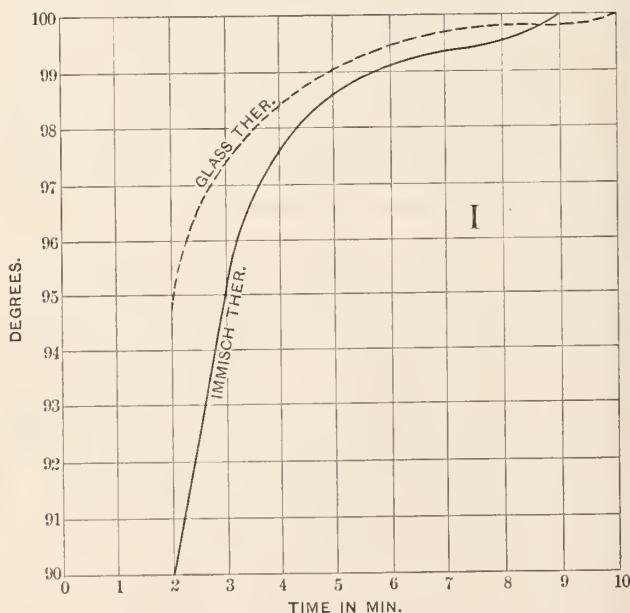

Kew Observatory. Both instruments were inclosed in a metal case filled with water. This metal casing was furnished with a glass cover to admit of the face of the "Immisch" thermometer being seen, and the stem of the glass thermometer projected from the case and was secured in one of the sides of the casing. The joints of the case were water-tight, to prevent any circulation taking place of the water inside the casing and the water-bath into which the casing was plunged. An assistant kept the bath in constant circulation by means of a rotating fan; a "Standard" thermometer and sundry taps were provided to enable him to keep the temperature of the bath absolutely constant for any length of time. Readings were taken every minute, and in some cases, as the diagrams will show, every five seconds. The diagrams thus plotted down clearly show that there is no appreciable difference between the two thermometers in point of time when the final heat was registered. In some instances the "Immisch" arrived there a little sooner, but in most cases the maximum was arrived at at the same time; but in all the observations the glass thermometer was in advance of the "Immisch" at the lower temperatures. We shall see later on that the converse of this feature is of the greatest importance and really constitutes a decided advantage of the "Immisch" over the glass thermometer.

Diagrams I and II represent what most frequently happened. The bath being at  $100^{\circ}$ , after three minutes the glass thermometer was about two degrees and a half ahead

These diagrams clearly show how easily a practitioner may be misled in pronouncing upon the merits of different instruments. If it is only a question of ascertaining what height a thermometer arrives at after three minutes of ap-

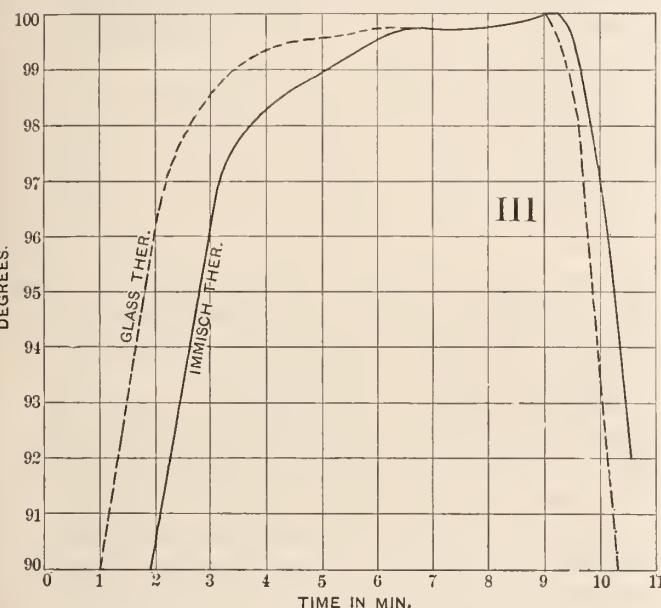

plication, the glass thermometer would have the advantage over the "Immisch"; but, if it is a question of ascertaining the true temperature of the patient, the apparent advantage disappears and even changes from one instrument to the other. The legitimate object of medical thermometry can never be attained by merely ascertaining what any thermometer shows after the lapse of three or four minutes. The instruments themselves vary and behave differently in this respect. Glass thermometers apparently alike show various degrees of sluggishness, owing to the thicknesses of the glass bulbs inclosing the mercury differing among themselves. But far greater errors—and this remark applies to all thermometers—are likely to occur through the cooling influences already named, and the effect which a greater or less circulation of the blood may have in supplying fresh heat at any rate which may be above or below the average. If the importance of these various influences is duly appreciated, it must be clear to every one that any reading taken, say, after three or four minutes is no guide whatever except to those practicing in hospitals, where the condition of the wards is expressly kept uniform, year in and year out, as much as possible. But even then it requires the experience of years to trust to this mode of taking readings. For outdoor practice it is highly improper to resort to it. When the practitioner is called upon to form an opinion of the patient's condition according to whether his thermometer shows one fifth or two fifths of a degree more or less, it is evident that readings taken after a certain fixed lapse of time of three or four minutes are quite useless, seeing that these readings may differ one or more degrees owing to conditions with which the patient has nothing whatever to do. It is, however, satisfactory that, as the diagrams show, there is no appreciable difference in the instruments themselves, of whatever make and construction they may be, in recording the true temperature of the part to which they are applied after a lapse of, say, nine minutes, and in an atmosphere of  $65^{\circ}$  or  $70^{\circ}$ . Six minutes may be taken as a safe interval, if a fourth or a half of a degree is added, according to the circumstances which affect the sluggishness of the instrument.

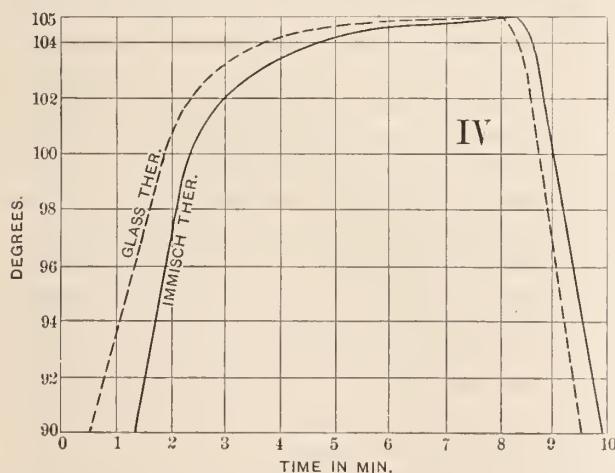

of the "Immisch," the former showing  $95^{\circ}$  and the latter  $97.5^{\circ}$ . This difference became less and less; after four minutes the difference was three fourths of a degree, and at six minutes the difference was one fourth of a degree; after eight minutes they stood equal, the whole being completed in between nine and ten minutes, the glass thermometer taking generally about half a minute longer to get to the maximum.

If it is considered that, even after such a reading has been taken, it refers only to the part to which the thermometer has been applied, and that we still have to exercise our judgment to determine what relation this reading bears to the actual blood heat of the patient, it is imperative that such reading itself should be without question. With an atmospheric temperature of  $80^{\circ}$  and upward, you get nearer the real blood heat in four minutes than in six minutes with a temperature of the room at  $65^{\circ}$ .

Diagrams III and IV refer to observations made with the heated box containing the two thermometers when at-

taining a true temperature of the bath. Being suddenly plunged into a bath of the temperature of the room, it is at once apparent that the time required for making these

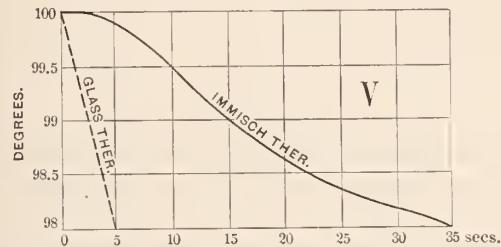

thermometers fall is just as short, or, in other words, they fall just as quickly as they rose when the difference of the temperatures was great. (See Diagrams I and II.)

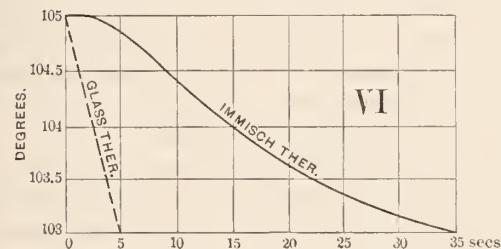

I must say a few words as to the apparatus chosen for the production of the diagrams. Objections may be raised because water was used for heating the instruments, whereas with a patient no water is present. Water has a great capacity for heat, and requires many more heat-units to raise its

temperature a given number of degrees than air, for instance. On the other hand, it is capable much more effectually to impart its heat to the instruments just because of its great capacity. In experiments with a box containing air instead of water, the time required by the instruments to record the temperature of the bath was more than three times as long. I chose, therefore, water as the medium, and of such a volume as closely to resemble the conditions obtaining with patients. In both cases the final temperatures are not attained before the lapse of nine or ten minutes. I therefore conclude that the conditions are conformable. Less water would have caused the maximum to be reached quicker; more water, slower than is the case with medical practice. The volume of water chosen was about one cubie inch and a half. The experiments can be easily repeated by any one who likes to verify the diagrams.

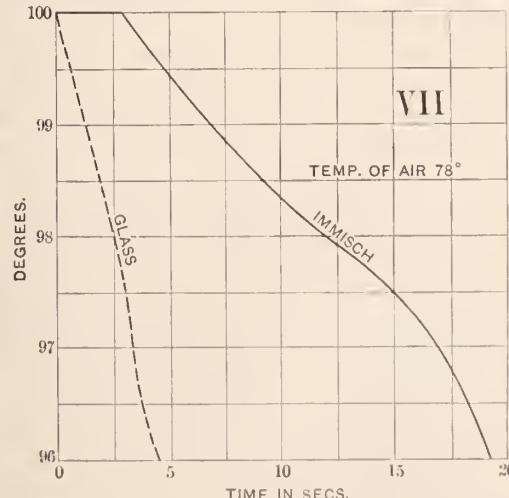

Diagrams V and VI refer to the two thermometers taken out of a warm bath and put immediately into another two

degrees lower; in one case the higher temperature was  $100^{\circ}$ , and in the other  $105^{\circ}$ . No water-jacket or box was used

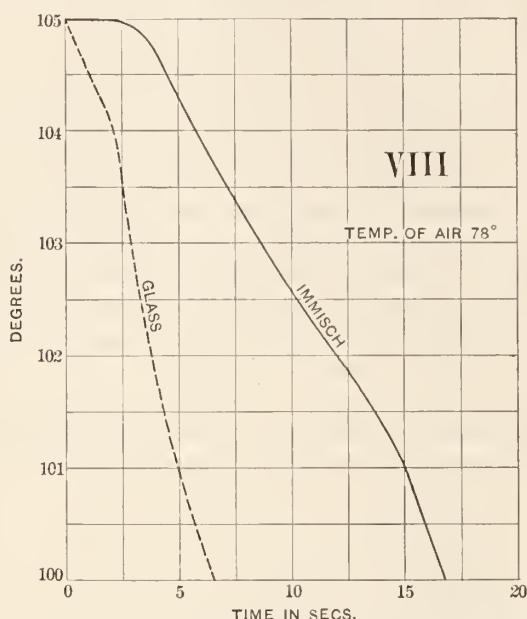

for this purpose, but the baths acted directly on the instrument. This was also done with regard to Diagrams VII

and VIII, which refer to the instruments being taken out of baths of  $100^{\circ}$  and  $105^{\circ}$ , respectively, and subjected to

the ordinary temperature of the room. Those last four diagrams were taken to show that an appreciable time elapses before the "Immisch" falls at all. I must remark, however, that in actual practice the stationary interval is longer

than in the diagram. This is owing to the instrument being wet when subjected to the air; and, although the precaution has been taken to dry them on a cloth after removal from the bath, this can not be done so quickly as to prevent a copious evaporation to set in, which we all know has a powerful cooling effect.

The "Immisch" thermometer is actuated by a "Bourdon" tube, which itself is surrounded by air inclosed in the case of the instrument. This air is warmed, and does not permit the colder bath or the colder atmosphere to affect the tube till the air itself is cooled first.

In Diagrams I and II we see that the "Immisch" was behind at the lower temperatures as compared with the glass thermometer; this was owing to the very same cause. The air had first to be warmed before the tube could be affected. The operation of cooling reverses this condition, and it is so far of great importance, as it shows on the one hand that a glass thermometer must be made self-registering in order that any reading can be taken at all; the "Immisch," on the contrary, can be withdrawn, and the pointer fixed after withdrawal. The operation of fixing the pointer takes less time than would elapse before the instrument begins to fall. Herein lies a distinct advantage which the "Immisch" thermometer has over the glass instrument. We can heat it to several degrees above the probable temperature of the patient before application. Two or three minutes would then suffice for the instrument to adapt itself to the real temperature of the part to which it is applied—to the axilla, for instance. The cooling, which takes place on applying the instrument, is counteracted by the instrument being warmer than the axilla, and we may be sure that the instrument has really parted with its excess of heat after two or three minutes. This, in my opinion, is the only legitimate way in which the time of application can be shortened.

The artificial heating is easily done by means of a lighted wax match. Care should be taken to heat both the back and the glass front—in fact, as evenly as possible, as otherwise the cold part would absorb the heat of the warmer portions of the instrument. A little management is, of course, necessary; but this is far easier acquired than is the case with many other instruments which medical men have to handle.

It goes without saying that the same thing can not be done with a glass thermometer; on the one hand we have seen that it must be self-registering in order to be used at all, but if made self-registering we can not overheat it before application, as in that case it would not accommodate itself to any lower temperature.

These diagrams are instructive in another way. They prove that any influence which causes the place to which the thermometer has been applied to cool to the extent of a quarter of a degree temporarily would retard the maximum reading by about two minutes. Not on account of the thermometer at all, because the instrument can not show more heat than is imparted to it, but on account of the axilla, or the mouth, or the hand, or any other part of the patient to which the thermometer has been applied requiring that time to rectify the disturbance.

Whenever the rise of temperature is so gradual as in point of fact it is with an axilla which has been partially cooled at the time of applying the instrument, it does not matter what sort of thermometer is used, as it is sure easily to accommodate itself to the gradual rise. If we had an instrument which instantaneously recorded from second to second the gradual rise of temperature of an axilla which had been temporarily cooled to the extent of half a degree, we should get a curve very much like that shown by our diagrams. But on analyzing these diagrams we find that both these thermometers, although differing so much in construction, are perfectly capable of accommodating themselves to the gradual rise, proving that an instantaneous thermometer, if any such existed, would have absolutely no advantage whatever over either of the two in question.

It is hopeless to get uniform diagrams from actual use with patients, as the conditions are subject to great changes; and I may now refer to a communication by a Dr. Makroeki, of Potsdam, to the "Deutsche Medizinal-Zeitung" of the 26th of March of this year. That gentleman gives, with the view of comparing three different thermometers (viz., Sack's so-called minute thermometer, Immisch's avitreous, and the ordinary glass thermometer), a series of readings—forty-three in all—half of which refer to ten cases with fever, and the other half to ten cases without fever. (See the table on the next page.)

The readings, originally Celsius, have been reduced to Fahrenheit. It is astonishing what a diversity of readings this gentleman gets with the three instruments. If diagrams were taken, some of them would be absolutely bewildering, and there are probably not half a dozen tolerably consistent. In Case 5 he gets, after five minutes' application of the minute thermometer, the same reading as he got after two minutes' application—viz., 97.16—and after ten minutes he gets 98.4; that is higher than he got with the

maximum glass one after ten minutes' application by as much as  $0\cdot6^\circ$ . In the next case (6) the difference is the other way; here the maximum thermometer shows three quarters of a degree higher than the minute thermometer, both after ten minutes' application, making a difference of  $1\cdot3^\circ$  in the two cases.

In Case 14 the minute thermometer shows after ten minutes' application nine tenths of a degree less than either the Immisch or the maximum, the Immisch in all cases being applied during six minutes only; and so I might go on through the whole of his work. When it is considered that these enormous discrepancies occur under circumstances presumably alike, one naturally asks himself, What use is thermometry at all? If the article in question and these figures prove anything at all, it is the difficulty of applying thermometers, pointing to the necessity of care and circumspection, which have evidently been wanting in the work of Dr. Makrocki. In no case can it be considered that the question which constitutes the proud title of the article, "What is the best Thermometer for Clinical Use?" has been satisfactorily answered. The gist of his article is that the minute thermometer in no case shows the same temperature after one or two minutes as the maximum after ten minutes. It would, indeed, be strange if it did. He might have gone further and pointed out (Case 14) where the minute thermometer after ten minutes shows  $0\cdot9^\circ$  less than the maximum; neither does the Immisch show after six minutes as high as the glass maximum after ten. Of course not. Nor would the maximum get as high in six minutes as an Immisch after ten.

Comparing thermometers can not be done on the patient, but such comparing must be done by some such apparatus which I have used and which is always uniform and under perfect control. A similar apparatus is used by the Kew authorities to test thermometers for verification. There are great pains taken at that establishment, which has a reputation for accuracy all over the world. Glass ther-

momters are apt to change; the glass alters its texture with time in the most capricious fashion, and, as the volume of the mercury remains the same, the change in the glass must affect the scale of the instrument. This defect is much more noticeable when the thermometers are new, but, unfortunately, they very seldom last long enough to give them time to settle. Recent improvements in the manufacture of glass for thermometer purposes look promising, but have not cured the evil; the certificate still contains the cautionary advice to have glass thermometers tested from time to time. This advice being omitted on the "Immisch" certificate, it is to be presumed that the authorities have satisfied themselves as to their permanency. The "Bourdon" tube in the "Immisch" does not change. The expanding liquid acting on the tube bends it. The tube is really a spring, which in opening and contracting is always within the limit of perfect elasticity like the balance spring of a chronometer. This does, however, not absolutely prevent the instrument from going wrong when it happens to be badly made. It must not be forgotten that watch-work is required to transmit the motion of the tube to the pointer. This can not be done without some friction, which is only negligible when the workmanship is first-class. It speaks well, however, for the "Immisch" that eighty per cent. on an average receive perfect certificates, whereas the average of perfect certificates is less than twenty per cent. with glass instruments.

It is a fact, which has been recognized by many, that all thermometers act more sluggishly with healthy persons than when applied to a patient suffering from fever, and some practitioners take this feature of greater or less sluggishness as indications of the patient's condition. This is quite independent of the actual temperature of the patient, and has only reference to the rate at which fresh heat is supplied to the system, or, more correctly speaking, to the thermometer itself. The importance of this remark can easily be made manifest. Take a thermometer in your hand, and after ten minutes you will find it registering, say,  $96^\circ$ . Then  $96^\circ$  is the resultant of all the influences which affect the thermometer. Now take a sharp walk (or any other bodily exertion will do as well), apply the thermometer for the same space of time, and you may get  $98^\circ$ , or may even reach normal point; not because the real blood heat has augmented, but the increased circulation has overpowered the cooling influences and the second reading is a faithful record of the resultant under new conditions.

**Long Intervals between Births of Twins.**—Dr. Engström, of Helsingfors, describes, in the "Finska Läkare sällskapets Handlingar," January, 1889, three cases of twin labors, where the interval between the births of the twins was unusually long. In the first case the second child was not born till thirty hours after the first had been delivered. Uterine contractions had ceased, the membranes were ruptured, and the child, ten pounds in weight, was delivered by turning. In the second case the interval was twenty hours. The waters were fetid, yet the second child, which weighed nine pounds, was delivered alive, by the aid of forceps. In the third instance the second child, weighing five pounds and a half, was delivered twenty-six hours after the first. In all the above cases both twins were saved. An interval of even twelve hours is not frequent in twin deliveries.—*British Medical Journal*.

## THE URETHROGRAPH.

A NEW INSTRUMENT FOR THE EXAMINATION OF THE URETHRA.

BY R. W. STEWART, M. D., M. R. C. S.,  
PHYSICIAN TO MERCY HOSPITAL, PITTSBURGH, PA.

In the treatment of urethral diseases the importance of being able to obtain reliable information regarding the caliber of the urethra, the presence or absence of strictures, their caliber, extent, and location, if present, as well as the location of painful spots, is self-evident. To obtain this information various instruments have been devised, but they are open to the objection that the results obtained by them are dependent so much on the skill of the operator that two persons examining the same urethra with the same instruments may arrive at different conclusions as to the condition of the urethra under examination.

What is wanted for the examination of the urethra is an instrument which will do for the urethra what the indicator has done for the steam-engine or what the sphygmograph has done for the pulse—an instrument which will make a record of the urethra at all parts, which shall be accurate and yet independent of the skill of the operator; a record which shall be the same whether the instrument is handled by the expert or by the novice.

Without entering into a discussion of the merits and demerits of the various instruments used in the examination of the urethra, I will describe an instrument which I have devised and called a urethrogram, which meets the requirements indicated above.

A brief report of this instrument has already appeared in an article on "The Diagnosis of Urethral Stricture of Large Caliber," published in the July number of the "Pittsburgh Medical Review." The instrument has since then been so materially modified that it merits a separate description.

It resembles closely a catheter inserted into a handle. Its anterior extremity, which is curved to permit of its introduction into the bladder, terminates in two jointed arms on either side, which present a smooth convex surface to the urethra. By means of a spring within the handle these arms are expanded until arrested by pressing against the urethra; the pressure exerted by these arms is uniform in all positions, and may be readily increased or diminished to any desired extent by means of a screw at the handle.

Beneath the handle there is a marking arm so connected with the jointed arms already mentioned that, as the latter expand or contract in following the irregularities of the urethra, the marking arm draws a line on a strip of card-board which is a reproduction of the contour of the urethra except that the irregularities of the urethra are magnified twice on the card-board. The card-board strips are marked longitudinally into millimetres and transversely into inches, so that at a glance the size and position of any portion of the urethra may be ascertained.

On the upper surface of the instrument there is an index which indicates in millimetres the circumference

of the urethra at the point where the jointed arms are in contact.

To use this instrument, it is inserted, with the jointed arms closed, into the bladder or, if the neck of the bladder is tender, as far as the prostatic urethra. Having the urethrogram introduced as far as desired, a strip of card-board is inserted into a slot beneath the handle. The diagram of the urethra is then taken by touching with the index finger of the right hand a movable pin which liberates the spring contained within the handle, expanding the movable arms at the extremity of the instrument until their expansion is arrested by the resistance of the urethra. The urethrogram is now withdrawn after the manner of withdrawing a sound, while the card-board upon which the diagram is taken is held stationary with the left hand. If desired, the card-board may be dispensed with and the condition of the urethra ascertained by simply observing the index on the handle of the instrument as it is withdrawn; but this method is open to the objection that one of the chief advantages of the urethrogram is dispensed with—that of furnishing a diagram of the urethra which may be examined at any time and kept for future reference or comparison with subsequent diagrams.

It may be mentioned here that on the back of these card-board strips a place is arranged for the name of the patient, the date, and any remarks the physician may desire to record.

Figs. 2, 3, and 4, for which I am indebted to Dr. Cartington, United States Marine Surgeon to the Port of Pitts-

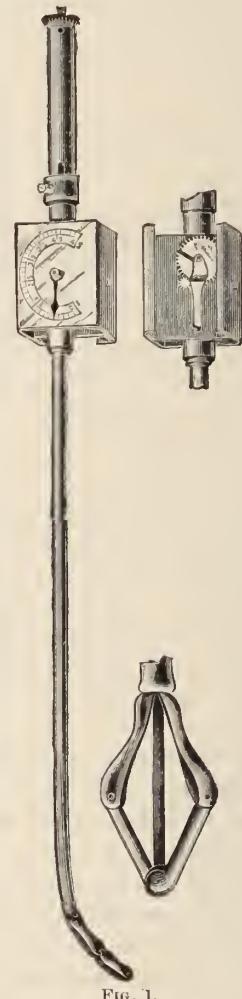

FIG. 1.

FIG. 2

FIG. 3

FIG. 4

burgh, who had in charge the patient from whom the diagrams were taken, represent the condition of the urethra of a patient before and during treatment for stricture, as indicated by the urethrogram. Fig. 2 represents the urethra previous to any instrumental interference whatever. It will be noticed that the prostatic urethra, which is represented

to the left, is the widest portion of the canal, being a little over thirty-five millimetres in circumference. Anterior to the prostatic urethra there is a stricture about two inches in length, and situated at the bulbo-membranous portion of the urethra; this stricture at its narrowest part is about seventeen millimetres in circumference. From the situation of this stricture, occupying the curved portion of the urethra, it would have been inaccessible to the urethrometer, which is only used in the straight portion of the urethral canal. About two inches from the meatus there is another stricture, more distinctly defined but less in extent than the previous one. Anterior to this stricture the urethra becomes dilated, but not so much as at the prostatic portion. At the meatus a third stricture is found, having a circumference of twenty-one millimetres.

The caliber of the urethra having been ascertained, Holt's divulsor was introduced and the strictures were stretched to the full extent of the divulsor; immediately afterward the urethrogram was introduced and Fig. 3 taken. Comparing this diagram with the previous one, it will be noticed that the stricture at the meatus has only yielded two millimetres, while the stricture at the middle of the pendulous urethra has yielded about six millimetres. The stricture at the bulbo-membranous junction has yielded less than the one anterior to it, but this may be accounted for by its depth in the urethra, placing it beyond the point of maximum distension of the divulsor. It will be observed in this diagram that at no point has the divulsor dilated the strictures up to the same width as the adjacent unstrictured urethra, so that we may readily draw the inference from this that Holt's divulsor, while materially aiding the dilatation of strictures, is insufficient of itself to obliterate them.

Fig. 4 was taken from the same urethra that the two previous diagrams were taken from, but not until a period of two weeks had elapsed, during which time the urethra was subjected to the introduction of sounds up to a size which was considered the full capacity of the urethra. It will be observed by this diagram that the urethra bears somewhat the appearance of a straight canal, that the stricture at the bulbo-membranous portion has disappeared, and the one in the pendulous portion almost so, while, in spite of all the stretching it has undergone, the meatus has only dilated four millimetres; surely this points emphatically to the fallacy of attempting to dilate strictures of the meatus. It will be noticed that under the use of the sounds even that portion of the urethra which was not considered as strictured has undergone some dilatation; to this the prostatic urethra is an exception, though it is still the widest part of the canal.

In considering this diagram the query arises, How near does the urethra, after instrumental treatment for stricture, resemble the normal urethra which has never been strictured? Is the prostatic urethra spindle-shaped, and the widest portion of the canal, as is shown here and generally taught? has the remaining portion of the urethral canal an almost uniform caliber? and is the meatus normally the narrowest part? These are vexed questions. The normal urethra is still debatable territory, but I venture to predict that the urethrogram, by presenting something tangible to

gaze upon and to form comparisons with, will yet shed light upon these disputed points.

In conclusion, I may add that the urethrogram, while designed for the examination of the urethral canal, is capable of modification so as to serve the same purpose in the examination of the other canals of the body that it does in the urethra.

## HÆMORRHAGE FROM THE LARYNX.\*

BY WILLIAM PORTER, M. D.,  
ST. LOUIS.

MANY objections have been urged against the use of the term laryngitis haemorrhagia, and it is probably well to begin with a few definite statements which I believe are supported by facts.

Haemorrhage from the larynx is seldom if ever unaccompanied by other symptoms or evidence of laryngeal disease, though sometimes these may have been previously unnoticed. It is rare, yet frequent enough to have been accurately observed and described. In most cases it is slight and, unless as a symptom of serious disease, is unimportant, yet in a few instances it has been profuse and alarming. Granting its frequency and the fact that it is generally in itself of little importance, it is still an interesting study, as an indication of pathological conditions and also because it is often erroneously credited to pulmonary lesions.

In examining the recent literature upon this subject, I can not but feel that careful observation will give it a more important place in the catalogue of symptoms of laryngeal disease. That it is not so is doubtless due to the fact that it has generally been found to be, when severe, but a symptom of some grave and definite morbid process, as of malignant, tubercular, or syphilitic character, and, when slight, to be of little importance.

Reasoning in the abstract, we might probably conclude that the larynx would be a favorite site for such local lesions as would result in hemorrhage. The parts have free vascular supply, as has the pharynx or naso-pharynx, where hemorrhages are not infrequent. The functions of the larynx require almost constant movement, and this is favorable to rupture of blood-vessels already weakened by disease. Such would be a reasonable hypothesis aside from recorded facts.

Against this supposition is the almost unanimous verdict of the members of the Section in Laryngology and Rhinology of the British Medical Association of last year. The president, in summing up the discussion, pointed out that there was an evident opinion among those present that hemorrhages from the previously healthy larynx and pharynx were extremely rare—far rarer than was supposed by the profession at large—and that in any case of hemorrhage into the upper air-passages of obscure origin it was probable that the hemorrhage was due to pulmonary tuberculosis, even in the absence of physical signs of that condition.

I would not thoughtlessly dispute the conclusions of

\* Read before the American Laryngological Association at its eleventh annual congress.

such high authority, and yet I must confess a doubt as to its entire accuracy. There might of course be on the part of some a disposition to hide behind technicalities. For instance, no one would oppose the statement: hæmorrhages from a previously healthy larynx are infrequent, for without previous lesion, small though it be, there could not well be hæmorrhage, which is a symptom of lesion. The thought intended to be conveyed, however, is plain enough, and while I grant that well-marked laryngeal hæmorrhage is rare, yet, as I have already intimated, I believe enough cases have been observed to make it worthy of study.

It seems to have been the experience of many observers that most of the cases of so-called laryngeal hæmorrhage are of pulmonary origin, or that pulmonary disease becomes evident sooner or later. It is generally true that bleeding through the mouth denotes pulmonary disease and is suggestive of grave conditions, but it is in some cases of this kind that the laryngologist is able to say that the hæmorrhage is not from the lungs, that it is purely local, and does not indicate a progressive course and fatal termination.

In twenty-two cases reported by six observers, most of whom are members of this association, phthisis followed in but three. The general tenor of replies to Gleitsmann's circular letter of interrogation upon this subject was "that hæmorrhage from the larynx can be regarded as a precursor of phthisis in exceptional cases only." The data furnished further tend to sustain the assertion made in this paper that many, if not the majority, of cases are not published, and that they are by no means so rare an occurrence as generally supposed." Regarding the first statement, I can say that three of the four cases of which I have notes have given no evidence of pulmonary disease, and am not sure but that in the fourth (No. 3 in the series) the pulmonary involvement has been the result of the hæmorrhage, as will be mentioned hereafter.

In this paper I will not attempt to present a full bibliography upon the subject, as this has been given by Dr. Gleitsmann in the "American Journal of the Medical Sciences" for April, 1885, with an additional series of cases compiled by the same author in the "Medical Record" for October 29, 1887.

Permit me, however, before mentioning several cases in my own practice, to recall a few well-marked ones which have been recorded by others.

Ten years ago Dr. J. H. Hartman, at the first annual meeting of this association, reported a case of laryngeal hæmorrhage from the rupture of a large capillary vessel upon the surface and about the middle of the left ventricular band. The patient had been singing, the hæmorrhage came on suddenly, several ounces of blood were expectorated, the next morning a recurrence, and two or three ounces of blood were again lost. The application of a strong solution of ferric alum was sufficient to stop the bleeding.

An interesting case was reported by Fraenkel in 1874 in which the patient, a woman in the fourth month of pregnancy, had repeated and severe hæmorrhage continuing at intervals for four weeks. As soon as the blood crusts which had formed on the laryngeal mucous membrane were re-

moved, parenchymatous bleeding from the cords and posterior wall could be distinctly seen.

During the past ten years a score of writers have contributed the history of cases to the literature on this subject, and of these I will mention but one which seems to me to be in every way typical. In the Section in Laryngology of the Ninth International Congress, Dr. Stockton, of Chicago, presented the history of a young lady, an opera singer, who suddenly lost her voice while practicing, and in a few minutes coughed up some bright frothy blood. The larynx was found coated with blood, and when it was removed, a small pulsating vessel was seen, and from it came the hæmorrhage, which was controlled by the galvano-cautery.

In my own experience I have records of but four cases of hæmorrhage from the larynx, not associated at the beginning with serious local disease or pulmonary tuberculosis. Elsewhere I have reported cases of pharyngeal hæmorrhage which were ascribed to pulmonary sources; but of necessity these are excluded here, though of the same general class as those under consideration and giving rise often times to the same errors in diagnosis.

CASE I.—Miss K., aged eighteen, with good family history, had repeated hæmorrhages with some hoarseness, and at times soreness in the glottic region. After failing the first time to find any chest complication and nothing to indicate laryngeal bleeding except a chronic laryngitis, I saw her a second time while she was expectorating blood. The site of the hæmorrhage was seen to be a small perforating ulcer of the right ventricular band. The bleeding was, after several recurrences, finally controlled, and the laryngitis has under treatment been relieved. It is two years since I first saw Miss K., and there has been no return of the bleeding and no evidence of pulmonary disease. This case is also reported in the proceedings of the last Medical Congress, vol. iv, p. 45.

CASE II.—In January of the present year I saw Mr. G., a Government inspector, whose duties frequently required him to be in the holds of boats which are often damp and foul. He was forty-two years old, robust, and with a good family record. He said that for a year he had had recurrent hæmorrhages which he feared were from the lungs. He was slightly hoarse and was expectorating blood when I saw him. I found nothing to indicate lung disease, but in the larynx discovered the bleeding to come from the posterior part of the right vocal cord, which was red and swollen. I believe that all the hæmorrhage came from this part of the larynx, because it was entirely controlled by the direct application of iron, and the local inflammation has improved under the usual treatment.

CASE III.—Miss L., a pale, delicate-looking little lady of about thirty-five years of age, consulted me three months ago on account of almost constant cough and repeated though slight hæmorrhages existing for six weeks. There was no expectoration other than the blood and a little mucus, half a degree of fever, pulse slightly quickened, but no loss of flesh, and fair appetite. The family history was free from any trace of so-called hereditary disease. A careful examination of the chest gave negative results. The larynx was red and the mucous membrane over the left arytenoid cartilage, and indeed the whole left side of the larynx, including to some extent the vocal cord, appeared swollen. There was at this time some hoarseness, but no bleeding. Although the circumstantial evidence was in favor of laryngeal hæmorrhage, it was not until her third visit that I could affirm it. While waiting in my office the

bleeding returned. At once making an examination, I found that the haemorrhage came from the suspected region of the larynx, especially from near the posterior attachment of the left eord. After this the bleeding returned a number of times, but has not appeared during the last two months.

A fortnight since, or nearly four months from the first haemorrhage, I found evidence of pulmonary consumption, not at the apex, where phthisis as a rule begins, but in the right lung at the third intercostal space anteriorly. There was and is now slight dullness, diminished vesicular murmur, and prolonged expiration.

It has been shown by Dr. Alexander Hodgkinson ("British Medical Journal," September 15, 1888) that blood may pass from the pharynx into the larynx and down the trachea with the utmost facility. After an operation upon the pharynx he found the blood trickling over the interarytenoid fold, and apparently giving rise to no laryngeal irritation.

In discussing this subject before the Section in Laryngology and Rhinology of the British Medical Association, 1888, Dr. David Newman, of Glasgow, raised the interesting question as to whether or not haemorrhages from the upper air-passages might act as a predisposing cause to tubercular disease. He reported a case which is so suggestive, taken in connection with Miss L.'s history, that I quote it. There was a "papilloma attached to the posterior pharyngeal wall from which repeated and sometimes copious haemorrhage took place. The blood escaped by the nose and mouth, but on several occasions it flowed into the trachea and was subsequently coughed up. For six months these haemorrhages were observed to occur at irregular intervals, and no symptoms developed nor could physical signs be discovered to support a suspicion of pulmonary disease, the patient being in perfect health with the exception of the growth in the pharynx. At the beginning of last year, however, the condition of the upper lobe became suspicious, and within three months marked signs of consolidation developed."

In the case of Miss L., it is true that the general condition pointed to something more than a recurrent haemorrhage that was never very severe, but, sustained by Dr. Newman's experience, I can not but believe that this is one of those instances of "phthisis ab haemoptoe," for it is a pathological fact that tubercular disease may follow a pulmonary haemorrhage. "The inhaled blood is simply dead organic matter, offering no resistance to the action of specific micro-organisms, and, when it becomes infected, induces changes in the surrounding tissues which result in consolidation and terminate in tubercular phthisis." It may be that in this case the laryngeal haemorrhage was but one of several factors in the development of the pulmonary condition, yet the bleeding was distinctly laryngeal and the pulmonary symptoms were not evident until some months after the haemorrhage began.

**CASE IV.**—Mrs. R. was brought to me by her husband, himself a physician, on account of two slight haemorrhages ten days apart. She was expectorating blood in small quantities when I saw her. Here there could be no doubt as to the nature or location of the lesions for the veins at the base of the tongue were distinctly varicose and one, and perhaps more, ruptured.

This case can scarcely be cited as one of laryngeal haemorrhage, but I mention it for the sake of completeness. Mr. Lennox Browne believes these conditions to be associated with varix in other parts of the body, and often manifested to such an extent as to constitute a "truly haemorrhoidal state of affairs." In confirmation I can add that there is a varicose condition of the veins of the left lower extremity in the case just reported.

Fortunately, I have not seen a case of marked submucous infiltration of blood in the larynx as described by Ingals, Schnitzler, Lewin, and others.

The subject is so interesting that any attempt at completeness or to include the study of laryngeal haemorrhage from well-defined general disease, or those of traumatic origin, would extend this paper far beyond its limit.

I beg to offer the following conclusions:

1. Laryngeal haemorrhage may occur from simple local conditions.
2. Unless associated with other and more positive symptoms, it is not indicative of pulmonary lesion.
3. It is possible, through the passing of blood from the larynx into the lungs, that pulmonary disease may be incited.
4. Care should be taken to distinguish between pulmonary and laryngeal haemorrhages, not only for the sake of more exact treatment, but especially because of the more favorable prognosis that may be given in many cases of the latter condition.

## WARTY GROWTHS IN THE NARIS.\*

BY E. FLETCHER INGALS, M. D.,  
CHICAGO.

A PECULIAR case of this rare affection has for some time been under my treatment, which I believe will be of interest to this association.

Mr. X., a gentleman forty-six years of age, came under my care three years ago, complaining of hawking and spitting, and hoarseness upon using his voice for a short time. These symptoms were found due to a recurrent pharyngo-laryngitis induced by thickening and deflection of the septum narium and swelling of the inferior turbinated bodies. He objected to operative procedures; therefore the treatment was limited to means for reducing the swollen condition of the turbinated bodies and relieving the congestion of the larynx. In a short time these measures were so far successful that he was relieved and had no more trouble for several months, but the following spring the difficulty returned, and was associated with a subacute tracheitis. I saw him occasionally for a few weeks, and subsequently he remained well, until he finally returned in March, 1888, complaining of similar trouble. At this time, in addition to the appearances formerly noted, I found a small, grayish, sessile, warty excrescence on the mucous membrane of the left nostril, about a centimetre and a half within the nostril. To this I applied chromic acid, which completely removed it, and there had been no return at the end of five weeks, when he started for New Mexico. Upon his return, about three weeks later, I found the left nostril about one half occluded by

\* Read before the American Laryngological Association at its eleventh annual congress.

a soft papillary growth, which sprang from the mucous membrane of the septum within about a centimetre and a half of the nostril. This was about seven millimetres in diameter by seventeen millimetres in length, and had a base fully as large as the diameter of the growth. I removed this with a snare and cauterized the base with chromic acid. A week later two or three small growths, grayish in color and hard to the touch (indeed, in all respects, excepting color, exactly resembling warts on the skin) were found—one on the floor of the naris, just within the line of union of skin and mucous membrane, and others on the anterior end of the inferior turbinated body. These were cauterized thoroughly with nitric acid. A month later two more warts were destroyed in the same way, and three weeks later two others had appeared on the septum, about fifteen millimetres from the nostril. These were also touched with nitric acid. A week later, finding that the warts on the septum and turbinated body continued to grow, I thoroughly cauterized them with the galvano-cautery. A month later other small warts had appeared in the same locality. These were cauterized with nitric acid, and when they reappeared were touched with a ninety-five-per-cent. solution of carbolic acid. Afterward, from time to time, chromic acid and nitric acid or acid nitrate of mercury were used to destroy the warts. Some were eradicated, others grew again, and still others were developed from the surrounding mucous membrane. In December, 1888, and the early part of January, 1889, I curetted out all of the warts to a depth of about three millimetres below the surface of the membrane with the galvano-cautery, but by the 19th of January another small wart had developed near by, and similar growths have continued to spring up at intervals ever since, so that altogether I must have destroyed twenty-five or thirty. Some places where the warts have been removed now appear perfectly healthy, and others show healthy cicatrices. I have not used the galvano-cautery often latterly because I did not wish to destroy so much tissue; besides, the results from it were not much better than from other caustics.

On the 20th of April the patient returned after an absence of two weeks, and I found, besides two or three minute warts on the septum and one of considerable size at the lower part of the nostril, a comparatively large mass of warty tissue at the anterior extremity of the inferior turbinated body which grew from a broad base about eight by sixteen millimetres in size, and was about six millimetres in thickness at its largest part. This was of a pink color, had a slightly raspberry-like surface, and the little nodules, which were somewhat lighter in color than the tissue between them, presented a few small red spots similar to those seen on ordinary warts. The smaller warts were touched with acid nitrate of mercury; the large mass I removed with the galvano-cautery, scooping out the soft tissue nearly down to the bone.

Professor Walter S. Haines has examined this and reports as follows: "The small tumor which you recently sent me has been carefully examined under the microscope conjointly by Dr. A. J. Ochsner and me, and we find it to be a papilloma similar in structure to a common wart. It consists of a central portion of connective tissue, sending off numerous delicate branches or papillæ, which are covered with a somewhat profuse layer of epithelium. The latter, however, although abundant, is entirely superficial, not extending down into the connective tissue itself. We find no nests of cells, nor any other important histological elements excepting those mentioned above."

For several months preceding the middle of April, 1889, the warts have developed less rapidly and have had almost exactly the density and appearance of cutaneous warts, ex-

cepting that they were somewhat lighter in color on account of the moisture of the parts. The patient has never had pain in the growths, has no cachexia, is apparently in perfect health, and wounds of the parts heal kindly; therefore I do not think these growths of a malignant or lupoid character. He has several healthy children, is a gentleman with a clean history, and has no sign or scar indicative of specific disease; indeed, there seems every reason for believing that there is no such taint. At only one time have the growths resembled condylomata, but for a period of about fifteen months they have sprouted up and grown rapidly to a moderate size like cutaneous warts which they so closely resemble; therefore I believe them essentially the same as the verrucæ so frequently seen upon the hands of children.

I have never observed this affection in other patients, and, though authors speak of papillary growths and condylomata in the naris, I have been unable to find a description of any case closely resembling this. I have had the library of the Surgeon-General's office carefully searched and can find records of only two cases at all similar to it, but in each of them there was only one growth which upon removal did not recur. The cases referred to are as follows:

First, "Condylomatous Polyps of Nasal Fossa," etc., by Dr. A. Testelin, "Jour. de méd., chir. et pharm." Bruxelles, 1859, xxviii, p. 147. The growth was described as tongue-shaped, slightly thickened at its edges, like a cock's comb, about six centimetres in length and about six millimetres in thickness; soft to the touch; nowhere vesicular in appearance, and with no evidence of serous infiltration. Its color grayish-yellow, dotted with minute red spots. It was apparently attached, by a portion about twelve millimetres in length, to the border of one of the turbinated bodies. This growth seems to have been very similar to the largest growth, which was removed in the early part of the treatment, in my case.

Case second, "Papilloma of Septum," by H. T. Butlin, "St. Barth. Hosp. Rep." 1885, xxi, p. 150. The author found a "warty growth" depending from the upper part of the front of the naris, nearly blocking the passage. He removed it with the galvano-cautery and it did not return. He says: "So far as the diagnosis is concerned it is easy, for the warty character of the tumor is distinctly visible as it lies in the interior of the nostril. It may, of course, be mistaken for a warty epithelioma, a disease even more rare."

I saw a warty growth similar to these in the person of an elderly lady about three years ago. It was about a centimetre in diameter, grew by a comparatively small pedicle from the mucous membrane of the anterior portion of the septum, and had the same general characteristics as that described by Testelin. I removed it with a steel-wire snare, and there has been no recurrence.

These cases seem to be of the nature of the large single warts or moles not infrequently met with on the back and sides. In the ease of Mr. X. the growth resembled as closely as possible the apparently contagious ordinary wart known as *verruca vulgaris*. There were two or three very small warts when the condition was first noticed, but others have grown near these and upon the opposite surface, apparently

spreading from the original warts. Many times the growths have seemed to be eradicated, but the warts have appeared again in the same or other places until altogether there must have been twenty-five or thirty, varying in size from three to eight millimetres in diameter.

If any of the members of this association have seen similar cases, I shall feel under great obligations if they will tell me how to cure this so that the growths will not return. It now appears that my present line of treatment may succeed with the efficient aid of time, but I should like to escape obligations to this ancient remedy.

70 STATE STREET, CHICAGO.

## LOCAL TREATMENT OF DIPHTHERIA.\*

BY J. C. MULHALL, M. D.,  
ST. LOUIS.

THERE is hardly a familiar disease concerning which the evidence of witnesses is more conflicting than in diphtheria, no matter from what standpoint it may be viewed.

Statistics based on mistakes in diagnosis, on the varying nature of epidemics, on faulty reports as to anatomical regions invaded, and on our general ignorance as to its method of diffusion, its aetiology and pathology, no doubt account for this confusion.

A vast number of agents have been employed in the local treatment of the disease with the usual conflicting testimony as to value.

It is, however, chiefly concerning the method used in their application that I desire to draw attention to a plan which for four years has yielded me gratifying results. When I originated this plan I took for granted several propositions commonly accepted by observers:

First, that the disease is a germ disease.

Second, that in the vast majority of cases the specific microbe selected the tonsils as their initial culture soil.

Third, that, unless checked by germicides, their colonization usually resulted in local putrefactive changes with general secondary septicaemia.

Fourth, that implication of the laryngeal or nasal chambers largely increased the mortality.

Fifth, that the disease is acutely adynamic.

It occurred to me, therefore, that, as was already largely practiced, the local treatment should be chiefly antiseptic, and that, as the disease spread rapidly and the salutary effect of antiseptic solutions in the upper air-passages, from anatomical reasons, could be of but short duration, this antisepsis should be, if possible, continuous. It will be readily admitted that it is of the utmost importance to maintain the patient's strength, and that, therefore, an element in ideal local treatment is, other things being equal, the employment of agent and method which least harass the child and which permit the recumbent attitude throughout. It suggested itself that a method which washed out from the throat the perverted secretions was preferable to that which invited a subject too young to expectorate to swallow them, and

which permitted the larynx to be bathed in them, as must occur in the use of a spray. The instrument with which these requirements can best be met is one which is found in nearly every domicile—namely, the common household syringe. It is a fact not generally known that if the end of such an instrument is introduced into the pharynx or into the back part of the mouth of a young child, the throat can be boldly flushed out without causing gagging, vomiting, coughing, or strangulation. Reflexly, the tongue immediately retracts and pushes the epiglottis down, making a water-tight glottis, and the child involuntarily ceases to breathe while the pharyngeal irrigation goes on. The first treatment, like any other first local treatment, in a young child is met with repulses, but even very young children soon learn to appreciate the agreeable effect of clearing the throat of foul and adhesive secretions, and soon quietly submit. With badly trained children, some of whom even repulse the nurse when she smears the nostrils and lips with a soothing ointment, I commonly use the rectal tip, or, better, a pewter tip which can be curved so as to be insinuated behind the last molars; but ordinarily I use no tip, simply the rubber hose, which is soft and has the further advantage of providing a larger stream. The physician himself carries out the first treatment as a demonstration to the nurse.

The child lies in a crib, one side of which is open; a rubber cloth conducts fluids into a vessel. The child's head is brought to the edge, the face turned toward the vessel, and the flushing is rapidly accomplished. The exertion, even of sitting up, is usually avoided. I direct the washing to be done every hour in the waking state, and to never permit the child to sleep three hours without it. I have used various antiseptics. I prefer a mixture of carbolic acid and compound solution of iodine properly diluted with warm water, which frequently, in addition, is saturated with boric acid. An ordinary water tumbler of fluid is consumed at each irrigation.

This plan is so far imperfect, since it does not provide for disinfection of the post-nasal region, and there are few cases of diphtheria which do not more or less implicate this region, rich in lymphatics and probably, next to the tonsils, most frequently the lie of poison march to the system at large.

I have been amazed in consulting practice to observe the frequency with which the nose had been neglected until serious nasal signs—such as hemorrhage, fetor, or total obstruction—had compelled some kind of attention, very often too late, for this triad of symptoms is most commonly the harbinger of death.

If we consider that the general practitioner is usually unacquainted with rhinoscopy, that even the expert has often failed in illuminating and seeing the nasal cavities of a young child, that the nose which the evening before seemed uninhabited is found in the morning to be seriously affected, it can hardly be gainsaid that prophylactic treatment of the nasal cavities in pharyngeal diphtheria is a wise therapeutic measure. Antisepsis of the nasal cavities can do no harm, while it may prevent or render mild invasion from the throat. Moreover, since for many reasons we can not in

\* Read before the American Laryngological Association at its eleventh annual congress.

these cases treat the pharyngeal vault from the mouth, the anterior nasal cavities form ready avenues of approach for the disinfection of this region, and this is an integral part of my plan of continuous antisepsis. Let me repeat that, apart from this being a channel for the antiseptic treatment of the throat, I desire to strongly recommend to the profession that in every case of diphtheria, whether the nose be affected or not, the nasal cavities be kept sterile from the first. The method of accomplishing this varies. When it is clear that neither the post-nasal nor nasal chambers are attacked, the frequent insufflation of a non-irritating antiseptic powder may be sufficient. When uncertainty exists, or it is apparent that invasion has taken place, the nurse is instructed to wash out the nasal cavities with the same antiseptic solution as that employed in the throat, except that it should be far weaker, so as to irritate the nose as little as possible, and should seldom exceed in amount more than two teaspoonfuls for each nostril. The child, if possible, clears the nose and the antiseptic powder is at once forcibly insufflated. This, as the child lies on its back, gradually trickles into the pharynx and assists in the plan of continuous antisepsis. I commonly use finely powdered sulphur, or iodoform, or salicylic acid highly diluted with a trifle of cocaine, to prevent irritation.

This cleansing of the nose should not be done with the household syringe, for it throws a stream too small in diameter, and one far too forcible in careless or unskillful hands; nor does it permit of the regulation of the amount of fluid to be injected. The point of the ordinary glass syringe introduced into the nostrils of an impatient child is apt to produce an undesirable wound of the septum. Moreover, the caliber of the nozzle is far too small, permitting a slender, swift, painful, and inefficient stream.

The syringe which I show you is made for me by Mr. J. M. Good, a druggist of St. Louis, and fulfills, I believe, the ideal requirements of a syringe for anterior nasal medication in young children. Its capacity is about two drachms. It terminates in a bulbous enlargement which prevents a forcible stream, forms a shoulder to rest against the margins of the nostrils, and, since it terminates abruptly in the nozzle, can not enter the nose and abrade the mucous membrane. The diameter of the outlet is one fourth of an inch, thus permitting a large yet gentle stream. Before I invented this syringe I was in the habit of filing through a small glass syringe at its neck, where the diameter was large, thus avoiding the objections of the tip. The nozzle thus altered should be held in an alcohol flame to smooth away irregularities. The frequency with which the nasal cavities should be irrigated is a matter of individual judgment. Gently and quickly done with agents that are not painful, children readily submit to it—an important matter, for, whatever the plan of local treatment be on the adynamic diseases of childhood, that plan is best which, other things being equal, meets with least resistance. The rapid dissolution of the membrane is undoubtedly an element of successful local treatment, and I frequently make use of solvent remedies immediately succeeding the cleansing of the diseased surface. I have best succeeded with papoid.

There is but one method of local medicinal treatment

which can be efficiently pursued in the laryngeal diphtheria of children—that by vapors. At appropriate stages, the inhalation of the fumes of slaking lime deserves always to be remembered.

I beg leave to call your attention to a modification of the plan of Deltil, which I have hitherto employed in seven cases, with a final result of four recoveries and three deaths.

A small apartment in the house is selected, the carpet and other belongings removed; the room is thoroughly fumigated with sulphur, and a sheet saturated with a disinfectant spread across the doorway.

A gas-stove is introduced which will support two vessels. Into each is poured a half-gallon of water. Into each of these a half-pint of pine tar is stirred, and a tablespoonful of oil of turpentine. As steam is generated, water is occasionally added, so that the half-gallon mark is maintained. The amount of tar will be sufficient for the entire treatment, but to each vessel there is added every hour a tablespoonful of the oil of turpentine. I have not as yet observed stranguary or the characteristic odor of the drug in the urine.

The air from outside should be admitted several times daily. The heat from the gas precludes this method in warm weather.

In three of my cases, with one death and two recoveries, I have been able to demonstrate membrane with the laryngoscope. The four children safely passed the laryngeal crisis with but little cough and no glottic spasm. In a boy aged four, seen with Dr. Holland and Dr. Frazer, of St. Louis, who died on the seventeenth day from exhaustion, but not the slightest dyspnoea was at any time observable, though total aphonia existed, and I was able to demonstrate to these gentlemen the presence of membrane in the larynx. The steam is generated day and night, and in one of my cases was continually done for six days.

In diseases in other parts of the body whose natural termination is in presence the surgeon, in anticipation of this event or on its actual arrival, thinks first of antiseptic measures. It is therefore probable that analogous measures are the best that can be employed in diphtheria. I have endeavored to describe a reasonable method of their execution.

**The Functions of the Cerebellum.**—“Is the cerebellum an organ for the storage of cerebral events which have become automatic? Do we first of all receive with the cerebral cortex and then practice with the same brain-bark, and afterward relegate to the cerebellum, as to a limbo, those things of which we are so tired of being conscious? Are all performances of the cerebral cortex conscious acts, and those of the cortex of the cerebellum unconscious? And so might questions, more or less unanswerable, be postulated without end. The functions of the little brain are scarcely known at all; even the dependence of the equilibrium on its existence may be called in question on the data supplied by pathology. It is perfectly certain that no obvious signs of nervous disease need exist when the lateral lobes are the seat of even extensive mischief. Some regard the cerebellum as the terminal organ of all visceral sensation, and on this assumption it has been thought that the curious perturbations in visceral epilepsy are to be ascribed to perversions of the vitality of the gray matter of the little brain. Anything is possible for the cerebellum. The most gifted imagination might guess strange things, yet pathology could perhaps find exact counterparts.”—*Lancet.*

THE  
NEW YORK MEDICAL JOURNAL,  
*A Weekly Review of Medicine.*

Published by  
D. APPLETON & CO.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, SEPTEMBER 21, 1889.

THE PASSAGE OF THE VIRUS OF RABIES THROUGH THE PLACENTA AND VARIOUS GLANDS.

ONE of the most brilliant professors of the school of medicine of Paris opened his course of lectures last year with a remark which has been widely repeated and which expresses the feeling of earnest men who are engaged in advancing the science of medicine to-day. Although some of the force of his words is necessarily lost by translation, yet, as nearly as we can recall them, they were as follows: "I think, considering the triumphs of science in this last quarter of the century, that it is good to live in these times, to those who interest themselves in the affairs of medicine." By these words he referred to the modern discovery of the presence of micro-organisms almost everywhere; to the knowledge acquired of the pathogenic influence of many of them; to the usefulness of many to the human race, which without them would not be able to subsist long upon the earth; to the recent knowledge of other pathological processes in the body more chemical or physicochemical in their nature than dependent upon the growth of microscopical parasites; and to the newly found methods of protection against morbid germs and the modern means, both surgical and medical, of removing from the human economy the effects of their injurious presence there. He showed a record of progress in the recent past which promised great results in the near future. One of the broad channels in which this progress is being continually made is the science of biology, which in a wide sense includes the relations of microscopical to human and other of the higher organisms, and of animal poisons to a healthy economy. This brings us to the subject of our article.

The fact that morbid germs of many varieties can live in human tissues and circulate in the blood is now beyond discussion, but the fact that they can also pass through the unbroken epithelial and membranous structure of certain glands and parenchymata, and be secreted with the normal products of such glands and parenchymata, has not until quite recently been proved. Not only has the virus of rabies been found to be secreted by the mammary glands in animals having that disease, but it has also undeniably passed through the tissues of the placenta of the rabbit and of the guinea-pig from the maternal blood to the foetal, and caused the death of the offspring *in utero*. Roux, who is so well known in bacteriological circles through his connection with the Pasteur laboratory, has endeavored to obtain this result, but without demonstrative success. Perroncito and Carita, however, have been more fortunate, and their experiments are recorded in the "*Recueil de médecine vétérinaire*" for 1887, No. 13. The latter practiced

intracranial inoculation of rabietic virus upon a pregnant rabbit shortly before the end of her period of gestation. Five days later the animal was delivered of a litter, of which four were dead and one was living, and the last also soon died. Four days after this the mother died of the paralytic form of rabies. Now comes the practical demonstration. With the brains of two of the still-born young two healthy guinea pigs were inoculated, of which one died of ordinary raging hydrophobia. Another pregnant guinea-pig was inoculated in the same manner as the first one, brought forth two living young two days later, and died nine days after the inoculation. Soon afterward the young both died, without very pronounced rabietic symptoms, however, but the brain of each was used as material for the inoculation of a rabbit and a guinea-pig. The former succumbed in eleven days, the latter in fifteen days, to clearly pronounced rabies, thus showing plainly that the mother of the two young guinea-pigs had transmitted the disease to her offspring yet unborn, and that they in turn had infected the rabbit and another guinea-pig with the original disease.

Some time ago Pasteur stated that the salivary glands were not the only ones whose secretions contained the rabietic virus, and that the lacrymal glands and also the pancreas secreted products containing the virus. Recently this list has been increased, and the mammary glands are now known to secrete the virus, to furnish poison with the food. Nocard, who reports his experiments in the same journal, tried four times to impart rabies to healthy animals by using the milk of rabid animals, and succeeded once. He took a few drops of milk from a nursing bitch that died of rabies, mixed it with two or three drops of water, and injected it into the anterior chamber of the eye of a rabbit, and the rabbit died of rabies about six days afterward. Roux also had one successful experiment among many. He inoculated a rabbit by trephining with a fragment of a lacteal gland of a suckling rabbit that died of rabies, the fragment being triturated in some of the milk of the dead female. After twenty-eight days the inoculated rabbit sickened and in two days more was dead of rabies. A still more important observation of this transmission was made with human milk by Bardach at the bacteriological institute in Odessa. A woman who had been nursing a child for six months was bitten by a mad wolf, and at the time of her admission into the hospital was suffering with hydrophobia. Four rabbits were inoculated with her milk by trephining. One died of rabies after eleven days. With its brain two other rabbits were inoculated, which died of typical rabies twenty days later. The three other rabbits of the first series all died of indubitable rabies in fifteen or sixteen days after the inoculation. To make assurance doubly sure, the experimenter inoculated a dog with the brain of one of the three rabbits, and with the brain of the rabid dog infected a rabbit again, thus establishing the genuineness of the disease of which the infecting agent was primarily contained in the woman's milk. An interesting fact remains to be chronicled. The nursing child of the woman who died with hydrophobia was still healthy four months and a half later.

In all these experiments and observations the morbid germ had penetrated and traversed organic tissues of a certain degree of compactness and density, in which there exist no apertures or natural orifices suitable to the passage of those germs. It must be admitted, therefore, that they forced a way for themselves through tissue everywhere continuous—the placenta in some instances, the mammary gland in others. It can not be urged from this fact, however, that the virus of rabies is amorphous, chemical, and soluble, instead of being of definite form and insoluble—in other words, consisting chiefly of microbes; for other well-defined structures, such as leucocytes and red blood-corpuscles, have been seen to force a passage through continuous tissue. Although the micro-organism of rabies has not yet been isolated, there are weighty reasons for believing that it exists—reasons as good as those that made Leverrier believe that the planet Neptune existed before Galle turned his telescope upon it to discover it. This is not the occasion to enumerate those reasons, but it may be said that most pathologists admit the probability of the early discovery of the micro-organism. No doubt exists, however, about the passage of another micro-organism through the mammary glands. The *Bacillus tuberculosis* is eliminated with the milk of tuberculous animals, and multiplies in the organism of the child that consumes it. Here is one of the recent discoveries included among those to which Professor Bouchard's remark, quoted in the opening paragraph of this article, is applicable. From a biological point of view, it is interesting to note how this micro-organism acts in order to preserve itself and to multiply in the organism of the animal; from a hygienic and pathological point of view, it is necessary to know this fact in order to guard against the encroachments of this same morbid germ. In rabies, as in tuberculosis, there is a certain danger in using the milk from the infected animal, although the danger seems at present more remote in the former than in the latter.

From the foregoing we conclude that the virus of rabies (almost certainly a micro-organism) is eliminated in the milk as well as in the saliva, the tears, and the pancreatic juice of rabid animals; that the presence of this virus in milk is comparable to a certain extent with that of the *Bacillus tuberculosis* in the milk of cows and of women; that the presence of these germs in milk constitutes a fact of the highest biological, hygienic, and therapeutical importance; and that, if the child mentioned in the account of the nursing woman bitten by a mad wolf did not die of rabies, it was because the virus did not find in the gastro-intestinal tract of the child an environment suitable to its development, as it might have found had it been injected directly into the tissues. But we have as yet only entered upon our knowledge of microbiology, and no doubt there is many a surprise reserved for us in the near future.

#### WAKEFULNESS IN NEURASTHENIA.

A wide range of opinion on the management of this condition found expression at a recent meeting of the Epidemiological Association. The use of drugs, with the exception of

sulphonal, perhaps, did not find much favor with the members. Some of them had found that their patients of this class slept when they were at the seaside, while others recommended the Colorado atmosphere. Some patients had been found to be able to sleep at sea, but not on land. The weight of evidence seemed to favor the resort to mountain air for patients who were anaemic, with a presumption in favor of sea air for those who were plethoric. Dr. Solly, of Colorado Springs, has found that a large proportion of anaemic neurasthenics find sleep on the mountain heights, but this can not be said of the entire class. It is not improbable that other conditions besides those of climate enter into the account where the patient travels from our Eastern cities to the Rocky Mountains in pursuit of sleep. The jaded matron leaves the worries of the household, and the business man, broken down by the rush of daily cares, finds many things changed besides the atmosphere among the far Western altitudes. Still, as a rule, the climate gets all the praise when an improvement takes place. Business men from the East report a larger percentage of recoveries than the matrons, however, probably because fewer of their anxieties can follow them. Improvement in the assimilation of food, it should not be forgotten, goes a great way toward sleep-production in those who are affected with derangement of the nervous system; and this is one of the frequent accompaniments of any change of scene and environment. Not that there is always any marked increase of appetite or in the amount of food taken, but there is an appropriation of the food by the nervous centers, to their consequent strengthening. It is often a prominent feature in neurasthenia that the food may be taken in and digested fairly well, but stops short somewhere in its distribution to the tissues and is largely wasted. Ordinarily, when this waste ceases there is a corresponding abatement of wakefulness and other neurotic symptoms.

#### MINOR PARAGRAPHS.

##### PESSIMISM AS A NEUROSES.

In a recent lecture delivered by Dr. A. Deschamps, of Paris, to the faculty of Clermont Ferrand, he successively reviewed all the neuroses—stopping at hypnotism—and showed that the neurasthenic was a social invalid who appeared at the commencement of the nineteenth century; scientific discoveries, the revolution that electricity and steam have made in industry and commerce, the equality of individuals before the law, and the power of money, had progressively developed the ambition and desires. The derangement of the sensibility and weakening of the will were the two principal causes of the general disease that had produced the abuse of science, the loss of the ideal, the crisis that traverses religions, and the influence on literature and art inspired by Schopenhauer, Tolstoi, Darwin, Herbert Spencer, and Stuart Mill. The physical causes were located in hereditary or acquired faults, such as alcoholism, hysteria, epilepsy, and morphinomania. There were, then, two kinds of pessimists—those by temperament and those by taste. The neurasthenic existed in letters, not in science. He asked if the century did not lean to fatality. Was not pessimism the crisis? The pessimist, convinced of the inutility of effort, preached general renunciation; consequently the exercise of the will mastered him. The question was solely, to conquer that patho-

logical state of the senses, that the will should triumph. He would not modify actual, social, and physiological conditions from top to bottom, but he would transform them by education and hygiene; the muscles should be toughened and the mind strengthened. To children he would give an education of the mind and body, physical exercises holding a very large place. Such exercises would fortify the entire economy and permit our sons and daughters to resist the crisis we were traversing, and definitely triumph over it. These suggestions of Dr. Deschamps's are not without value; and probably many, without having made any particular analysis of the question, have considered pessimism as, if not a mental alienation, a neurosis. Why Darwin and Herbert Spencer are in this company is not clear; and, while Germany, Russia, and England are represented, what modesty has prompted the omission of the country of Descartes, Bayle, Gassendi, Voltaire, Diderot, Baudelaire, Coppée, and Leconte de Lisle? Another question arises, that of whether firm muscles and a well-regulated digestive system would have made these hierarchs of pessimism optimists.

#### AN ASSOCIATION OF FRENCH MEDICAL JOURNALS.

A SYNDICATE has recently been formed in France by the editors of many of the medical journals. Desirous of knowing somewhat more of the limitations of this syndicate than we could gather from the printed reports, we addressed ourselves directly to Dr. Auvard, editor of the "Archives de tocologie," and one of the syndicate's founders. From his courteous reply we gather that, although the society has been formed for the protection of the common and individual rights of its members, the powers conferred upon them by the French law have not yet been, and probably will not be, examined until such a time as one of their members is attacked. Neither has it been decided in what manner an unworthy member shall be eliminated, although a vote of the majority will probably decide the matter. "There are therefore in this society, as in all others newly formed, many *lacunæ*, but the ultimate good obtained more than counterbalances the *desiderata*," says Dr. Auvard. At present the society has no other force than that formed from the aggregate power of its members. The laws of the society are twelve in number, bearing upon the conditions of government and membership. Founders and titular members enjoy the same rights and privileges. In order to become a member it is necessary to be a physician; to be an owner, director, or editor of a medical journal, or delegated by the latter as a representative; to be presented by two members of the association; and to be elected in assembly by a majority of the members after hearing the deductions of a report drawn up by a member other than either of the two who proposed the candidate.

Absent members can vote by correspondence or by proxy. The association is governed and represented by three syndics eligible to re-election at the expiration of their annual terms of office. The present syndics are Dr. Cézilly, Dr. Cornil, and Dr. De Rause. Meetings are held three times a year.

#### THE BRITISH DEGREE IN STATE MEDICINE.

ACCORDING to the educational number of the "British Medical Journal," nearly all the examining bodies of Great Britain and Ireland grant special degrees in public health or state medicine. The Royal College of Physicians and the Royal College of Surgeons hold examinations, consisting of two parts, in July and December. Candidates must be at least twenty-three years of age before admission to part first, and at least twenty-four years of age before admission to part second, of the examination; and they must be registered as qualified practitioners.

Both examinations may be taken in the same month. Part I consists of: 1. Physics in its application to health, with reference to (a) warming and ventilation; (b) water-supply, sewerage, and drainage; (c) sanitary construction. 2. Meteorology in relation to health. 3. Chemistry in relation to the examination of air and water. 4. Microscopical examinations as applied to air, food, and water. 5. Geology in relation to drainage and water-supply. 6. Statistics in relation to health. Part II: 1. The origin, growth, and prevention of disease: (a) the special pathology of endemic and epidemic diseases; (b) the influence of climate, season, and soil; (c) the effects of unwholesome air, water, and diet; (d) diseases of animals in relation to the health of man; (e) the influence of occupation and lodging; (f) isolation, quarantine, disinfection, and vaccination. 2. Sanitary work and administration: (a) the health requirements of houses, villages, and towns; (b) the sanitary regulations of households, establishments, and occupations; (c) the prevention and control of epidemic and endemic diseases. 3. Statutes and hy-laws relating to public health. 4. The duties of sanitary authorities.

#### THE KÜSTER-DOLBEAU OPERATION.

DR. E. LAPLAQUE writes in the "New Orleans Medical and Surgical Journal," for June, favoring the employment of Küster's modification of Dolbeau's operation for vesical calculus and for the removal of foreign bodies from the urinary bladder. This procedure consists in a paraprostatic section of the urethra with subsequent dilatation of the incised urethra and neck of the bladder. The perineal incision is dilated to the size of a No. 8 Simon's dilator, which is sufficient to admit of the introduction of two fingers for exploratory and cleansing purposes. A certain proportion of the foreign contents of the bladder can be extracted by the fingers; what is too large to be brought out in this way can be readily managed with the ordinary surgical forceps. Dr. Laplace reports his experience in one case, in which the perineal wound permitted of the passage of urine until the tenth day, when it closed; on the twenty-sixth day the wound was fully healed. Although the operation is but little known, it has been performed often enough to demonstrate the dilatability of the prostatic urethra with ease and impunity. Dr. Laplace thinks that this operation will be found to be safe and easy where foreign bodies in the deep urethra and bladder require surgical interference.

#### THE JOHNS HOPKINS UNIVERSITY.

PRESIDENT GILMAN has authorized the announcement that this university will be opened on October 1st, and that there is no foundation for the rumor of its financial difficulties. The salaries of the president and professors have not been cut, and several new appointments have been made. While it is true that the income from the Baltimore and Ohio Railroad bonds has been cut off, yet there is an accumulated income from former years, the receipts from tuition average \$40,000, and \$108,000 is available as an emergency fund during the coming three years. Within six months the university has received \$300,000, and other gifts are expected. The hospital funds are distinct from those of the university, and are so invested that the income is an assured one.

#### PROLONGED GESTATION.

WILL widowhood prolong the period of gestation? A discussion before the German Obstetrical Society has elicited views, on the part of some of its members, giving an affirmative response to that inquiry. A commission has been appointed to

collect the evidence, said to exist, that pregnancy may last for 320 days, or ten months, especially in the case of widows. Dr. Olshausen declares his opinion that 160 days should stand as the minimum limit of pregnancy, and that the maximum should be raised to 320 days. The Imperial Civil Code gives 300 days as the maximum figure.

## ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 17, 1889:

DISEASES.	Week ending Sept. 10.		Week ending Sept. 17.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	53	7	55	14
Scarlet fever.....	24	3	22	2
Cerebro-spinal meningitis....	0	0	1	0
Measles.....	7	1	11	0
Diphtheria. ....	62	12	61	16

The Continental Anglo-American Medical Society will hold its first general meeting at the Grand Hotel, Paris, on Monday evening, the 30th inst. The honorary presidents, one of whom is expected to take the chair, are Sir Speneer Wells, Sir Joseph Lister, Dr. Richard Quain, Dr. Benjamin Ball, Dr. C. E. Brown-Séquard, Dr. P. Ricord, Dr. J. S. Billings, Dr. Fordyce Barker, and Dr. S. Weir Mitchell. The meeting will be followed by a dinner.

**The Medico-chirurgical College of Philadelphia.**—Dr. Ernest Laplace, of New Orleans, has been appointed professor of pathology. Dr. Samuel Wolfe, of Skippack, Pa., will fill the chair of physiology for the coming year.

**The American Academy of Medicine.**—The next annual meeting will be held in Chicago, on the 13th and 14th of November.

**Change of Address.**—Dr. Valentine Mott, to No. 62 Madison Avenue.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 1 to September 14, 1889:* By direction of the Secretary of War, a board of medical officers—to consist of VOLLUM, EDWARD P., Colonel and Surgeon; McELDERRY, HENRY, Major and Surgeon; MATTHEWS, WASHINGTON, Major and Surgeon; and MERRILL, JAMES C., Captain and Assistant Surgeon—is constituted to meet in New York city on the 1st day of October, 1889, or as soon thereafter as practicable, for the examination of assistant surgeons for promotion, and of candidates for admission into the medical corps of the army. The board will be governed in its proceedings by such instructions as it may receive from the Surgeon-General. Par. 1, S. O. 203, A. G. O., September 2, 1889.

JANEWAY, JOHN H., Major and Surgeon. With the approval of the Secretary of War, the leave of absence granted in S. O. 52, July 29, 1889, Division of the Pacific, is extended two months. Par. 1, S. O. 206, A. G. O., September 5, 1889.

CLEARY, P. J. A., Major and Surgeon, is hereby granted leave of absence for two months on surgeon's certificate of disability. S. O. 59, Headquarters Division of the Pacific, San Francisco, Cal., August 27, 1889.

EWING, CHARLES B., Captain and Assistant Surgeon, is granted leave of absence for twenty-one days, to commence on or about September 21, 1889, provided that at that time the post surgeon now on leave has returned to duty. Par. 5,

S. O. 201, Headquarters Division of the Atlantic, Governor's Island, New York, September 4, 1889.

BANISTER, W. B., First Lieutenant and Assistant Surgeon, is granted leave of absence for fifteen days. Par. 2, S. O. 82, Headquarters Department of Arizona, Los Angeles, Cal., August 23, 1889.

By G. O. 69, A. G. O., August 31, 1889, the garrisons of Fort Laramie, Wyoming, Fort Hays, Kansas, and Fort Lyon, Colorado, will be withdrawn, and the posts named will be abandoned as soon as it can be done with due regard to economy.

WALKER, FREEMAN W., First Lieutenant and Assistant Surgeon. By direction of the Acting Secretary of War, the leave of absence on surgeon's certificate of disability, granted in S. O. 92, April 20, 1889, from this office, is extended one month on surgeon's certificate of disability. S. O. 211, A. G. O., September 11, 1889.

WALKER, FREEMAN W., First Lieutenant and Assistant Surgeon, by direction of the Acting Secretary of War, is relieved from duty in the Department of Texas, and will, upon the expiration of his present leave of absence, report in person to the commanding officer, Jackson Barracks, Louisiana, for duty at that station, and by letter to the commanding general, Division of the Atlantic. Par. 2, S. O. 212, A. G. O., September 12, 1889.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending September 7, 1889:*

NASH, F. S., Passed Assistant Surgeon. Detached from the Dale and ordered to duty in the Bureau of Medicine and Surgery.

RUSSELL, A. C. H., Passed Assistant Surgeon. Ordered to the Naval Hospital, Yokohama, per steamer of September 28th.

HALL, C. H., Passed Assistant Surgeon. Detached from the Naval Hospital, Yokohama, on reporting of relief, and to return home.

WHITE, S. S., Assistant Surgeon. Detached from the Naval Hospital, New York, and ordered to the Minnesota.

STONE, E. P., Assistant Surgeon. Detached from the Minnesota and to wait orders.

BRYANT, P. H., Assistant Surgeon. Detached from the Ajax and ordered to the Naval Hospital, Norfolk, Va.

WENTWORTH, A. R., Assistant Surgeon. Detached from the Naval Hospital, Norfolk, Va., and to wait orders.

#### Society Meetings for the Coming Week:

MONDAY, September 23d: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

TUESDAY, September 24th: New York Dermatological Society (private); Buffalo Obstetrical Society (private); Medical Society of the County of Lewis (quarterly), N. Y.

WEDNESDAY, September 25th: New York State Medical Association (New York—first day); New York Pathological Society; American Microscopical Society of the City of New York; Auburn, N. Y., City Medical Association; Medical Society of the County of Albany; Philadelphia County Medical Society; Berkshire, Mass., District Medical Society (Pittsfield).

THURSDAY, September 26th: New York State Medical Association (second day); New York Orthopedic Society; Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private); Cumberland, Me., County Medical Society (Portland); New London, Conn., County Medical

Society (extra—New London); Pathological Society of Philadelphia.

**FRIDAY, September 27th:** New York State Medical Association (third day); Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

## Proceedings of Societies.

### MEDICAL SOCIETY OF VIRGINIA.

*Twentieth Annual Meeting, held in Roanoke, on Tuesday, Wednesday, and Thursday, September 3, 4, and 5, 1889.*

The President, Dr. E. W. Row, of Orange, in the Chair.

**Man and his Development** was the subject of the annual address, by Dr. THOMAS J. MOORE, of Richmond.

**The Status of Cocaine in Surgery** was the title of a paper by Dr. JOHN A. WYETH, of New York (present by invitation). After a note or two on the history of cocaine as a surgical anaesthetic, in which he accorded to Dr. Karl Koller, now of New York, but formerly of Vienna, the credit for its introduction into ophthalmic surgery, and to Dr. J. Leonard Corning, of New York, the credit of its practical application to other branches of surgery, he remarked first upon its dangers, due to idiosyncrasy, etc. Its dosage was uncertain, differing widely, not only in different individuals, but in the same individual at different times. He spoke from personal experience and observation. The general rule should be to begin with the minimum dose, gradually increasing it, always watching the pulse, face, respiration, and pupil. In small doses it increased the number of respirations, and was a cardiac stimulant; in large doses it arrested the heart in diastole and the action of the respiratory muscles. Cocaine was never applicable to children under ten or twelve years of age. In his several hundred applications in adults, in all parts of the body, he had several times observed pallor of the face and fainting, but they had been due most probably to the patient's being overcome by the sight of blood, etc. In some, however, they had been due to absorption of the drug. Exhilaration was not an uncommon symptom, and in rare cases it increased to boisterousness. In one instance convulsive movements had occurred, opisthotonus being rather well marked. In another case a convolution occurred fourteen hours after a gradual injection of thirty minims of a four-per-cent. solution of cocaine (one grain and a half). In many cases, when it was not applied about the eye, dilatation of the pupil occurred, indicating absorption by the blood. For hypodermic purposes he used twenty grains of cocaine and three grains of boric acid dissolved in an ounce of distilled water—approximately, a four-per-cent. solution. A more decidedly aseptic solution was one in equal parts of distilled water and saturated solution of salicylic acid. Cocaine should always be dissolved in water free from lime. In operations upon the extremities, the circulation might be temporarily arrested. In amputation of the last phalanx of the finger, one might first immerse the hand for half an hour in a 1-to-2,000 solution of corrosive sublimate. It was best not to apply Esmarch's bandage to the finger, but to constrict it with a piece of rubber tubing. Direct injections (in the line of incision) retarded union to a slight degree. Hence the indirect method (by injections about the nerves at the base of the finger) should be employed when possible, although this method required a little longer time and a little

more of the cocaine solution. Just before applying the rubber, the smallest-sized hypodermic needle should be inserted through the skin on the lateral aspect of the dorsum of the digit, about an inch from and on the distal side of the ligature. About two minims should be injected, and the needle pushed a quarter of an inch farther, and two minims more injected, and so on until the needle-point rested just beneath the skin on the plantar aspect of the finger, when the same quantity was to be injected. Thus one half of the finger was injected, and the operation was immediately repeated on the other half—the entire procedure occupying not more than thirty seconds. A smarting, burning pain was felt as the fluid entered. The tourniquet should be tightened at once, thus holding the solution in place for absorption, which might be hastened by massage over the injected area. Insensibility supervened in about two minutes. Usually about fifteen minims were sufficient, but thirty minims might be thus used safely. The operation being finished, the band should be loosened for only a minute, which restored the circulation, and (under sublimate solution) the wound would bleed freely, thus giving escape to whatever of the solution the arterioles might have absorbed; but, of course, a certain amount was carried into the general circulation. The rubber should be tightened again for two or three minutes, the sutures inserted, and the dressing applied. Gradually the general circulation should be accustomed to the cocaine by alternately loosening and tightening the tourniquet. The heart and nerve centers might be overwhelmed if the entire excess was suddenly let loose into the general circulation.

The advantages of the direct method were rapidity of anaesthesia, the small quantity of cocaine used, and escape of much of the solution through the wound of incision. This method was preferable for incising felonies and removing diseased nails, foreign bodies, etc. Indeed, any procedure where the necessary anaesthesia could be obtained by not more than a drachm of a four-per-cent. solution might be safely done with this agent by the direct method. In operations upon the trunk, the immediate absorption of the solution rendered greater precaution necessary. For instance, if a fatty tumor was to be removed, the needle should be inserted into the deeper layers of the skin (not the subcutaneous fat) along the line of proposed incision, and half a minim or a minim injected: the needle should be advanced a quarter of an inch, and the injection repeated, and so on, as far as the needle would reach from the original puncture. The injections should be repeated, if necessary, for a length of three inches until anaesthesia was established. The anaesthesia was evident by the pallor of the overlying cuticle. The skin should be divided through the middle of the anaesthetized line, and the dissection continued laterally until pain was experienced. Insensibility often spread an inch or more on either side of this line. Half a minim or more should be injected at all sensitive points in the line of incision. Since scars were to be avoided, cocaine was not so free from objections on the face and neck as elsewhere. In eye surgery the uses of this agent were too well known to require remark. In the buccal cavity it had a wide range of application. Tumors from half an inch to not more than an inch in diameter could be excised painlessly. Small epitheliomata or suspicious ulcers were painlessly removed from the tongue when five to twenty minims of a four-per-cent. solution were injected beneath and around their bases. He had twice dissected out ranulae successfully. Complete cleft of the soft palate in the adult could be closed painlessly by applying the solution to the mucous surface with a brush. Cocaine was in every-day use for the larynx, nose, and naso-pharynx. For internal urethroscopy, regardless of location, he rarely employed general anaesthesia now. The urethra having been disinfected with boric-acid solution (gr. x

to  $\frac{3}{4}$  j), he injected 3 j-ij of a four-per-cent. solution of cocaine with the ordinary syringe. At the end of a minute or so all of the cocaine solution was allowed to run out of the urethra that would run out. If the operation was to be in the membranous portion, Otis's long-curved tube was passed into the part, and from twenty to thirty minimis were injected. For the introduction of the sound on the third day after urethrotomy, one should be careful not to over-distend the canal with the preliminary cocaine solution; about a drachm of the solution was then as much as should be used. For bladder examinations cocaine was very useful. Circumcision in adults no longer required general narcosis. The penis having been constricted near the pubes, the prepuce should be pulled forward and the hypodermic needle inserted at the free border in the middle line on top, between the mucous and cutaneous layers. Then the point should be carried back as far as the proposed line of section, and one minim of the four-per-cent. solution forced out. The needle should then be withdrawn half way and carried forward again to the right and left, and a minim forced out for every quarter of an inch of the line of section. On account of the sensitiveness about the frenum, it was best to inject two or three minimis here. In Levis's operation for hydrocele, the point where the trocar was to enter should be cocainized. If the hydrocele was small, Volkmann's operation might be done with cocaine anaesthesia. In the open operation for varicocele, cocaine was not sufficient; nor was it sufficient for external urethrotomy, cystotomy, hernia, etc.; but small haemorrhoids might be injected or cut away after cocaine injections. Cocaine was sufficient also for fissures and ulcers of the anus and rectum, and for single and superficial anal and rectal fistulae.

Dr. HUNTER MCGUIRE, of Richmond, did not think that Dr. Wyeth had dwelt sufficiently on the dangers of cocaine. The speaker had used this remarkable agent almost every day for the past five years; but he had come very near killing one or two patients with it, so uncertain was its paralyzing effect in some cases, which cases could not be distinguished until the danger was recognized to be at hand. In one of the journals he had read that Dr. Sims had injected a few minimis of a twenty-per-cent. solution of cocaine hydrochloride into the male urethra, and in twenty minutes his patient was dead. The speaker had cocainized a great many children without observing the very serious effects referred to by Dr. Wyeth; in fact, they seemed to stand cocaine as they did chloroform anaesthesia—very well. But there were objections to cocaine. Undoubtedly it interfered with the repair of wounds by the first intention. During the session of the society two years ago, in Richmond, he had heard a distinguished authority in such matters—then a resident of New York—affirm that a cocaine habit, in the sense in which the term habit was applied to the whisky habit, the morphine habit, etc., could not be established. But he was certain he had seen a case or two of the cocaine habit in patients who had come under his care.

Dr. WYETH indorsed everything that Dr. McGuire had said. In fact, the dangers of the indiscriminate use of cocaine were very considerable. He had not meant to imply in his paper that the danger of cocaine, when used with children, was in the drug itself, but in the imperfect manner in which it was generally administered to them, because of their struggling to resist its administration, and the peculiar feeling of loss of sensation in the part, which frightened them.

**Medical Reforms, with Special Reference to the Profession of Virginia,** was the subject of the President's address. He advocated the establishment of a general hospital, to be sustained by the State, like the asylums. But he thought that matters of professional interest connected with the management of such an institution should be placed under the control or

direction of the Medical Society of Virginia. In other words, he thought that the medical affairs of the State should be directed by the medical men of the Commonwealth, just as its legal affairs were by the legal men, etc. The medical profession had shown its ability to manage such matters as belonged to it, as evidenced by the excellent work done by the Medical Examining Board of Virginia—the creature of this society. The insane hospitals and like institutions should be more directly under the supervision of this society, so far as the medical affairs connected with them were concerned. It was a duty of the society to set to work to secure for the State Board of Health an annual appropriation from the State sufficient to pay all its necessary expenses, for it appeared that the law establishing the board, some seventeen years ago, very foolishly concluded with some such proviso as: "Provided the said board of health shall not be an expense upon the State."

**Croupous Pneumonia.**—An appointed discussion on this subject was opened by Dr. B. L. WINSTON, of Hanover Court-House, who would confine his remarks to uncomplicated cases. The diagnosis was not difficult, although sometimes the disease escaped detection unless resort was had to the physical signs. Pain was probably never present unless more or less pleurisy complicated the pneumonia. Rusty-colored sputa, though pathognomonic when seen, did not by any means occur in the majority of cases, according to his experience; and on this point he thought the text-books should be corrected. The causes might be classed as specific, exciting, and predisposing. The view that pneumonia was due to a specific organism did not meet with common approval. He thought that pneumonia was not simply a local inflammation of the lung, but an expression of a general disease; and pneumonia deserved no higher classification than the intestinal ulcers of typhoid fever. Croupous pneumonia was not produced by extension of inflammation, but, in such cases, lobular pneumonia was the result. It was not produced by inhaling irritating gases, nor by traumatism, nor by "cold," as other inflammations of the air-passages were. It was a self-limited disease, and frequently occurred as an epidemic. The common asthmatic tendency could not be due to the height of the fever, nor to cardiac weakness, nor to the amount of lung consolidated (for the amount invaded was often very small). It was at least certain that the cardiac failure in no way corresponded with the severity of the other symptoms. It seemed to the speaker that the tendency to heart failure, which was the most alarming symptom in uncomplicated cases, was due to a morbid agent acting on the nerve centers. But the exact cause of croupous pneumonia was a subject for further investigation. The germ theory might or might not be true. The predisposing causes were age (under sixty years), the male sex, the negro race, certain diseases, such as typhoid fever, winter and spring seasons, etc. The exciting causes were, in general, such things as tended to lower the vital powers—such as exposure to inclement weather, insufficient clothing, neglecting the wearing of flannel in winter and spring, etc. It was more common South than North, pneumonia being almost unknown in the frigid zone. During the winter and spring almost every article of food had the stamp of age upon it; and it seemed more probable that the character of food then taken, when the vital powers were at their lowest, contributed most largely to the development of the disease. As to treatment, almost every drug had been tried; yet the mortality among adults was second only to that from consumption. A certain author abstracted from five to ten ounces of blood on the fourth or fifth day, when the heart was on the eve of being overpowered by the pneumonic toxic matter, but the speaker thought stronger evidence needed to justify resort to bleeding on such occasions, although there might be times when venesection was

useful. He also thought large blisters of doubtful propriety, although he had seen blisters relieve pain. Calomel had no place in the treatment of croupous pneumonia. Aconite in the beginning, and quinine, given early, as an abortive, might be useful. But he had got the best results when he had given the least medicine. Hot poultices, opium to relieve pain, stimulants when needed, food, hygienic measures, and, above all, skillful nursing, would be all that could be of use in uncomplicated cases.

Dr. H. C. BECKETT, of Scottsburg, thought that the specific cause of croupous pneumonia was undetermined. No age had a notable proclivity to the disease, and no age was exempt. It rarely occurred in children under five years of age. It was perhaps most frequent between the ages of twenty and forty and after sixty. In adult life it occurred in males three times as often as in females. In females it occurred most frequently at the catamenial periods. Outdoor laborers were more liable to it than indoor workers. Habitual alcoholic drinkers, malarial subjects, convalescents from severe acute diseases, etc., were most liable to it. Erysipelas, measles, diphtheria, small-pox, etc., were predisposing causes. Traumatism, especially in the aged, and a previous attack of pneumonia, were also predisposing causes. It occurred more frequently in the Middle and Southern States than in the Northern. It often prevailed as an epidemic in the mountainous regions of the South. The first five months of the year were its season. Thus it was seen that all things predisposed to pneumonia that depressed vital action. Dr. Shaw, of St. Louis, believed that perturbations of the vaso-motor center in the medulla caused pneumonia by impressions conveyed through nerves connecting this center with the stomach. As to treatment, stimulants or depressants should be used as required. If both lungs were involved, so as to leave little breathing surface, it was proper to bleed. In such cases venesection afforded immediate and remarkable relief. Large hot poultices over the lungs reduced blood-pressure, while the heat stimulated the heart. Aconite was preferable to veratrum as a cardiac sedative, but he preferred acetanilide as the antipyretic, to be followed by quinine, which latter he considered the sheet anchor in pneumonia. He usually prescribed five grains every four hours until the fever broke. In the second and third stages he generally used ammonium carbonate, and digitalis also. The early administration of a large dose of calomel was useful. Opium was useful to allay pain and restlessness. Expectorants had no place in the treatment of pneumonia. Blisters at the beginning of the third stage hastened resolution. Alcohol was essential as a food and to sustain the heart. Many believed that the disease was contagious, and that four days was the period of incubation.

Dr. LEWIS G. PEDIGO, of Roanoke, spoke of *Sedative Doses of Calomel in Acute Croupous Pneumonia*, referring to doses of thirty grains and upward. He gave a history of the use of this treatment in various acute diseases by a few members of the profession for years past, and then explained the method of administering the drug. He reviewed the condition of the secretions and the various indications of treatment in pneumonia, gave a systematic and detailed account of the numerous and apparently diverse effects of the large doses of calomel, classified these effects, and showed how they were all dependent on two general principles—namely, stimulation of the secretions and a sedative influence on the nerves. He argued the adaptability of these effects to the chief indications in pneumonia. His entire remarks were based on clinical experiences, and one case was briefly reported to illustrate the treatment advocated. The important effects alleged were the promotion of the salivary, gastric, hepatic, and intestinal secretions, unloading of the portal circulation (followed by improved digestion and assimilation), increased and improved action of the

kidneys and skin, loosening of the bronchial and pulmonary secretions, relief of cough, lowering of temperature, and promotion of sleep.

Dr. BEDFORD BROWN, of Alexandria, gave a *Résumé of his Personal Experience of Forty-one Years in the Treatment of Croupous Pneumonia*. During this period he had seen four or five different methods of treatment adopted and practiced, and finally discarded. The depletory plan had at first been used in every case, then in only certain cases, and finally it had been entirely discarded. Then came the mercurial plan, in which calomel in small doses, with Dover's powder and with mercurial inunction, was used until ptyalism occurred. The great majority of patients recovered under this treatment. Then followed the sedative treatment, consisting of the use of veratrum viride, aconite, and ultimately digitalis. The sedative treatment of Norwood had given birth to all our subsequent ideas of sedation. This was an advance on the pure depletory treatment, and had resulted in real good. Then came the stimulant treatment. This was a still further advance, and had brought more and better fruits than any other single treatment. This also might be modified and combined with elements of other methods with advantage. The speaker had not seen benefit from the pure antipyretic treatment. He had in former years seen much of the epidemic forms of typhoid pneumonia, with a tendency to collapse, which was constant and great. In this form he had used large quantities of whisky—a quart per diem—carbonate of ammonium, tincture of nux vomica, and chloroform internally. In this form he had also used, in connection with stimulants, solution of acetate of ammonium, tincture of nux vomica, and tincture of chloride of iron, with benefit. He did not think, from this long experience, that adherence to any one single routine treatment exclusively would give as good results as the plan of combining the good features of all; but the value of stimulants and nourishment should never be forgotten. He had seen cases of pneumonia, with slight fever, slow pulse, moderately excited respiration, etc., end in recovery without medication.

Dr. J. H. NEFF, of Harrisonburg, believed that acute croupous or lobar pneumonia was a general disease, due to a specific poison. This theory had been ably presented for some years, and much could be said for and against it. But each year's experience had strengthened his opinion in its favor. The future organic chemists and bacteriologists must prove whether the contagium was a chemical poison or an organized germ. Believing that pneumonia was a general disease, due to a specific cause, for which there was no specific medicine capable of aborting its course, he thought the treatment must be determined by the nature of the attack in each individual constitution. He had never bled nor given a dose of aconite or veratrum viride, nor used mercury except to give occasionally an ordinary dose of calomel in the beginning. Many patients would recover without medicine, if properly nursed; this had been observed and recorded more than twenty-five years ago. He had seen cases of double pneumonia with scarcely a bad symptom. The area of lung involved did not always determine the gravity of the disease. He gave opium or morphine to allay pain, lessen shock, produce sleep, etc. He regarded quinine as the safest antipyretic; besides, it had special virtues in lessening the gravity of all local inflammations. He had never seen it produce collapse, and hence preferred it to other arterial sedatives. If not needed as an antipyretic, it might be of benefit in small tonic doses. He gave antipyrine to children; and, if he had any routine treatment, it was to envelop their chests with an oil-silk jacket lined with soft, fine flannel. Digitalis, alcohol, ammonia, and chloral had all, in their places, been of much service.

Dr. J. G. WILTSHIRE, of Baltimore (present as a delegate), said that, studying the subject of croupous pneumonia after Lépine, Sevestre, Charcot, and others, one must accept the theory that it had its origin in a specific pathogenetic germ; yet it could not be denied that there were certain meteorological conditions that stood in a strong causative relation to its production. We were constantly exposed to the invasion of the pneumococci; but, for the want of the necessary conditions to render the mucous membrane of the lung a suitable soil for their culture and growth, it was able to resist them for a time, only to yield when such exciting causes as cold and traumatism supplemented the specific influence of the germs. Apropos of the theory that the pneumococci had other habitats than the lungs, he called attention to the study of Sevestre of an epidemic of broncho-pneumonia, complicating cholera infantum and other enteric troubles, in which he had found the microbes of pneumonia in the intestinal tract, whence they were carried to the lung by the lymph channels. The treatment of croupous pneumonia called for heart sedatives, heat, and moisture in the form of hot cloths. These, if used in the first stage, might abort the disease; should it, however, pass into the stage of red hepatization, a supporting and stimulating plan should take the place of the sedative one. The temperature and heart should be watched as closely as the powers of the patient. Alcohol was important in the second and third stages. Quinine and antipyrine, when used together, were the best antipyretics. They not only reduced the temperature, but preserved the power of the heart. Carbonate of ammonium did the twofold work of aiding in liquefying and facilitating the expectoration of the fibrinous deposit and of keeping the heart's force up.

Dr. HENRY M. PATERSON, of Staunton, said that, if this was a specific disease, the treatment given had certainly been at variance with such an idea. He did not believe that it was a simple hyperæmia of the lungs. The gravity of the attack depended on the amount of exudation. How to remove the engorgement was the question. This was the time to abort the disease, if such a thing was ever possible. His present success with the lancet was as great as it had been when he began practice, in 1851, and compared most favorably with the results of other plans of practice to-day. As a food and stimulant, he gave alcohol during the second stage in almost every case. He had also had some remarkably satisfactory experience with ergot.

**Officers for the Ensuing Year** were elected as follows: Dr. Oscar Wiley, of Salem, president; Dr. J. M. Estill, of Tazewell Court-House, Dr. Alfred C. Palmer, of Norfolk, and Dr. Casper C. Henczel, of New Market, vice-presidents; Dr. Landon B. Edwards, of Richmond, recording secretary; Dr. J. F. Winn, of Richmond, corresponding secretary; and Dr. Richard T. Styll, of Hollins, treasurer. Dr. John S. Apperson, of Glade Spring, was chosen to deliver the address to the public and profession during the session of 1890. Dr. C. T. Lewis, of Clifton Forge, was selected as the leader of the discussion of the selected subject for 1890—"The Treatment of the Summer Diarrhoea of Children." Dr. R. F. Young, of Love's Mill, and Dr. P. B. Green, of Wytheville, were nominated for commission as members of the Medical Examining Board of Virginia, to fill vacancies occasioned by two resignations. Rockbridge Alum Springs was selected as the place for the annual session of 1890, some time between the 25th of August and the 5th of September, as the Executive Committee might hereafter determine.

The Report of the Section in Anatomy and Physiology, in the form of a paper entitled "Mental Action—Material Action," was read by Dr. E. T. BRADY, of the Southwestern Lunatic Asylum at Marion.

The Report of the Section in Materia Medica and Therapeutics was presented by Dr. WILLIAM B. COOPER, of Woodville.

The Report of the Section in Obstetrics and Diseases of Women and Children was presented by Dr. R. S. MARTIN, of Stuart, in the form of a paper entitled "Advances in Diseases of Women."

The Report on Advances in Obstetrics was read by Dr. CHARLES W. PRITCHETT, of Keeling.

The Report on Advances in Diseases of Children was read by Dr. A. S. PRIDDY, of Keysville.

**A Further Contribution to the Study of the Aetiology and Prophylaxis of Puerperal Septic Infection** was the title of a paper read by Dr. GEORGE T. HARRISON, of New York, an honorary fellow. The doctrine of self-infection, he said, which had recently been brought into prominence, and the industrious researches of the bacteriologist, with the practical deductions from them, had divided obstetricians into two parties diametrically opposed to each other. The one side attached all importance to the disinfection of the obstetrician ("subjective disinfection"). The other regarded it as a matter of necessity to subject the parturient woman, in a greater or less degree, to antiseptic measures ("objective antisepsis"). The writer had taken the ground of those who advocated the paramount importance of subjective antisepsis in a paper read before the society in 1885, and had not had reason to change his ground. Of course, this position did not exclude the thorough cleansing and disinfection of the external genitals. The views of Kaltenbach were quoted, who insisted upon it that an obstetrician, even with clean hands, might induce infectious forms of disease. He believed that, as the surgeon disinfected his field of operation, so must the obstetrician disinfect the parturient canal as well as the vicinity. Winter, as the result of bacterial investigations, had drawn the inference that it was necessary to disinfect the cervix and vagina to avoid self-infection. Steebeck and Dolderlein had arrived at the same conclusion. The writer believed that, if the demands made by the bacteriologists were generally acceded to, and it became a universally accepted rule of practice that the cervix and vagina of every parturient woman should be subjected to thorough and energetic disinfection, an immense amount of injury would be inflicted. These disinfective procedures deprived the vagina of its physiological mucus, and rendered it more vulnerable. It became more liable to the attack of infective germs. Moreover, labor was mechanically retarded when the vagina lacked its normal mucus, and it must not be forgotten that disinfection of the vagina and cervix was a painful manipulation. Probably the most serious objection that could be urged against the self-infection doctrine was that it diminished the personal responsibility of the obstetrician, and that that wholesome dread of infection disappeared which every one should have who examined a parturient woman. The distinction was made between septic infection and putrid intoxication. Cases of so-called self-infection were really cases of ptomaine intoxication. The micro-organisms of septic infection were streptococci. According to Bumm, the streptococci of erysipelas and those of phlegmonous inflammations were identical. Bumm's careful and exact bacteriological studies lent no countenance to the doctrine of self-infection. Leopold's clinical experience had been very striking. Of five hundred and ten women treated without vaginal douches, only nine had slight febrile phenomena. When the cervix and vagina were disinfected there was a marked rise of morbidity. The doctrine of self-infection was a retrograde movement, and tended to imperil our present attainments in the prophylaxis of septic infection.

**Some Gynæcological Work of the Past Year** was the title of a paper by Dr. J. S. STONE, of Lincoln. The author stated that his cases had been treated in his private sanatorium, where the patients could have good surroundings, nursing, etc. Four

cases of abdominal section for cystic tumor of the peritonæum with cancer of the transverse colon, salpingitis, chronic peritonitis following salpingitis, and one Battey's operation, were reported. The specimens shown (three in number) were characteristic of the disease in question. Other cases of lacerated cervix and peritonæum were alluded to briefly. The author still advocated Emmet's operation for lacerated cervix, but did not now perform it so frequently as formerly. One case of modified hysterorrhaphy was mentioned in which Alexander's operation was done on the left side and a partial hysterorrhaphy on the other. It was maintained that many minor disorders not surgical were to be successfully treated with massage, electricity, and over-feeding by the Weir Mitchell method. The author had had several years' experience in treating these cases, and affirmed that a very large percentage of cases came under this heading. Electricity was not spoken of at length, but enough was said to show some skepticism in regard to its value in all cases save those of nervous complications.

A Report on the Practice of Medicine was read by Dr. JOHN W. SCOTT, of Gordonsville.

**Enteralgia and Chronic Peritonitis.**—Dr. A. JACOBI, of New York, contributed a paper on this subject, in which he said that enteralgia was always an irritation of a branch or of branches of the sympathetic nerve. Its cause lay in the nerve, or the intestinal tissue, or its contents. Hysteria, hypochondria, malaria, gout, poisons, etc., might start the disease; or the pain might be reflected from spinal, hepatic, genito-urinary, or cutaneous disease, sudden chilling of the skin being a frequent cause. The pathological changes were congestion or inflammation, with their results. Acid foods, certain drastics, scybala, fermenting foods, etc., were the common causes of enteralgia. The attacks were indefinite in length and suddenness. The temperature was rarely raised; the pulse was irregular; the skin became cold and clammy; sometimes dysuria, nausea, vomiting, constipation, or diarrhoea occurred. The tumidity of the abdomen changed its place under palpation, etc. Priapism and seminal discharges might occur with spastic retraction of the testicles. A common cause of enteralgia, often overlooked, was chronic peritonitis of a secondary nature. New abdominal formations, peritoneal adhesions, swollen pelvic glands, etc., pointed to previous peritonitis. A floating kidney might give rise to peritonitis, and thus become fixed in its abnormal position. Vertebral disease, psoas and iliac abscesses, hip-joint abscess, etc., might cause chronic peritonitis, often not recognized except post mortem. Catarrhal diseases of the female genitals were frequent causes, as were also violent cohabitation, the puerperal state, etc. Biliary calculi, perinephritis, splenic and pancreatic diseases, infantile intussusception, a preceding attack of peritonitis, etc., were also causes. Simple intestinal catarrh might speedily grow into enteritis. Inflammation was likewise communicated to the muscular and mucous tissues from the peritonæum, and thus gave rise to oedematous infiltration, paralysis, and consequent constipation. Thus, also, diarrhoea, intestinal ulceration, without perforation, etc., might cause local peritonitis. The diagnosis of chronic peritonitis was not always easy. The respiration need not be accelerated in pelvic peritonitis. Vomiting was sometimes wanting; diarrhoea was not infrequent, but constipation was the rule; the abdomen might be tumid; and the horizontal posture was often uncomfortable. The seat of inflammation or adhesion might sometimes be told by placing the patient on his back, extending and then flexing the extremities, and then using pressure, soft or hard, sudden or gradual. Often, however, it was best to make deep pressure; if there was no pain, the pressure should be relaxed suddenly, when localized pain might be felt. Change of position of the bowels might arouse pain; sharp pain after a full meal might

point to adhesions of the stomach; if pain occurred three or four hours after eating, chronic colitis should be looked for; if it occurred after quickened inspiration, then perihepatitis, etc. The variability of the pain depended on the degree of irritation or congestion. Extensive pelvic peritonitis might not give rise to pain except on defecation, cohabitation, micturition, etc. In pericystitis, when the urine was about half voided and the bladder began to contract more efficiently, a localized pain above the pubes, increased by pressure, developed, much resembling the spasmodic pain of vesical catarrh. Flatulence, etc., developed enteralgia in chronic peritonitis. Stenosis of the bowel, twisting, adhesions, etc., resulted, thus interfering with the intestinal functions. In short, the sequelæ of chronic peritonitis were very various. The indications of the treatment of enteralgia from chronic peritonitis were determined by its results and symptoms, such as intestinal sluggishness, adhesions, etc. Subacute and acute peritonitis required absolute rest, support for the knees, ice or hot applications according to circumstances, opiates, etc. Some were now recommending large doses of magnesium sulphate and turpentine enemas; but a treatment under which an occasional patient might escape death must not supersede one that had proved successful in most cases and beneficial in all. Localized attacks, mainly in the right hypochondrium, demanded local applications; a few leeches occasionally and morphine subcutaneously might be required. Old adhesions, etc., were not amenable to medicines. Great physical exertion, pressure on the abdomen, etc., must be avoided. The bowels should be kept regular. A snug bandage should be worn over the whole abdomen for years after the last complaint of pain. Generally this bandage, held down by a perineal band, gave immediate relief. Without the immobility given by it to the sore intestine, he did not expect a case of chronic peritonitis to do well.

(To be concluded.)

#### NEW YORK ACADEMY OF MEDICINE.

##### SECTION IN LARYNGOLOGY AND RHINOLOGY.

Meeting of May 28, 1889.

Dr. CLARENCE C. RICE in the Chair.

**Rhinoplasty.**—Dr. R. T. HOWE gave a description and demonstration of an operation of this sort done by the late Dr. T. T. Sabine, the details of which had not all been published up to that time. The patient, a man of thirty years, had had perfect features when born. At the age of twelve he had received a blow on the nose, with fracture of the bones and a wound which had never fully healed. At length erysipelas had appeared in the wound and destroyed much of the surrounding tissues, leaving a very unsightly cicatrical formation. It was to remedy this condition that the little finger had been ingrafted to take the place of the destroyed feature.

Dr. J. H. GIRDNER, who had watched the operation and the subsequent history of the case, recalled some points of interest. Great difficulty had been met with in destroying the matrix of the finger nail. The finger had been frozen and the nail removed; then the stump had been cauterized with fuming nitric acid. Nevertheless, after the finger was implanted, the nail had repeatedly grown out again. At the time of operation no tracheotomy-tube had been provided among the instruments in the operating-room, since no one had expected that need for one would arise. No bleeding had occurred until the finger was being stitched into place just over the mouth, when suddenly the man's breathing had stopped, and his face had become intensely cyanotic. With perfect coolness and marvelous rapidity Dr. Sabine had made an opening into the trachea, bled the sides

of the wound apart with his fingers, at the same time preventing haemorrhage into the trachea by pressing on the tracheal rings, and so had kept the patient breathing easily until a tube could be brought from a distance. A third point of interest in the history was that the patient had suffered from prolapse of the rectum a few days after the operation, although never before or since that time.

From time to time, after the finger had grown to the face and traction on the hand had shown that the skin was perfectly adherent, efforts had been made in the way of preparing for the final step of severing the finger from the hand. Pressure on the digital arteries had continued to produce pallor in the tissue which it supplied, and doubt had arisen whether the implanted finger could ever be nourished when its own blood-supply was cut off. However, the two digitals had been tied, one at a time, and, although the finger had continued to be bloodless for a considerable time, a collateral circulation had at last become established. The artificial nose finally obtained had been considerably shorter than the operation had at first promised to give, owing to necrosis of the end of the bone and retraction of the skin of the first phalanx of the finger.

**Amygdalotomy.**—Dr. C. H. KNIGHT presented a patient from whom he had removed a very much enlarged tonsil by the use of the galvano-cautery loup, and called attention to some advantages connected with this mode of operation as compared with the use of the steel amygdalotome.

**New Instruments for Operations on the Nasal Septum.**—Dr. J. M. W. KITCHEN presented a set of instruments designed to facilitate the dissecting up of flaps of mucous membrane from the septum. It consisted of two knives and two spuds, all having flexible shanks four inches long, so that any part of the nasal cavity could be reached. The blades of the knives were round in form and about an eighth of an inch in diameter. The blade for making antero-posterior cuts had its cutting edge parallel with the shank of the knife, while the knife for making vertical cuts had its blade set at right angles to the shank. The spud, intended for lifting the mucous membrane, was ovoid in shape, and about a third of an inch long and a fourth of an inch wide. At best, these operations were difficult. Where the mucous membrane was thick and vascular, the speaker thought it best to attempt no operative treatment of this sort.

**A New Tube for Intubation adapted to the Movements of Deglutition.**—Dr. J. M. BLEYER presented a new intubation-tube of which the most important feature was its automatic closing whenever the patient swallowed, so that neither fluids nor solids in the diet could enter the trachea through the tube. Its light weight and cheapness constituted additional advantages. This tube was made partly of hard and partly of soft rubber, the three sections being melted together by a process invented by Tiemann & Co. Its head was composed of wire and hard rubber, the latter being vulcanized over the wire; this gave it great firmness, and precluded the possibility of its breaking during extraction. The neck was of soft flexible rubber, and the tracheal portion of the tube of hard rubber. During deglutition the adduction of the vocal cords and the action of their accessory muscles closed this soft portion of the tube completely. Afterward it reopened by its own elasticity.

The idea had been first suggested to the speaker by direct observations made in a case of syphilitic ulceration of the epiglottis in which this organ had been completely destroyed by the disease. Finding that, simultaneously with the act of swallowing, a very marked adduction of the cords took place, he had introduced into the larynx a piece of soft-rubber tubing, and had found that the closure occurred with force sufficient to compress the tubing and effectually preclude the entrance of food.

He had also experimented on a dog, laying open the thyreoid cartilage, introducing his finger into the larynx, and at the same time bringing about acts of deglutition. His finger had been squeezed between the cords with considerable force at these times.

**Electricity for Medical Purposes as supplied by the Edison Dynamo.**—Dr. O. B. DOUGLAS read a paper on this subject, showing the many advantages of such an arrangement as compared with the difficulties incident to obtaining a supply from galvanic cells. The doubts raised as to the therapeutical value of electricity at a recent meeting of the Academy he could not share. He believed good results depended, more than was usually recognized, upon an exact adjustment of the length of a sitting to the nervous condition of each patient.

Now that he got all of his electricity from the wires of the Edison company, paying for what he took only, and being always certain of having whatever amount of current he desired, he was more than ever satisfied with its practical value and its great convenience in the physician's repertory of resources. The speaker then described the method (an adaptation of Parcell's) by which he regulated the strength of the current. He expected to have the total yearly cost of his electricity come within one hundred dollars, and this provision included the supply in his office of a smooth, soft electric light during the hours from darkness to midnight. He had provided himself with six storage cells, but used only three of them, and found two sufficient for supplying a galvano-cautery.

Dr. W. B. VANDERPOEL compared the results obtained by Dr. Douglas with those secured from an apparatus in which galvanic cells were used to charge a storage battery, and concluded that, no matter at what expense the supply of galvanic electricity was arranged for, the method which Dr. Douglas had just described was the best which had as yet been suggested, especially as regarded its reliability and its not requiring an expert to keep the plant in order.

Dr. GIRDNER concurred in this opinion, but thought a thoroughly constructed apparatus consisting of gravity cells and a storage battery must remain the best device for supplying those who did not happen to have a wire of the Edison system passing through their neighborhood. Such a battery, moreover, could be constructed and maintained with but little trouble, and at a cost still much below that of electricity from the Edison system, and would furnish every form or strength of current used in medicine.

Mr. MEDICROFT, an electrical engineer, present by invitation, stated that a connection with the wires of the Edison system involved no risk of accident in case the wires were handled. He thought Dr. Girdner had had better results from a galvanic storage battery than were usually met with. In most instances a sufficient outlay was not made at the outstart, so as to get good connections. A storage battery and gravity cells would give much better satisfaction if the wires connecting the latter to the former were not carried through the flooring and out of reach. The speaker then stated that the Edison current could be supplied in New York anywhere between Fourteenth and Fifty-ninth Streets and Sixth and Madison Avenues. The first cost of its introduction, including connections, was \$125. It was always better to be liberal in the first cost of electrical apparatus. This outlay would furnish a light of from sixteen to twenty-four candle power. Once connected, the current never stopped. A light of sixteen candle power cost one cent and a fifth an hour, or at the rate of two dollars a thousand feet of gas. A motor could be supplied at the cost of the amount of current it consumed only.

**The Diagnosis and Treatment of Certain Forms of Rhinitis.**—Dr. C. H. KNIGHT read a paper with this title. (See p.

32.) The general conclusions reached were strongly indorsed by Dr. M. J. Asch, Dr. Douglas, and Dr. Beverley Robinson, especially as regarded the essentially constitutional nature of catarrhal affections of the nose, and the primary importance of constitutional treatment for their relief. Dr. Robinson believed douches and sprays to be, therefore, essentially irrational; most people found themselves "stopped up" in cold, moist weather, and why should we hope that the direct application of a cooling spray should relieve this condition? On the other hand, we often found patients doing better in high, dry, and equable pine-tree regions, or around mineral springs. Following this suggestion, he had of late adopted the use of volatile agents, and with good results. The chief drawback was that we had no means of using them that did not involve too much time and trouble. If we directed our attention to the general constitutional state, we must be prepared to do so in a very intelligent manner. He had little belief in our ever getting lasting relief in asthma by nasal operations. In a record recently kept of thirty-one cases, in five of which a notable stenosis of the nasal passages had existed, an operation had been done in all of the latter; but with no effect whatever (on the asthma) in one of the five patients and only a temporary alleviation in the other four. Asthma was, in his opinion, a disease connected with a deranged condition of the stomach and heart closely allied to gout. It was folly to suppose any one local trouble, such as nasal stenosis, could occasionally and entirely of itself cause an affection which had really so complex an *aetiology* as asthma. Till we were able to abandon the almost axiomatic truths which the wisdom of the ages had brought us, we ought to be very careful in our active interference with an organ like the nose, the functions of which were not fully understood—else we were likely to accomplish more harm than good.

The CHAIRMAN, while he appreciated the necessity of constitutional treatment, believed the time was now come when rhinologists could study, and, in certain cases, treat locally, the various obstructions of the nose to some purpose. He spoke particularly of his success in the use of cocaine and chromic acid in hyperplasia of the nasal mucous membrane, and also in chronic hyperæmia. In operating for obstruction we should aim to restore the nasal function (to the extent of restoring a circulation of air through the nares) without destroying too much of the tissues in which other functions were seated.

## Book Notices.

*Lectures on Nervous Diseases, from the Standpoint of Cerebral and Spinal Localization, and the Later Methods employed in the Diagnosis and Treatment of these Affections.* By AMBROSE L. RANNEY, A. M., M. D., Professor of the Anatomy and Physiology of the Nervous System in the New York Post-graduate Medical School and Hospital, etc. Profusely illustrated with Original Diagrams and Sketches in Color by the Author, carefully selected Woodcuts, and reproduced Photographs of Typical Cases. Philadelphia: F. A. Davis, 1888. Pp. xiv-778. [Price, \$5.50.]

DR. RANNEY's book is in some respects a unique contribution to neurological literature. It is largely a compend of previous papers and publications by himself; and yet so deftly is the old material which is thus utilized woven in with the new matter that the combination forms a congruous whole, and no one not conversant with the author's previous works would recognize that the present work was thus pieced together or

would be able to indicate the lines of junction of its component fragments. This appearance of symmetry and completeness in a book so constituted is largely due to the logical and orderly arrangement of the separate parts—an arrangement which insures the presentation of the different subjects according to a natural and easy order of development. In other words, the author builds his work from the ground up—stating first the anatomical, physiological, and pathological facts upon which the science of neurology is based; then giving in full detail the means of recognizing the pathological conditions which may exist, and thus showing how the knowledge of these basal facts of the science can be utilized for the investigation of nervous diseases; and finally taking up in order the individual diseases themselves, enumerating first the structural affections of the brain and spinal cord; secondly, the functional nervous affections; and, thirdly, those diseases which do not seem to fall certainly under either of the former heads, or which are of toxic origin. A section on electro-therapeutics, which is mainly a re-edition of the author's "*Electricity in Medicine*" and of his brochure on "*Static Electricity*," completes the book.

While each one of these subdivisions of the work is satisfactory in point of both style and matter, being readable, apparently well brought down to date, and containing much useful new material, the section which will especially engage the attention both of the specialist and of the general practitioner is that upon functional nervous diseases. It might be thought that but little or nothing that was new or interesting could be advanced in regard to such well-worn themes as epilepsy, chorea, and neuralgia; but the author's recognition of the reflex element which undoubtedly plays such a large part in the causation of these affections, and his own most interesting experience in regard to the relief of them by the "*Stevens*" method when, as is often the case, they are due to derangement of the ocular muscles, should demand careful study and appreciation. To those who, without examination of its merits, have hitherto ridiculed this method in its application to nervous disease, we cordially commend a perusal of Dr. Ranney's book.

An excellent feature of the work is found in the numerous colored diagrams, many of them either original with the author or modified by him from the designs of others. Such diagrams elucidate more clearly than any mere pictorial illustration, or than any amount of descriptive text, some of the most difficult points in cerebro-spinal anatomy and physiology.

The book is written in a clear, unpretentious style, equally free from involved discussions and from dogmatism of statement; and, in the controversial portions, the reviewer notices with pleasure a marked absence of personality or of anything approaching abuse or unfair treatment of an adversary.

The mechanical execution is excellent, the type, paper, and in general the illustrations also, leaving little to be desired.

### BOOKS AND PAMPHLETS RECEIVED.

*Annual of the Universal Medical Sciences. A Yearly Report of the Progress of the General Sanitary Sciences throughout the World.* Edited by Charles E. Sajous, M. D., Lecturer on Laryngology and Rhinology in Jefferson Medical College, Philadelphia, etc., and Seventy Associate Editors, assisted by over Two Hundred Corresponding Editors, Collaborators, and Correspondents. Illustrated with Chromo-lithographs, Engravings, and Maps. Vols. I, II, III, IV, and V. Philadelphia and London: F. A. Davis, 1889.

*A Text-book of Human Physiology, including Histology and Microscopical Anatomy; with Special Reference to the Requirements of Practical Medicine.* By Dr. L. Landois, Professor of Physiology and Director of the Physiological Institute, University of Greifswald, Third American, translated from the Sixth German Edition. With Additions by William Stirling, M. D., Sc. D., etc. With Six Hundred

and Ninety-two Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. xxxi-33 to 974. [Price, \$6.50.]

A Text-book of General Therapeutics. By W. Hale White, M. D., F. R. C. P., Senior Assistant Physician to and Lecturer on *Materia Medica* and Therapeutics at Guy's Hospital. With Illustrations. London and New York: Macmillan and Co., 1889. Pp. xi-371. [Price, \$2.50.]

A Manual of Chemistry for the Use of Medical Students. By Brandreth Symonds, A. M., M. D., Assistant Physician to Roosevelt Hospital, Out-patient Department, etc. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. 154. [Price, \$2.]

Lectures on Obstetric Nursing. Delivered at the Training School for Nurses of the Philadelphia Hospital. By Theophilus Parvin, M. D., Professor of Obstetrics and Diseases of Women and Children at Jefferson Medical College, etc. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. viii-9 to 104. [Price, 75 cents.]

Essentials of Pathology and Morbid Anatomy. By C. E. Arnnand Semple, B. A., M. B. Cantab., L. S. A., M. R. C. P. Lond., etc. With Forty-six Illustrations. Philadelphia: W. B. Saunders, 1889. Pp. xvi-160.

Inebriety: Its Aetiology, Pathology, Treatment, and Jurisprudence. By Norman Kerr, M. D., F. I. S., Fellow of the Medical Society of London, etc. Second Edition. London: H. K. Lewis, 1889. Pp. xxxii-471.

Index-catalogue of the Library of the Surgeon-General's Office, United States Army. Authors and Subjects. Vol. X. O to Pfutsch. Washington: Government Printing Office, 1889.

Transactions of the Gynaecological Society of Boston. New Series. Vol. I. Boston: Published by Cupples & Hurd, 1889.

Transactions of the American Surgical Association. Volume the Seventh. Edited by J. Ewing Mears, M. D., Recorder of the Association. Philadelphia: P. Blakiston, Son, & Co., 1889.

Transactions of the Thirty-ninth Annual Meeting of the Illinois State Medical Society, held in Jacksonville, May 21, 22, and 23, 1889.

On Disordered Digestion and Dyspepsia. By Frank Woodbury, A. M., M. D., Fellow of the College of Physicians of Philadelphia, etc. Detroit: George S. Davis, 1889. [The "Physicians' Leisure Library."]

Prolapse of the Womb, with Especial Reference to the (so-called) Hypertrophic Elongation of the Supra-vaginal Portion of the Cervix, with Report of a Case. By Lewis H. Adler, Jr., M. D. [Reprinted from the "Medical News."]

Spinal Caries: Operative Treatment, Laminectomy, or so-called Trephining of Spine. By De Forest Willard, M. D., Ph. D., etc. [Reprinted from the "Transactions of the College of Physicians of Philadelphia."]

Nephrectomies for Gunshot Wound and for Tuberculous Kidney. By De Forest Willard, M. D., etc. [Reprinted from the "Transactions of the American Surgical Association."]

by ingestion of flesh or milk; and that though the disease might seem limited to the viscera, the flesh appearing healthy, yet the tubercle bacillus might be there. It was ruled that, "except on the footing that the meat was the medium of transmission of the disease, it would be unnecessary and wasteful to exclude from the food-supply the carcasses of animals which had suffered from tuberculosis, however generalized and extensive." The interest of the public health, however, was paramount to the question of a small loss to the food-supply.

**The Distribution of Disease in Southern India.**—In a paper on this subject by Surgeon-General George Bidie ("Brit. Med. Jour.", July 20, 1889), the results of a long residence in the Madras presidency are given. The territory has an area of about 149,000 square miles, with a population varying from 91 persons in Kurnool to 583 in Tanjore to the square mile. During the past five years the mean annual death-rate in towns was 24·9 in a 1,000, in the rural districts 19·9 in a 1,000. The cold season is most fatal to natives, the hot months being healthiest. The moisture in the air, the daily range of temperature, and the character of the soil are determining causes of disease. The cold, damp, clay soils cause pulmonary diseases, the alluvial soils cholera and bowel complaints, while the sandy and gravelly soils are generally wholesome. During twenty years the mortality from cholera was at the mean rate of 44·02 to 1,000 inhabitants; the disease occurred in the water-logged alluvial land, the villages and towns being very dirty, and the drinking water being taken from filthy irrigation ditches and shallow wells. Malarial fevers are generally prevalent in the low-lying districts, shunning the coast as a rule, and are rather rare in the rice districts; the death-rate is greater in the country (8·6) than in towns (6 in 1,000). Fogs seem to increase the prevalence of fever, the moisture containing the malarial germs that are introduced through the lungs. Small-pox is quite prevalent—endemic, the author says. There is popular opposition to vaccination, and not more than 16 to 17 per cent. of children are protected by vaccination; the mean annual death-rate is from 1 to 4 to 1,000 of the population. Phthisis and syphilis are common, and the author considers that the latter predisposes to the development of the former. Beri-beri is endemic in various places, sometimes epidemic in the wet season, the germs being bred in the soil and carried in the air. Madura foot is due to a fungus, usually introduced by traumatism. Elephantiasis is endemic also; it is supposedly due to a *Filaria*. Leprosy, 4·4 to 10,000, is held in check by the high mortality and low fecundity of those affected. Segregation is not practiced.

**The Pasteur Institute, Paris.**—According to the recently published proceedings of the Academy of Sciences, Paris (*ibid.*), 1,673 persons had been treated in the institute. It was certified that all had been bitten by rabid dogs; and that the animals were rabid was often demonstrated by inoculation. There were thirteen deaths, six occurring during treatment that was probably begun too late, four taking place soon after treatment, and three seeming to show complete failures of inoculation protection. It would have enhanced the value of the statistics if the number of dogs proved to be rabid by inoculation experiments was given.

**The Health of Children in Fourteen London Schools.**—A committee to investigate the physical condition of the pupils in London schools was appointed by the psychological section of the British Medical Association ("Brit. Med. Jour.", July 27, 1889), and, on account of the refusal of the London School Board to allow the investigation to be made in their schools, the observations had to be confined to fourteen elementary schools. The results of the examination are given, without comment, in a series of lengthy tables. There were 1,944 boys and 1,987 girls examined; among these there were signs of nerve weakness—nervous hand, weak hand, lordosis, toneless orbicular muscles of the eyelids, and finger twitches—in 207 boys (10·6 per cent.) and 144 girls (7·2 per cent.); with defective nutrition, there were 100 boys (5·1 per cent.) and 84 girls (4·2 per cent.); with mental dullness, there were 153 boys (7·8 per cent.) and 78 girls (3·9 per cent.); with cranial abnormalities—rickets, large head, small head, dolichocephalus, narrow forehead, etc.—there were 166 boys (8·5 per cent.) and 65 girls (3·2 per cent.); with diseases or defects of the eyes—squint, hypermetropia, myopia, disease of the cornea, disease of the lids, cataract, nystagmus, loss of the eye—there were 74 boys (3·8 per cent.) and 75 girls (3·7 per cent.). One or more of the conditions were found in the same child

## Reports on the Progress of Medicine.

### HYGIENE AND PUBLIC HEALTH.

BY S. T. ARMSTRONG, M. D.,  
U. S. MARINE-HOSPITAL SERVICE.

**The Sale of Tuberculous Flesh and Milk in Scotland.**—At a recent meeting of the Scottish Veterinary Association ("Glasgow Med. Jour.", July, 1889) the Government was petitioned to stop the sale of milk from animals suspected of being infected with tuberculosis, and to suppress the consumption of the meat of such animals, owners being recompensed for the value of the latter. This petition seems to be the outcome of a recent trial in Glasgow relative to the question of the condemnation of a whole carcass if tuberculosis was present in a limited portion, in which two carcasses were adjudged unfit for food. The grounds of the judgment were that tuberculosis in the lower animals was the same disease as tuberculosis in man; that it was transmissible

occasionally. Only in defective nutrition and ocular defects were the sexes equal; strange to note, nerve-weakness was greater in the boys than in the girls, and the other defects were almost twice as common in boys as in girls.

**The Training of Local Health Officers.**—The chairman of the Section in Public Medicine of the British Medical Association (Dr. E. Ballard) has presented the results of his extensive experience with local health officers in a consideration of their necessary qualifications ("Brit. Med. Jour.", August 31, 1889). He considers that such an official should have a wider range of information than is requisite for the general practitioner, adding to the knowledge required by the latter an acquaintance with meteorology, geology, sewer and water engineering, the construction and ventilation of houses, bacteriology, and the laws governing epidemic contagia, and even the pathology of animals. His scientific education should be supplemented by a course of training under a health official; and he must never forget that he is not an autocrat, but always display tact in dealing with his constituency. In the discussion on the paper it was agreed that the local health officer should be appointed by the state, to hold office during life and good behavior, and that the salary should be sufficient to permit general practice to be prohibited, no one being appointed to such a position unless holding the special qualifications in hygiene above noted, and, in addition to his general duties, to have charge of vital statistics, medical registration, and public vaccination.

**The Incubation Period in Infectious Diseases.**—Dr. James Finlayson ("Glasgow Med. Jour.", May, 1889), in preparing a code for the regulation of the school attendance of children exposed to or affected by infectious diseases, found that there was a decided diversity of opinion among authorities as to duration of the incubation period and as to the time of quarantine for children that had been exposed. The incubation period in scarlet fever is given as low as 1 day and as high as 14 days, with an average duration of quarantine from 10 to 14 days; measles, from 3 to 17 days—quarantine 16 days; rötheln, from 4 to 21 days—quarantine from 16 to 21 days; mumps, from 4 to 24 days—quarantine from 21 to 24 days; whooping-cough, from 4 to 14 days—quarantine from 16 to 21 days; chicken-pox, from 2 to 18 days—quarantine from 18 to 21 days; small-pox, 5 to 19 days—quarantine 16 to 18 days; diphtheria, 1 to 14 days—quarantine 10 to 12 days; enteric fever, 1 to 30 days—quarantine 28 days; typhus fever, 1 to 21 days—quarantine 21 to 28 days; erysipelas, 1 to 13 days—quarantine 10 days. As in the United States local ordinances involving this question require the physician to furnish a certificate to the child, the periods of quarantine above given may serve as precedents.

**The Influence of the Closure of Schools on an Epidemic of Measles.**—The health officer of Cardiff, Dr. Edward Wolford, reports ("Sanitary Record," May, 1889) that in the autumn of 1888 an epidemic of measles occurred among the children attending school, and, notwithstanding every effort to stamp out the outbreak by careful inspection, enforcing and advising ordinary precautionary measures, and distributing printed circulars of information, the disease became so prevalent that by the end of November almost one third of the pupils were ill or confined at home. The schools were closed for four weeks, and the number of cases at once decreased; only four cases appeared among twenty thousand scholars after the schools were reopened. The author considers that the material was not exhausted, but that the comparative isolation of the children stopped the epidemic. This opinion is supported by the fact that in a previous epidemic, when the schools were not closed, the mortality was double that in the present instance,

**Child Mortality in Dublin.**—Dr. T. W. Grimshaw ("Dublin Jour. of Med. Sci.," July, 1889) calls attention to the fact that, while the annual death-rate to 1,000 in children under twelve months (145·5) and five years (36·6) is less in Ireland than in England or Scotland, yet in Dublin the rate in the first-mentioned class increases to 210·1 to 1,000, and is higher than that of any other city in the United Kingdom. He considers that it is caused by: 1. The large proportion of poor in Dublin, statistics proving that the infant mortality in the working class is six times as great as in the professional class. 2. The inferior house accommodations of the artisan and laboring classes, the larger tenement houses accommodating 7·5, the smaller 4·8 families. 3. The intemperate habits of the laboring classes, statistical tables showing that

a high death-rate is coincident with a high drink-rate, and that Dublin leads the United Kingdom in the latter feature. 4. Carelessness regarding the care of young, and especially sick children, this being demonstrated by the large number of uncertified deaths.

**Disinfection by Steam at High Pressure.**—Dr. A. D. Lübitzoff ("St. Petersburg Inaug. Dissert.," 1889, p. 54) has experimented with the steam disinfection apparatus of Geneste and Herscher and with a disinfection chamber in the St. Petersburg Clinical Military Hospital. The steam current had a pressure of six atmospheres. Strips of Swedish filter paper saturated with various microbes were put into test-tubes; these were placed in pillows, mattresses, and bundles of clothing, and kept in the disinfecting chamber from half an hour to three hours. The inoculated paper was then introduced into agar-agar or broth cultivation media. The experiments demonstrated that sporeless bacteria were killed in half an hour, while pathogenic microbes were entirely destroyed after an exposure to steam at 113° or 114° C. The disinfecting chamber must be able to maintain this temperature for an hour and distribute the steam uniformly to all parts of the apparatus. Articles to be disinfected must be dry, because if damp they interfere with the height of the temperature; and they should be distributed singly in the chamber, or be done up in small parcels. The management of such chambers should invariably be in the hands of medical men, and each municipality should have a public disinfecting chamber, as in Berlin. [The disinfecting apparatus of Geneste and Herscher is a metallic cylinder 1·3 metres (4 $\frac{1}{4}$  feet) in diameter and from 2 to 4 metres (6 $\frac{1}{2}$  to 13 feet) long. The cylinder is closed and made air-tight by means of two doors, supported on wheels, one at each end; the doors are made steam-tight by clamp-screws. In the interior of the cylinder there is a car running on an iron track, on which the soiled articles are placed. Steam, generated by a neighboring boiler, enters the chamber by two sets of tubes—one to raise the temperature to 130° C., the other, pierced with holes 40 millimetres in diameter, to allow steam to enter the chamber when it is desired. The necessary pressure-gauges, thermometers, etc., are placed on the exterior of the cylinder.]

**Disinfection and Isolation in Reference to the Control of Epidemics.**—In opening a discussion ("Brit. Med. Jour.", Aug. 31, 1889) on this subject, Dr. H. Franklin Parsons, after referring to the epidemic diseases, mentioned the experiments of Koch in destroying the spore-bearing and non-spore-bearing micro-organisms, in which that observer had proved that carbolic acid had an inhibitory effect on their growth, spore-bearing forms requiring immersion for one or two days in a five-per-cent. solution, whereas a two-per-cent. solution only killed them in a week. Sulphurous-acid gas, in a six-per-cent. mixture, failed to kill spore-bearing organisms after four days' exposure. Dry heat (284° F.) would destroy spores in three hours; but this temperature would injure all textile materials. Steam at 212° F. would destroy spore-bearing forms in five minutes; and articles to be disinfected were easily penetrated by it. A watery solution of iodine or corrosive sublimate (one per cent.), or chlorine or bromine (two per cent.), would destroy spore-bearing organisms after one day's immersion. The carriers of infection were the body of the patient, the excreta and the skin, the air tainted by exhalations from the sick, clothes, bedding, etc., articles of food, walls and floors of dwellings, collections of filth, dust on walls or in cracks, and sewage. The body may be disinfected by suitable washes, and, after death, buried in lime or charcoal. The air may be extracted from the sick-chamber and burned in a furnace or in a ventilator containing burning gas-jets. Discharges from the nose and throat may be received on rags and burned; those from the bowel and kidneys should be received in vessels containing a five-per-cent. corrosive-sublimate solution. Clothing, bedding, etc., should be exposed to steam, or, where that is impracticable, boiled after having been immersed for some hours in a bichloride-of-mercury solution. Books and letters should be exposed to dry heat for some hours. Thorough boiling of water or milk, or cooking of food, will disinfect food stuffs. For house disinfection, sulphurous acid or chlorine is recommended, followed by scrubbing of the walls, removal of paper, and whitewashing where practicable.

In the discussion that followed, Dr. P. C. Smith, of Glasgow, considered that there were two divisions of the subject: disinfection and isolation; first, in hospitals; second, at home. Cities should have pavil-

ions for the different zymotic diseases; towns, a cottage hospital, with a tent (or portable house) for small-pox; they should have steam disinfecting chambers, and the clothing of typhus and small-pox patients should be burned. At home the room occupied should be in the top story, divested of carpet and furniture, save a bed and chair for the nurse. There should be no communication between the nurse and the occupants of the house; food, etc., being placed on a table at the door. Disinfection of discharges, clothing, the room, etc., should be done as mentioned by the first speaker.

Dr. W. Squire, of London, considered the public establishment of good wards, good nursing, and care to attract the attention of those in need, as the first essential. If the hospitals could not care for patients until convalescence was completed, there should be convalescent homes. In the scarlet-fever hospitals in London, in 1887, 3,000 patients had been treated, with a mortality of 267; in 1888, 4,408 patients; in 1889, 5,900 patients. These figures showed the increasing usefulness of those hospitals, and showed that the mortality from the disease had decreased.

Dr. Hope, of Liverpool, considered "domestic isolation" a fallacy, and instanced eighty cases of typhus fever so treated, in which the disease had spread to 386 individuals of the families, with 62 deaths. Contrasted with this were eighty cases in which the patient was at once removed to the hospital and the house disinfected and cleansed, and no extension of the disease took place.

Dr. C. H. Allfrey spoke of the isolation of persons with infectious diseases in hotels, citing a case where great care had failed to secure vigorous quarantine. He advocated an association of hotel-keepers that would insist upon the removal of all members of an infected family as soon as possible, the declaration of all visitors that they were free from and had not been exposed to infection, and the establishment of a register of sanitarily certified hotels. [The British Medical Association adopted a resolution to this effect.]

Dr. Littlejohn stated that in Edinburgh the removal of patients with infectious disease was compulsory.

**The Contamination of Drinking-water with Lead.**—Dr. Sinclair White (*ibid.*), as the result of extensive experiments, concludes that acid water invariably acts on lead, the intensity of action varying with the acidity; new lead pipe being acted on more than old, the amount of lead dissolved increasing for the first twenty-four hours, and materially decreasing at the end of six days. Other things being equal, the greater the pressure of the water the greater the amount of lead taken up, and the greater the temperature the greater the solvency. A small amount of lime or soda diminishes the solvent power of the water, and filtration through limestone, charcoal, or spongy iron causes the water to become inert; filtration of water containing lead through the two latter substances will remove the lead. Where lead-dissolving water exists, wrought-iron, tin, or glass-lined iron pipes and tanks should be employed, or the water should, before distribution, be filtered through beds of fine sand and broken limestone.

Dr. Fairclough believed that much of the anæmia of town people was due to drinking water containing small quantities of lead. He referred to the fact that some waters formed an insoluble crust on the interior of new lead pipes in two or three weeks, thus forming a permanent protection.

Dr. Whitelegge recommended that water pipes be made of Borff iron, as it had the property of withstanding rust.

**The Physiological Value of Meat Foods for Invalids.**—Surgeon-General C. M. Jessop (*ibid.*) believes that there is considerable waste in the preparation of beef teas, because nurses and cooks try to make a "clear" solution. Referring to the physiological metamorphosis of nitrogenous substances, he concludes that at least 138 grains of nitrogen, or six ounces of meat, is the smallest daily amount necessary for the bare maintenance of life. Yet the extractum carnis made by slowly heating, until it boils, a pound of finely chopped beef in an equal quantity of water, is nothing but a solution of excrementitious substances and blood salts. Baron Liebig says: "By the addition of meat extract to our food, we neither economize carbon for the maintenance of the temperature nor nitrogen for the sustenance of the organs of the body, and therefore it can not be called food in the ordinary sense. Dogs fed exclusively on extractum carnis die sooner than those not fed

at all, which seems to be due to the deleterious influence of the potash salts contained in the extract." In prolonged illnesses the potash salts may impede nutrition by diminishing the absorption of oxygen by the blood globules, and, increasing the salts in the serum, interfere with the exhalation of carbonic acid. In an emergency one or two drachms of beef may be chopped to a pulp, placed in a cup with two tablespoonfuls of water, a pinch of salt being added, and the mixture heated for ten minutes and given at once. In making fluid meat-food there should be no remainder. Mince one pound of good beef, place it in a double boiler with two quarts of water, and boil for three hours, stirring it frequently with a wooden masher; pass it through a colander to remove the fiber, and season with salt if necessary. The mixture is wholesome and may be administered in necessary quantities every three or four hours.

**Cholera in Malta during 1887.**—In an interesting review on the Seventeenth Annual Report of the Local Government Board (for 1888), Lieutenant-Governor Hutchinson's "Note on the Present Prevalence and Extent of Cholera in Malta," and Dr. S. L. Pisani's report as chief government medical officer for that colony, the "Practitioner" for May, 1889, concludes that an analysis of these reports demonstrates that, in the interests of public health and of the commercial interests of the world, "the antiquated and ever-failing quarantine restrictions should be done away with, and an efficient sanitary administration substituted for them." Cholera first prevailed in Malta from June 9 to October 11, 1837—4,462 cases occurring in towns, 3,105 in villages; 2,207 deaths took place in the former, 1,585 in the latter. The second epidemic, imported from Barbary, lasted from June 9 to October 13, 1850; there were 4,029 cases, with 1,736 deaths. The third epidemic lasted from June 9 to November 11, 1865; there were 2,362 cases and 1,479 deaths. In the fourth epidemic, from July 5 to November 25, 1867, there were 403 cases and 259 deaths. From August 3 to November 11, 1887, there were in the towns, with a population of 60,629, 155 cases with 110 deaths; in the villages, with an aggregate population of 76,161, there were 471 cases with 352 deaths. In the villages the houses were often overcrowded, the ventilation was poor, there was no sewerage, and there was often no good potable water—the supplies being liable to pollution. In the towns the houses are drained, there are sewers, and there is a plentiful supply of good water. Consequently the epidemics have decreased in severity in the towns and increased in the villages. During the last four epidemics quarantine has been practiced; nevertheless, means have been found to evade the restrictive law. Dr. Pisani concludes that, if the villages were drained and supplied with water, the houses of the poor inspected and improved, and all blind alleys opened, the island would become "an unfertile soil for the cholera germ." The "Practitioner" believes that a recognition of these facts—supported by the statistics of the towns of the island—and a disbelief in any efficiency in quarantine will enable Malta (as well as other localities) to avoid future epidemics.

**Leprosy in the British Possessions.**—In 1884 the medical profession of the Cape of Good Hope, says the "Practitioner," became convinced that leprosy was increasing, and an act was passed reciting this fact and providing that if a person was certified to be suffering from leprosy, he or she should be removed to a leper hospital, to be there detained. The disease is chiefly confined to the blacks and half-castes, though Europeans are affected. In Jamaica, where there are seven or eight hundred lepers, there is a difference of opinion as to its increase. In Trinidad the number of patients in the hospital has increased, and it is maintained that this is out of proportion to the increase in the population. In British Guiana, where one in five hundred of the population is leprous, the disease is believed to be increasing, not only among the coolies but among creoles as well. In Barbadoes the population has increased six per cent., leprosy twenty-five per cent. In New Brunswick leprosy has decreased, but it has appeared among the Chinese in British Columbia. In India the census of 1881 gave 131,168 lepers; there is no evidence as to its increase or diminution. In the Mauritius leprosy is at a standstill. In Australasia it has appeared among the Chinese, Malays, Arabs, and Hindus. [There is certainly some leprosy in the Bahamas, for cases have appeared at Key West from there.]

**The Heredity of Leprosy.**—Dr. G. A. Hansen, the discoverer of the *Bacillus leprae*, has made an investigation of the present condition of

160 Norwegian immigrants that had settled in Wisconsin, Minnesota, and Dakota ("Arch. f. path. Anat. u. Physiol. u. f. klin. Med.", exiv.) He has been able to find only thirteen of the original immigrants; a few more may be living, but nearly 147 are dead. Of all their descendants, so far as great-grandchildren, not one has become a leper. There are many Norwegians in those States descended from or related to lepers, yet the disease does not increase nor has it proved hereditary.

**The Royal College of Physicians on Quarantine.**—The arrival of the steamship *Neva* at Southampton, in June last, with one case of yellow fever on board, caused the Privy Council Office to order her into quarantine for seven days. The "Practitioner" thought the Privy Council was to be congratulated that the occurrence took place at the only spot on the British coast that maintained a quarantine station (two hulks, at the entrance of the harbor). The Secretary of State for the Colonies submitted to the Royal College of Physicians the question of the proper periods of detention for purposes of quarantine in yellow fever, cholera, and small-pox. The college reported that the incubation period of yellow fever and cholera was uncertain, and that the committee was of the opinion that it was unwise to impose quarantine restrictions in the case of these diseases. The committee was further strongly opposed to such restrictions generally, which it considered harmful and vexatious. In the case of small-pox the committee was of the opinion that the incubation period did not usually exceed a fortnight, and that suitable precautions based on this knowledge were desirable. The "Practitioner" does not consider the last paragraph of the report very helpful, especially as vaccination is the obvious means of preventing small-pox.

## Miscellany.

**The New York State Medical Association** will hold its sixth annual meeting at the Hotel Brunswick, Fifth Avenue and Twenty-seventh Street, New York, on Wednesday, Thursday, and Friday, the 25th, 26th, and 27th inst., under the presidency of Dr. William T. Lusk. The programme includes the following titles: An address by the president, on "Tubal Pregnancy"; "Inversion of the Uterus; Novel Treatment," and "The Latero-dorsal Position in Gynaecic Irrigation," by Dr. George E. Fell, of Erie County; "The Treatment of Uterine Fibroids by Electricity," by Dr. Henry D. Ingraham, of Erie County; "Pelvic Cellulitis in Women," by Dr. W. H. Robb, of Montgomery County; "Report of a Case of Laparotomy for Ruptured Pyosalpinx; Error in Diagnosis; Recovery," by Dr. C. S. Wood, of New York County; "The Use and Abuse of the Forceps in Obstetrics," by Dr. J. P. Garriish, of New York County; a discussion on "Tubal Pregnancy," by Dr. William T. Lusk, of New York County, Dr. William Goodell, of Pennsylvania, Dr. George T. Harrison, of New York County, Dr. Howard Kelly, of Pennsylvania, Dr. Thophilus Parvin, of Pennsylvania, Dr. Isaac E. Taylor, of New York County, Dr. T. Gaillard Thomas, of New York County, Dr. Ely Van de Warker, of Onondaga County, Dr. W. H. Parrish, of Pennsylvania, and Dr. W. H. Wathen, of Kentucky; "Prognosis in Pulmonary Phthisis; How much has it been Improved and by what Means?" by Dr. Avery Segur, of Kings County; "Affections of the Eye Symptomatic of Disease of the Central Nervous System," by Dr. Alvin A. Hubbell, of Erie County; "A New Portable Accumulator," by Dr. Robert Newman, of New York County; "The Warming and Ventilation of Public School Buildings," by Dr. Ira B. Read, of New York County; "A Word in Favor of Free Dispensary and Free Hospital Work," by Dr. E. J. C. Minard, of Kings County; "The Microscope in Diagnosis; Personal Observations," and "Forced Respirations; Additional Observations," by Dr. George E. Fell, of Erie County; an address in surgery, by Dr. Francis Bacon, of Connecticut; "Alcoholic Paralysis," by Dr. T. D. Crothers, of Connecticut; "A Few Fads," by Dr. H. D. Didama, of Onondaga County; "Some of the Uses of the Transfixion Ligature," by Dr. T. H. Manley, of New York County; a discussion on "The Treatment of Hernia," by Dr. Joseph D. Bryant, of New York County, Dr. William T. Bull, of New York

County, Dr. Charles W. Brown, of Chemung County, Dr. T. H. Squire, of Chemung County, Dr. Charles L. Squire, of Chemung County, Dr. W. S. Tremaine, of Erie County, Dr. Roswell Park, of Erie County, Dr. Charles McBurney, of New York County, Dr. John A. Wyeth, of New York County, Dr. D. M. Totman, of Onondaga County, Dr. Leroy J. Brooks, of Chenango County, and Dr. Frederic S. Dennis, of New York County; "Lantern Views of Bacteria," by Dr. Edward K. Dunham, of New York County; an address in medicine, "On the Bacteriological Test of Drinking Water," by Dr. Edward K. Dunham, of New York County; "The Cure of Haemorrhoids by Excision and Closure with the Buried Animal Suture," by Dr. Henry O. Marey, of Massachusetts; "Report of a Case of Ataxic Paraplegia," by Dr. Darwin Colvin, of Wayne County; "Observations on Dislocations of the Hip," by Dr. U. C. Lynde, of Erie County; a discussion on "The New Hypnotics: Sulphonal, Amyl Hydrate, Hydrobromate of Hyoscine, Hypnone, Paraldehyde, Urethane—their Therapeutic Applications, Contra-indications, Toxicology, and Methods of Administration," by Dr. William H. Flint, of New York County, Dr. Austin Flint, of New York County, Dr. E. G. Janeway, of New York County, Dr. Charles Rice, of New York County, Dr. Charles G. Stockton, of Erie County, and Dr. John G. Truax, of New York County; "Extraction of Cataract without Iridectomy," by Dr. Charles Stedman Bull, of New York County; and "Two Cases of Angular Deformity of the Knee Joint," by Dr. Lewis Hall Sayre, of New York County.

**A Foreign Body in the Urethra.**—Dr. Albert Krog writes to us as follows:

"A mother called upon me with her little boy, of about five years of age. Upon examination of the boy, I found an extremely tender penis. The glans was very much swollen and inflamed, and from the opening of the urethra a very thick, greenish-yellow pus made its appearance. The little fellow seemed to suffer much pain. Micturition was hardly possible. The mother then informed me that her little boy had already been under the treatment of an old physician for the preceding four or five days, who, under the impression of a gonorrhœa purulenta, had well dosed him with eubeba and copaiba. Nevertheless, his condition had grown worse and more alarming. A more minute examination seemed to reveal to me a specially tender spot along the urethral canal, and, on introducing a slender forceps, I extracted a small piece of wood, which had been the cause of all the trouble. Cold applications allayed all the concomitant symptoms."

**The Southern Surgical and Gynaecological Association** will hold a meeting in Nashville, Tenn., on the 12th, 13th, and 14th of November, under the presidency of Dr. Hunter McGuire, of Richmond. The preliminary programme includes the president's annual address and the following titles of papers: "Report of Gynaecological Work, with especial Reference to Methods," by Dr. R. B. Manry, of Memphis; "Direct Kelotomy, with Cases," by Dr. W. O. Roberts, of Louisville; "Open Abdominal Treatment," by Dr. B. E. Hadra, of Galveston; "The Abortive Treatment of Acute Pelvic Inflammation," by Dr. Virgil O. Hardon, of Atlanta; "The Importance of Early Treatment of Inflammatory Affections of the Uterus," by Dr. William C. Dabney, of University of Virginia; "The Relation of the Nerve System to Reparative Surgery," by Dr. Thomas O. Summers, of Jacksonville; "Concerning the Causes of Frequent Failure of Relief of Reflex Symptoms after Trachelorrhaphy," by Dr. W. F. Hyer, of Meridian, Miss.; "Cranial Surgery," by Dr. De Saussure Ford, of Augusta, Ga.; "The Treatment of Ectopic Pregnancy," by Dr. W. H. Wathen, of Louisville; "Laparotomy in Extra-uterine Pregnancy," by Dr. Waldo Briggs, of St. Louis; "Epithelioma of the Penis, with the Report of a Case," by Dr. D. W. Yandell, of Louisville; "Laparotomy in Intestinal Obstruction," by Dr. C. Kollock, of Cheraw, S. C.; "An Experimental Study of Intestinal Anastomosis," by Dr. John D. S. Davis, of Birmingham, Ala.; "Operative Interference in Ascites," by Dr. Hugh M. Taylor, of Richmond; "Observations pertaining to Pregnancy and Parturition," by Dr. W. Duncan, of Savannah; "Puerperal Convulsions," by Dr. J. Herbert Claxton, of Petersburg, Va.; "Some Remarks upon Aneurysms, relating more especially to their Surgical Treatment," by Dr. F. T. Meriwether, of Asheville, N. C.; "Coccygodynia and its Treatment," by Dr. Hunter P. Cooper, of Atlanta; "The Improved Caesarean Section versus Crani-

otomy," by Dr. W. D. Haggard, of Nashville; "Conservative Surgery in Injuries of the Foot," by Dr. J. T. Wilson, of Sherman, Texas; "Gunshot Fractions of the Femur," by Dr. John Brownrigg, of Columbus, Miss.; "Tropho-neuroses as a Factor in the Phenomena of Syphilis," by Dr. G. Frank Lydston, of Chicago; "Trophic Changes following Nerve Injury in Fractures, with a Report of Two Cases," by Dr. W. Perrin Nicholson, of Atlanta; "The Treatment of Malignant Diseases of the Rectum," by Dr. W. T. Briggs, of Nashville; "The Achievements of Modern Surgery," by Dr. J. Ewing Mears, of Philadelphia; and "The Treatment of the Pendle in Suprapubic Hysterectomy," by Dr. William M. Polk, of New York. In addition, papers on subjects not yet determined are announced to be read by Dr. W. L. Robinson, of Danville, Va.; Dr. W. B. Rogers, of Memphis; Dr. L. S. McMurtry, of Danville, Ky.; Dr. E. J. Beal, of Fort Worth, Texas; Dr. E. Burke Haywood, of Raleigh; Dr. Paul B. Barringer, of University of Virginia; Dr. J. F. Y. Paine, of Galveston; and Dr. Joseph Price, of Philadelphia.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the abstract of sanitary reports received by him during the week ending September 13th:

CITIES.	Week ending—	Estimated population.	Total deaths from all causes.	DEATHS FROM—										
				Cholera.	Yellow fever.	Small-pox.	Variolic.	Varicella.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Measles.	Whooping-cough.

**The Rarity of Christian Charity.**—In the Journal of the 10th ult. we referred to the refusal of the Mayor of New York to furnish dogs from the pound to some gentlemen engaged in making certain surgical and bacteriological experiments. The request of one of the experimenters was given considerable newspaper notoriety, and he was recently the astonished recipient of the following letters, written from widely separated localities. We print these anonymous communications *verbatim et literatim*, leaving all comment to our readers:

"You vile merciless rascally friend. I judge from your name you are a nasty Frenchman with no heart, and without a God. If you think you will be permitted to set up a place of torture in this country for poor animals you are vastly mistaken. You will have to betake yourself to the vile and Godless country from which you came or to the

Hell to which you are destined, and if you wish to indulge in such fiendish performances when you reach the latter place—which I hope you will soon—unless you *repent* you will have an opportunity with kindred friends of torturing yourselves through the endless ages of eternity. I am a woman who despises brutes and all brutal actions."

"When *pain* the most awful sensation of the human frame exists—let its alleviation or study prove the sole lawful guide to future eases.

"Only the most *damnable* fiend cloaked in human form ever lifted the knife in *vivisection*. May the curse of an all merciful God rest upon you. Laugh, sneer, such as you do. But may every agony your hellish minds and hand inflicts be trebled upon yourself in this world and the one to come—and upon all like you. May your death bed be such a scene of horror that all will forsake you. May God's curse be upon you."

Possibly some may recall that once Professor Brown-Séquard, while demonstrating to his class certain physiological experiments on a dog, was assailed by a woman armed with a parasol; and we have been informed that Paul Bert once had a similar experience. So our experimenter, who, by the way, is not a Frenchman, may congratulate himself on having had only a verbal excommunication.

**To Contributors and Correspondents.**—The attention of all who purpose favoring us with communications is respectfully called to the following:

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

## Original Communications.

A HITHERTO UNDESCRIPTED  
DISEASE OF THE OVARY;  
ENDOTHELIOMA CHANGING TO ANGIOEMA AND HÆMATOMA.BY MARY A. DIXON JONES, M. D.,  
BROOKLYN.

So far as I know, this peculiar formation, or degenerative disease, of the ovary has not been described. The name kirsoma has been proposed on account of the peculiar convolutions that are manifested. The first one or two microscopic specimens showing this change I considered as curiosities, or as the initial stage of a growth which would possibly, upon further development, be alveolar sarcoma.

I have studied the subject, first by carefully considering the individual characteristics of each case, the symptoms, etc., and afterward the pathological condition of the specimen. Probably now it will be best to present the subject in that order: 1. Individual cases. 2. The microscopic appearances of the disease.

The patient in whom I first recognized this formation was operated on in my private hospital on May 25, 1885. She was thirty-five years of age, single. Her trouble commenced with a severe aching pain in the left side of the pelvis, which gradually increased year by year, extending to the other side of the pelvis, and frequently the pain was so sharp and lancinating that she screamed with agony. She consulted many physicians. Fly-blister were repeatedly applied to the lower part of the abdomen. For nine months she was treated for "inflammation and misplacement of the uterus"; pessaries were used and only made her worse. Subsequently she was treated for "ulceration and uterine congestions," with no better results.

When I first saw the patient she was pale, emaciated, anaemic, and had very much the appearance of one who has phthisis. Examination showed the uterus to be acutely anteflexed; ovaries tender and intensely sensitive. The patient was nervous, hysterical, and her mental conditions were much disturbed. Her friends said she was "not exactly right in her mind." I was fully convinced that the ovaries were in some way exceedingly diseased, and that all her abnormal nerve symptoms were due to reflex irritation from these diseased organs. I so informed the patient, and told her that an operation for their removal might be necessary. Still, I commenced with a course of treatment, hoping, if possible, to save her from the necessity of an operation; but she showed no improvement, and I became convinced I was only wasting time. So, on the 25th of May, I performed the operation. She made an excellent recovery, and since, her health has been good and she has been able to work. It would have been better if the diseased structures had been removed ten years before; every day they remained they were doing injury to the general system and interfering with her general health. A few months after the operation she took entire charge of her paralyzed mother through a long sickness. She stood it well, and ever since has been able to attend to her usual duties. I saw the patient on June 28, 1889. She seemed to be in good health and strength, and was doing the work for an ordinary-sized family.

This case was one of a series reported in the "Medical Record," August, 1886. A microscopic examination was

there given, and a drawing of the formation. I studied the subject in Dr. C. Heitzman's laboratory, and he said: "This tumor we shall have to term either an endothelioma or an alveolar sarcoma."

The next person in whom I found this growth or degeneration was a patient in the Woman's Hospital of Brooklyn. She first came with her mother to see me, March 30, 1887, a pale, emaciated, cadaverous-looking woman, apparently with tubercular consumption. She had been married some years, and had never had any children. She suffered with constant pain on both sides of the pelvis, increased by walking, and at times the pains were especially sharp and severe. The patient said she had had for years tenderness and soreness in the lower part of the abdomen; did not menstruate till she was sixteen, and then it was accompanied with great suffering. Examination showed that the ovaries were prolapsed, enlarged, and so sensitive that the patient shrunk from the slightest touch, and it was evident they were the seat of some form of disease which was in some way seriously deranging her general health. She had been treated by many excellent physicians, both locally and constitutionally, and they had done everything possible for her; still, I commenced a course of constitutional and local treatment, but with no better results, and finally decided there was but one way to relieve or cure the patient, and that was by removing the hopelessly diseased organs. This operation I performed in the Woman's Hospital of Brooklyn on May 10, 1887; it was completed in about fifteen minutes, and the patient recovered without a bad symptom.

Sections of the ovary showed this growth in great perfection and in a very advanced stage of development (Fig. 1). It seemed to occupy the whole ovary, extending quite

FIG. 1.—Endothelioma of the left ovary, extending to the periphery.  $\times 25$ . S., surface of the ovary; A, alveoli filled with endothelia.

to the periphery, and replacing all the special ovarian tissue. In one ovary there were some cysts the walls of which were formed by stratified layers of inflammatory tissue,\* and this growth seemed to be extending or infiltrating itself into the already diseased tissue. In other instances the cyst wall is composed entirely of this growth, which seems so curiously to destroy all healthy or diseased tissue of the ovary, gradually occupying the whole structure.

Another remarkable feature of this case, and one which I have since recognized in many others—indeed in every instance of this disease—was an abnormal condition of the ova. There was not a normal ovum to be found. Many of them were broken up into inflammatory corpuscles. No epithelia, no maculae, no yolk; in some the wall was changed into fibrous connective tissue; in some the follicles were enormously swollen and contained a hydropic yolk; others contained granular matter and haemato blasts, while in other places there was a complete atrophy of the ova, thus exhibiting a destruction of the most vital part of the ovary.

This fact opened a most interesting field for investigation, and presented a new cause for sterility. The patient had come to me not only to be relieved of her suffering, but, with a sorrowful heart, she wanted to know why she did not have children. Her cry was that of Hannah's: she had that deep-seated longing which is in every true woman's heart, which we all so fervently respect and admire, and which, if not gratified, makes life a disappointment. But the condition of this patient showed, as I have seen in many cases, that *the disease which had caused the suffering had also produced a confirmed sterility.*

This patient had long complained of tenderness and soreness in the pelvis, and that the marital relations were not only painful but repulsive and unendurable. After the operation her emphatic statement to me, as well as similar statements of many other patients, disprove the assertion that the removal of the ovaries destroys sexual desires. So far from it, this patient assured me to the contrary, and similar statements have been made to me by other patients.

In May, 1887, I presented to the New York Pathological Society a microscopic section of this growth. At my request Professor Prudden took a small section of the ovary of this patient, and had it prepared and mounted in his laboratory. He wrote me it was carcinoma, also sending one of the sections so labeled. I sent a microscopic section of the ovary of the same patient to Waldeyer, of Berlin; he replied, October 18, 1887, that it was *carcinoma*.

But, from studies and drawings I had made during the summer, I could clearly see that the protoplasmic bodies seemed to round themselves, the coarse granules wonderfully shaping themselves into blood-corpuscles. In some places the elongated protoplasmic bodies seemed to fuse together, forming canals in which were the shadows of

blood-corpuscles, and then would appear the completely formed blood-vessel, and near by many cross-sections of blood-vessels completely filled with blood-corpuscles. These changes I traced over and over again, and saw them in other specimens; so it was clearly proved to my mind that *this growth was a new formation of blood-vessels and blood-corpuscles.* This statement was presented to the New York Pathological Society, December 12, 1888.

From further study I thought the growth essentially started from some mysterious change in the menstrual follicle, as represented in Fig. 2; the living matter shoots up

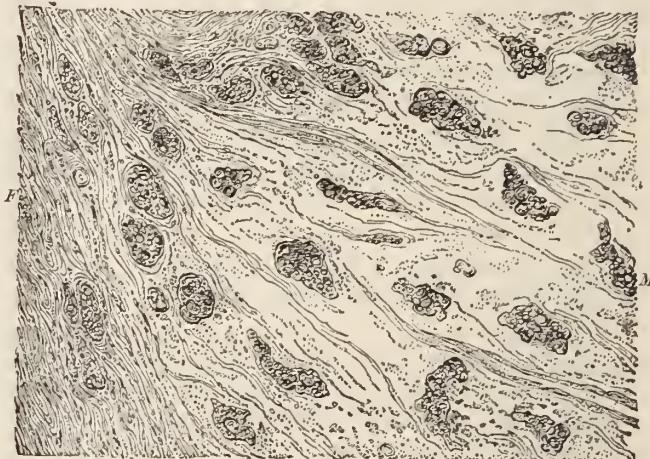

FIG. 2.—Myxomatous tissue of a menstrual follicle.  $\times 500$ . F, fibrous portion of the follicle; M, myxomatous portion filling the follicle. The protoplasmic bodies filled with haemato blasts.

like the lines of light of an aurora borealis; soon are found the granules and haemato blasts, and then commences the rapid growth, spreading and increasing. Other figures show a more advanced stage; the myxomatous portion is composed of nucleated tracts of protoplasm. But why this growth should have the power of destroying every structure of the ovary, even firm secondary fibrous connective tissue, or why an ovary should so degenerate, or what is its pathological significance, are still questions for consideration. Certain it is that this formation is as surely accompanied with manifestations of ill-health as is the breaking down of lung tissue, and the symptoms of both diseases are in many respects similar. It destroys normal structure as effectually as does tubercle. When we look at this rapidly growing formation and the great masses of granules, the impression forces itself upon us that it *may* be malignant. Future investigation may prove it so. The cancer epithelia do not multiply more rapidly, or destroy the tissues more surely, or seem more threatening or monstrous in their appearance and growth.

If it were so that we could watch and study this growth from day to day, see its progressive changes and its general effects upon the system, we might tell the final result. Who knows how disastrous it is, or how fatal, or how many deaths it may have caused? Certainly it destroys the health, comfort, and usefulness of the individual, and as surely its removal has restored health, comfort, and happiness, as well as ability to work. If it were as possible to remove tuberculous lungs as this growth, or as we would a gangrenous

\* In the microscopic study of the ovaries I have frequently found these small cysts, and never have seen one but it was surrounded by newly formed layers of inflammatory tissue, showing long-existing disease; frequently layers of secondary fibrous connective tissue, the results of the inflammation, again in a state of acute inflammation. These small cysts have a history of suffering; they are either the outcome of inflammation or have produced the inflammation.

toe, or as successfully as we do diseased ovaries, how many could thereby be given relief and years of restored health!

Though this growth is apparently so fearful in its appearance, so destructive to healthy structures, yet from it develops only an army of little blood-corpuscles and forming blood-vessels. But may not this, apparently so innocent a formation, have a serious pathological significance? Why should these autochthonous collections of blood be here, while there is pallor on the face, a tallowy hue to the skin, and an emaciation of the whole body?

This disease seems in some way to destroy such important formations as the ova. Yet in the early stages, before the disease has so much extended, in some instances women with this growth have borne children. A healthy ovum even in the midst of a sea of disease may develop and fulfill its final destination.

The clinical features in this disease are so marked that in many instances I have diagnosed it on the first examination, and this diagnosis was subsequently verified by microscopic examination of the diseased structure. All the patients complain of a special and characteristic pain in the region of the ovaries, at times severe, sharp, and lancinating; there is a peculiar pale or cachetic look, or the cadaveric pallor of the consumptive; they all have a marked emaciation. Some, who are naturally strong with a tendency to *embonpoint*, from the time of the development of the disease begin to emaciate; in some instances lose twenty, thirty, or forty pounds. The further advanced the disease, the more emaciated and the more extreme the pallor. The more the ovary is occupied or filled with this growth, the more serious the manifestations in the system. So pronounced are these symptoms, and especially in connection with the characteristic manifestations that usually accompany diseased ovaries, that a diagnosis can usually and with confidence be made. I have so verified it in many instances. Not long since I had two patients. Both had all the symptoms mentioned—pain, pallor, some loss of flesh, etc.; in both I diagnosed this disease, and subsequent history of the cases proved it to be correct. A young woman came to me last spring. She had always been in good health. No suffering in any way till the previous five or six years, when, as she remarked, she had at times such pain and distress that she rolled on the floor in agony, and was so faint and weak that she could keep up only two or three days successively. She had been under the care of good physicians, and had been in two hospitals. In one an operation was proposed; in the other she was pronounced incurable. I felt confident she had endothelioma of the ovary, and an operation would relieve her sufferings. She was anxious for the operation, and, as it was evident her condition was growing worse, it was right that she should be relieved. The operation was performed in the Woman's Hospital of Brooklyn. She made an excellent recovery. Fig. 3 is a representation of the ovary. The same form of degeneration spreads elsewhere in both ovaries. The patient had chronic oophoritis, and much of the normal structure of the ovaries was changed in consequence; the arteries were seriously affected with endarteritis obliterans, and some were waxy. The ova were diseased. In the tubes many of

the epithelia were destroyed or changed to muco-pus, and there was an inflammatory infiltration of the mucosa.

FIG. 3.—Left ovary with an endothelioma loosely imbedded in the cortex. The ovary is halved; so is the nodule on the right upper periphery. On the lower half is seen the cavity previously occupied by the nodule.  $\times 2$ .

A few weeks ago a patient came to my office who had been married fifteen years and had no children. At the age of sixteen she was well and rugged; when twenty years of age she began to have pain in the pelvis, to lose flesh, and looked as if she were going into decline; now, at the age of thirty-five, she is worn out with suffering, and I feel confident she has endothelioma of the ovary which is surely and prematurely destroying her life. On August 9th a lady called to see me complaining of similar pains in the pelvis; had the same pallor, not so much emaciation, though she says she has lost thirty pounds in flesh; has been married ten years, and had no children. Without doubt she has the same trouble of the ovary, which has produced the pain and destroyed the ova. By carefully considering all the symptoms the disease can be diagnosed in every instance.

The third patient in whom I found this peculiar growth was a Mrs. B., thirty years of age; came to me in March, 1887; the same story of suffering, distress, cramps, and extreme pain; not able to be around. Examination showed both ovaries enlarged, prolapsed, and extremely sensitive. Every motion of her body gave her distress, and she was entirely unable to attend to her household duties. Operation May 20th of the same year, in the Woman's Hospital of Brooklyn. Right ovary very much enlarged, pear-shaped, one end measuring two inches in diameter; the left ovary was less enlarged. The patient made an excellent recovery, and has now the physical vigor to carry on a large business, besides attending to her household duties.

Microscopical examination showed that both ovaries were entirely filled with this growth in an advanced stage of formation. The growth also formed the walls of some large cysts, and the ova, as far as examined, were diseased.

The fourth case of this form of degeneration was Miss C., single, twenty-eight years old, sent to me by Dr. B., of Bridgeport, Conn. The patient had been sick for more than a dozen years; had much suffering at her menstrual periods; had so broken down in constitution, and her general health was so enfeebled, that she was no longer able to attend to her ordinary

duties. Dr. B. writes "that everything possible had been done, and now evidently an operation was demanded." The patient was pale and emaciated. Her friends supposed she had consumption and that she was going into a decline. Examination showed that her lungs were sound and as strong as any part of her body, but that the ovaries were enlarged, dislocated, and exceedingly painful to the touch. She was admitted into the Woman's Hospital of Brooklyn. Further treatment gave her no relief, so an operation was deemed advisable, and, after consultation, was performed. The patient made an excellent recovery, and has since gained in health, strength, and flesh. She was able soon to resume her ordinary avocations, and she wrote me some months after: "It seems so strange to be free from pain"; said she "could not thank me sufficiently for all that was done; that before the operation she was the most miserable creature in the world; since, she was the happiest." She wrote June 14, 1889: "I am now in perfect health after fifteen years of suffering."

In this case also the entire ovary was filled with this remarkable and peculiar growth, except some little patches on the border, which were in a state of intense inflammation. No ova could be found. Near the periphery were some cysts, the walls of which were formed of this growth. This growth could be seen gradually invading and replacing every tissue. Some fields under the microscope looked like a sea of blood; near by were large blood-vessels clearly defined, with a well-marked endothelial lining and filled with blood-corpuscles.

CASE V.—Mrs. A., twenty-eight years old, married some years, no children, has pain in the pelvis all the time; ovaries and tubes extremely sensitive; marital relations so painful she can not endure them. She has suffered so much that she was anxious to have the operation. The ovaries were small, cirrhosed, not much larger than a bean, and covered with fine adhesions. All the ovarian structure was completely destroyed by the growth. The tubes were larger than the ovaries, and in a state of interstitial salpingitis. The patient seemed to do well.

CASE VI.—Mrs. II., forty-three years old. For some years her sufferings had been unusually severe, low down in the pelvis on both sides. At times the pain was agonizing; said she had not been able to perform any kind of labor. On September 9, 1887, I removed the diseased uterine appendages; they were in a mass of adhesions. The left tube was the size of a lemon; it, with the ovary, was firmly bound to the posterior part of the uterus. On the right the appendages were wedged down deep into the pelvic cavity. The ovary proved to have been transformed into a dermoid cyst. The tube was enlarged, firmly adherent, closed at the outer extremity, and all traces of the fimbriae gone. The patient made an excellent recovery, and while there were serious complications in this case, probably this growth in the ovaries caused most of the patient's suffering.

CASE VII was also complicated by a diseased condition of the Fallopian tubes. The patient was twenty years old, had suffered for some time with diseased ovaries, married three years and a half, two children; last parturition followed by some septic troubles. She came to me suffering with severe pain in the pelvis, unable to walk or to attend to her household duties. Examination showed deep transverse laceration of the cervix; perinæum gone; also there was serious disease of the uterine appendages; but, as she had so lately borne children, I decided to do nothing more than repair the cervix and the perinæum. She was admitted into the Woman's Hospital of Brooklyn, treated for some six weeks, injuries repaired successfully, and the patient sent home. After her return home she still complained of such constant distress and so much suffering that she begged to re-enter the hospital, and was admitted. The uterine appendages were in such an extremely diseased condition that there was no relief for her except by their removal, which

I did in August, 1887. On both sides the appendages were buried in a mass of adhesions. Each of the ovaries formed part of the wall of an abscess cavity; each tube was completely closed at the fimbriated extremity, and in a state of intense interstitial salpingitis. There were numerous miliary abscesses in the walls of each of the tubes.

The patient made an excellent recovery, and is now in the enjoyment of perfect health. Microscopical examination of the ovaries showed that almost the entire structure was replaced by this growth. The ova were ruined. Her irreparable sterility had already been produced by the condition of the tubes.

CASE VIII.—Mrs. G., thirty-five years old, feeble and emaciated, complaining of constant pain in the pelvis. Her pulse and temperature varied little from 100. Her friends thought she was going into consumption. Examination showed the uterus retroflexed at the internal os, ovaries enlarged, tender, and low down in Douglas's *cul-de-sac*. All efforts were made by constitutional and local treatment to improve her general health and strength and relieve her suffering, but the distress in the pelvis continued, and an operation seemed to be her only hope. She was not only anxious for the operation, but disappointed at any delay. I performed laparotomy on May 2, 1887. The whole broad ligament was like wet paper; it melted under the ligature, bled profusely, tore off even to the corner of the uterus, but all was properly secured, and the patient did well. She has since been a woman of remarkable strength and vigor, without indications of decline or consumption, has done the work for a family of eight persons, and looks remarkably well.

All the normal structure of the ovary was destroyed by this growth. The ova were in a retrograde condition, many of them filled with granular matter, the nuclei breaking up into medullary corpuscles.

CASE IX.—Mrs. R., a pale, feeble, emaciated woman of twenty-three years, married five years, two children, youngest three years of age, has constant pain in the lower part of the pelvis, especially severe during the menstrual period and five days before; evacuation of the bowels produces great pain; coition also extremely painful; uterus retroverted and retroflexed; ovaries prolapsed; pessaries had been used without any good results, only increasing her distress. She entered the Woman's Hospital of Brooklyn, and I performed laparotomy on October 24, 1887. The growth in the ovaries is represented by Fig. 4. In one ovary two large cysts were found, surrounded by layers of inflammatory tissue. The ova were diseased.

CASE X.—Mrs. M., also a delicate, emaciated woman, with apparent consumptive tendencies and such constant distress in the pelvis that life was a burden. She was not able to care for her family, neither could she submit to the marital relations. I performed laparotomy for her in April, 1887. She made a good recovery. Both ovaries were small and in a state of cirrhosis, and occupied by this growth; tubes in a state of slight interstitial salpingitis.

CASE XI.—Miss W., thirty-nine years of age, single, pale, feeble, and emaciated. She commenced to be sick when she was twenty-five years of age, and has continued to grow in worse conditions, the pain increasing in severity. Much of her time not able to be out of bed. She was for a while in the Massachusetts General Hospital, also under an eminent specialist of Boston. He informed her that her ovaries were diseased, but that an operation would be exceedingly dangerous on account of her debilitated condition. She was in the Woman's Hospital of Brooklyn during the summer of 1888, returned in the fall, and in November of that year I removed the diseased tubes and ovaries. She made an excellent recovery, and has told me since "she was so much better, and so glad that she had had the

operation." She spoke of once being "rosy and fleshy," and how her sickness had made her "thin and pale," but that "since the operation she was regaining her flesh and rosy complexion."

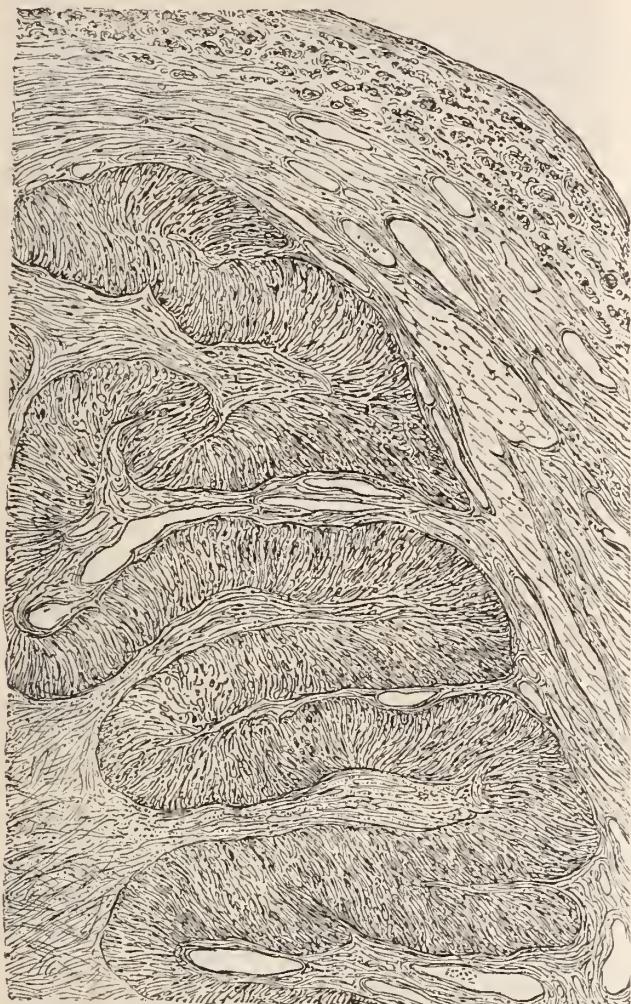

FIG. 4.—An endothelioma of the ovary approaching the surface.  $\times 250$ .

She also said that "before she went into the Woman's Hospital she had suffered so much she did not expect to live, but that now she was gaining health and strength."

The ovaries of this patient showed a most remarkable and well-advanced condition of this growth. The whole ovarian structure seemed to be replaced by it.

**CASE XII.**—Mrs. T., forty years of age, consulted me in August, 1888; was in feeble health, pale, and emaciated; suffered constant distress in the pelvis; ovaries extremely sensitive; uterus pulled to the right by shortening of the right broad ligament. Nine years previously she had consulted an eminent specialist of Philadelphia, who told her she had inflammation of the ovaries. Since then her sufferings had continued to increase and her condition to grow worse till her nervous system was broken down and in an extremely irritable condition. So cachetic was she in appearance that some imagined she had malignant disease. She informed me that she wanted to be relieved, even if it were necessary to perform an operation. She asked me that the ovaries might be removed. This operation I performed in October, 1888, and immediately she began to gain in health and strength, and in a few weeks showed very much improved conditions.

The right ovary was somewhat enlarged, and most of it occupied by a fibroid growth. Microscopical examination showed a number of nodular fibromata, also enlarged blood-vessels, many of them in a state of endarteritis obliterans.

The left ovary was cirrhotic, changed to cicatricial tissue, the outcome of chronic oophoritis. In some portions of the same ovary I discovered globular deposit of lime salts, and within them angular protoplasmic bodies, like bone corpuscles—osteoid tissue. The Fallopian tubes showed chronic inflammation and were atrophied. But the most remarkable feature was this growth, invading and taking possession of both ovaries. The ova were diseased.\*

*Microscopical Representations of the Growth.*—Fig. 4 represents the general appearance of the ovary in an advanced stage of development. Right ovary,  $\times 25$ . P, peritoneal layer. C, cortical layer, with numerous bundles of smooth muscles. V, fibrous connective tissue, in which the ovary has been transformed, freely supplied with capillary and venous blood-vessels. E, endothelioma of a markedly convoluted form, the depressions between which are filled outwardly with freely vascularized connective tissue, and inwardly by non-vascularized. F, coagulated fibrin. S, dense fibrous connective tissue, likewise exhibiting faint convolutions, and holding protoplasm in a reticular arrangement with pigment granules.

Here we see a narrow zone of the cortical substance of the ovary left, not exceeding in diameter one to two millimetres. The greater portion of the cortex is replaced by a convoluted tissue visible to the naked eye, being characterized by the presence of coarsely granular corpuscles arranged in a radiating direction and interrupted in many places by light gaps, which, on close examination, prove to be forming blood-vessels. A peculiarity of this formation is that it is bordered by a fibrous connective tissue on all sides. The difference, however, is that the connective tissue entering the depressions between the convolutions toward the surface of the ovary is richly supplied with blood-vessels, mostly capillary and venous in nature, while the connective tissue in the depressions looking toward the hilus lacks blood-vessels either entirely, or shows only a limited number, not exceeding the amount usually found in the cortical substance of the ovary. In many instances the spaces between the convolutions looking toward the hilus are filled with coagulated fibrin, and frequently coagulated fibrin fills all the space left between the convolutions and the hilus.

In another case, perhaps still more advanced, there is but little ovarian tissue left at the cortex, and the rest of the ovary is taken by a partly convoluted and partly irregular tissue, holding in its central portion numerous and large cavities, apparently filled with blood and fibrin. The growth seems to replace by degrees all the original structures of the ovary, transforming them into its own, and yet, in many instances, apparently not increasing the size of the ovary. In the most advanced stage of the disease, or in the highest degree of change, there may be no visible aug-

\* Microscopical specimens from these ovaries were presented to the New York Pathological Society, December 12, 1888.

mentation of the volume of the diseased ovary. Sometimes it is really diminished in size.

Toward the outer periphery of the convoluted tissue we not infrequently meet with patches of an extremely dense fibrous connective tissue, the bundles of which are separated by branching protoplasmic masses, often supplied with dark-brown pigment granules.

Solid masses of either hyaline or slightly fibrous structure are often met with in ovaries, and are usually considered as the remnants of menstrual follicles. Hyaline masses especially are considered to be remnants of the structureless or basement membrane of a bursted follicle, and are probably the product of a plastic or formative inflammation ensuing after the rupture of a menstrual follicle. Not infrequently such a dense convoluted wall surrounds a markedly myxomatous structure, as is represented in Fig. 5, a menstrual follicle at the boundary between cortex and medulla of an ovary affected with endothelioma in a high degree,  $\times 100$ . A, fibrous connective tissue, such as we see in the medulla of the ovary, with numerous convoluted arteries of varying

more clearly represented by high powers of the microscope, as in Fig. 6, a menstrual follicle at the boundary between cortex and medulla,  $\times 600$ . F, dense fibrous connective

FIG. 6.—A myxomatous menstrual body.  $\times 600$ .

FIG. 5.—A myxomatous menstrual body.  $\times 100$ .

sizes. V, vein. C, convoluted wall of a probable menstrual follicle surrounding a myxomatous structure. N, transition between a dense fibrous and a less dense myxomatous tissue.

Low powers of the microscope suffice to show that the convoluted wall of such a follicle is not uniformly dense throughout, but often exhibits transitional features from a dense fibrous to a less dense myxomatous tissue. The wall under these circumstances still shows an irregular protoplasmic reticulum, when the meshes are filled with fibrous basis substance. This tissue blends with ordinary myxomatous tissue in which the meshes are filled with a hyaline or slightly granular basis substance. These features are

tissue composed of coarse bundles between which are few nuclei left. B, transitional tissue between fibrous and myxomatous, made up of protoplasmic tracts with nuclei at the points of intersection, and holding in the meshes a less dense basis substance. M, myxomatous portion composed of nucleated tracts of protoplasm, the meshes being filled with a mucoid basis substance, in which delicate offshoots of the protoplasmic tracts produce a delicate reticulum. The center of the mesh usually holds a nucleus-like body, apparently suspended in the mucoid basis substance.

Here we observe changes in the morphology of the basis substance from a purely fibrous to a purely myxomatous tissue. As an additional feature in the myxomatous portion we often observe light- or dark-brown pigment granules imbedded in the protoplasmic tracts, which is another proof of these bodies being remnants of menstrual follicles.

I have described these formations because some of my specimens tend to prove that the follicular wall is the tissue in which occur the morbid changes under consideration. I have seen the transitional portion between fibrous and myxomatous basis substance becoming transformed into polyhedral medullary corpuscles, known by the term endothelia. By this term histologists designate corpuscles of the connective-tissue series, meaning a growth of the medullary corpuscles to such an extent that they flatten one another, and thus assume similarity with epithelia. In developing bone such bodies have long since been known by the term osteoblasts—that is, bodies ready to be trans-

formed into basis substance. Whenever bone tissue becomes inflamed, the reappearance of the osteoblasts is one of the first symptoms of osteitis. Judging from analogy, the tissue of the follicular wall may likewise return into its medullary or embryonal condition, and cause the reappearance of medullary corpuscles in the shape of endothelia. The convoluted figure of the follicular wall may explain the convolutions of endothelioma.

There may be another source, however, of the convoluted dense formations in the ovary, more especially at the boundary zone between the cortex and medulla, or in the medulla itself. This process is endarteritis obliterans. I simply allude to this by no means rare occurrence, which I propose to study up at some future time. We find convoluted masses of considerable length, and can trace their origin from previous arteries, which, as is well known, have a markedly tortuous course in the medulla of the ovary. See Fig. 7, a solid convoluted mass of fibrous tissue—the early stage of endothelioma.

In specimens of endothelioma I have often seen obliterated arteries, especially at the boundary zone between cortex and medulla, and in the medulla. The final result is not only a transformation of a pervious artery into a solid tract, apparently structureless, or made up of dense fibrous connective tissue, but sometimes broad convolutions arise from hyperplasia of the adventitial coat leading to the new formation of convoluted granular masses, in the centers of which remnants of the arteries are recognizable by a few muscular fibers left unchanged. No trace of caliber is rec-

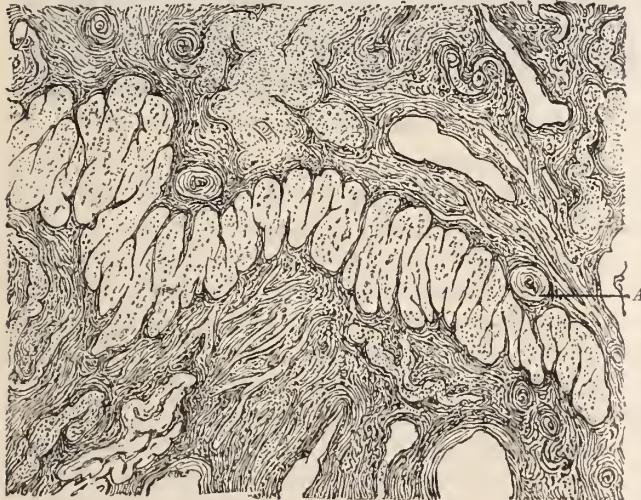

FIG. 7.—Convoluted fibrous tissue, the result of endarteritis obliterans.  $\times 100$ .  
A, a transverse section of a permeable, unchanged artery.

ognizable in such a remnant of an artery. This process may be another source of endothelioma, although I have not yet seen positive proof of a transition of such remnants into endothelial formations. On the other hand, endothelioma is often traversed by arteries exhibiting a marked condition of endarteritis.

The next question to be considered is, What are these coarsely granular corpuscles building up the formation under consideration? The nature of these bodies can best be seen in places where they are yet scanty and scattered in the fibrous connective tissue, as we often find in the vicinity

of well-developed endothelioma. Here we observe bodies of varying sizes between the bundles of fibrous connective tissue, distinctly flattening one another, whether they are present in groups or rows. See Fig. 8, hæmatoblasts changing to capillary blood-vessels, from a specimen of endothelioma

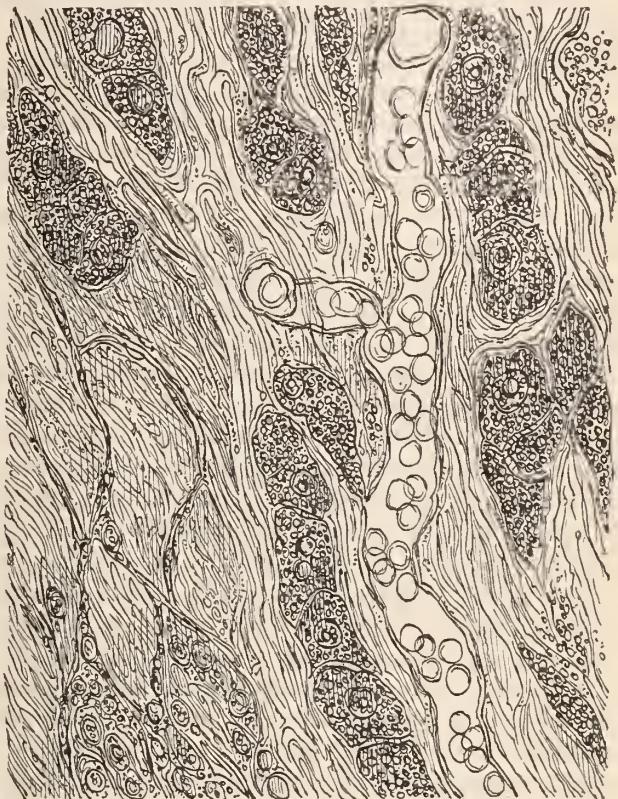

FIG. 8.—Hæmatoblasts changing to capillary blood-vessels.  $\times 600$ .

in the initial stage of formation. F, dense fibrous connective tissue, with a reticulum of protoplasm between the bundles, the bundles themselves partly transformed to lymph corpuscles. E, isolated and grouped endothelia. E', a bundle of fibrous connective tissue transformed into coarsely granular masses. C, capillary blood-vessels springing or developing from a row of coarsely granular bodies.

Bodies of this description are known since 1839, when Theodore Schwann described them as blood cells and, in his wonderfully acute power of observation, claimed that from them arose both the blood-corpuscles and the walls of the blood-vessels. Whenever an active new formation of blood and blood-vessels is going on, we invariably meet with such bodies. This is the case, for instance, whenever one tissue changes into another, when cartilage breaks up into medullary tissue preceding the formation of bone tissue, also at the border of the external epithelium of the enamel organ of the developing tooth, together with the active proliferation of the external epithelium thereof, and its transformation into medullary tissue. In 1872, pp. 100 and 341 of his "Microscopical Morphology," C. Heitzman described the same corpuscles as hæmatoblasts, claiming that every granule may eventually become a red blood-corpuscle, while the peripheral portions of the corpuscles, by fusion of hæmatoblastic substance, produce the walls of the blood-vessels. Since 1867 we have known, through the

studies of S. Stricker, that the capillaries originally are solid cords, which by vacuolation become hollowed out. Hayem (1877) discovered corpuscles in the blood smaller than red blood-corpuscles, and likewise termed them haematoblasts. Still later Ehrlich described coarsely granular bodies which were termed by him "Mastzellen," which means well-fed cells, which also proved to be either fat- or blood-forming elements.

In studying the coarsely granular corpuscles under consideration, we find a large number of homogeneous glistening granules and lumps within them, or scattered without being in the interior of sharply defined corpuscles, of a bright-yellow color, not taking up the stain of ammoniacal carmine. The close study of these granules shows their gradual change into red blood-corpuscles—a change easily traceable in almost any part of the specimen. There is no doubt we have before us haematoblasts in large numbers, either arranged in sharply circumscribed bodies or scattered in the fibrous connective tissue, from which in time red blood-corpuscles do originate. At the same time the peripheral portions of such coarsely granular bodies serve for the building up of the walls of blood-vessels, first of all of capillaries. Such newly formed capillaries have peculiarly fluted contours, reminding one of their origin from previous rows of coarsely granular bodies, and invariably contain a certain amount of red blood-corpuscles, or so called ghosts, apparently even before entering any communication with the vascular system. Not infrequently we see sprouts arising from the walls of such capillaries, either solid or filled with haematoblasts, or hollowed out, and being in connection with the main vessels by means of a comparatively narrow neck.

That the bodies filled with haematoblasts mainly serve for the new formation of blood-corpuscles and blood-vessels is easily demonstrated on any marked formation of endothelioma with high powers of the microscope. See Fig. 9, Ridger.

FIG. 9.—An endothelioma in full development, showing the change of endothelia into capillary blood-vessels.  $\times 600$ .

F, fibrous connective tissue at the border, showing the initial stage of formation of haematoblasts. E, endothelia more or less filled with haematoblasts. V, blood-vessels traversing the growth mainly in a radiating direction.

We observe radiating rows of polyhedral bodies which either contain a well-marked central nucleus, or, instead of this, one or several glistening lumps of a high refractive power. Between the bodies we can trace light narrow rims, usually traversed by delicate offshoots, obviously serving for an interconnection of the polyhedral bodies.

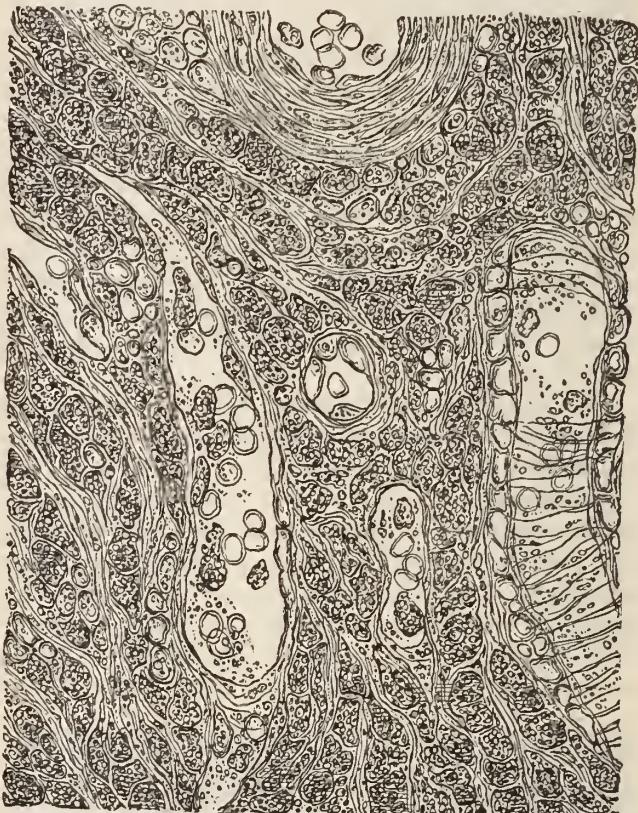

FIG. 10.—Endothelioma with a marked new formation of blood vessels.  $\times 300$ .

Ever since Bizzozero, of Turin, Italy, drew attention to the occurrence of endothelial growths strictly of a connective-tissue nature, the attention of the pathologist was drawn to tumors, holding a varying amount of such bodies, for which the name of endothelioma has been suggested. Further research has, however, revealed the fact that a tumor deserving the name of endothelioma does not exist. Endothelia, if grouped together in large masses, are either a prestage for the formation of a lipoma or an angioma.

In some instances I have been able to trace a large number of newly formed arteries at the periphery of an endothelioma, near the surface, where arteries, especially large arteries, do not occur in a normal ovary. The formation of arteries is represented in Fig. 10, an endothelioma with new formation of arteries, veins, and capillaries.

E, endothelia of comparatively small size filled with haematoblasts. L, lymph corpuscles in clusters. A, artery in transverse section. A<sup>1</sup>, artery in longitudinal section. V, sinuous veins holding haematoblasts and red blood-corpuscles.

The development of veins goes on the same plan as that of capillaries, the only difference being the large caliber and sinuous or bay-like cavities along their course. The wall of such veins is made up of endothelia seen in edge view, or the wall appears to be continuous or homogeneous.

The arteries develop on the same plan with the addition of smooth muscle fibers around the wall. Whenever arteries are newly formed, we invariably find in their neighborhood clusters of lymph-corpuscles — viz.: medullary corpuscles more or less homogeneous, lacking nuclei, and not transformed into medullary corpuscles filled with haemato blasts. So far as I could trace the formation of arteries, I am convinced that the muscle fibers arise from the previous lymph-corpuscles in a manner described by Dr. Jeanette B. Green in her studies on the decidua.

Hæmatoma of the ovary is considered usually as an extravasation of blood into an ovarian cyst, in many instances giving very little disturbance to the system.

Endothelioma, on the contrary, leads to and terminates in a collection of blood by a change of tissue or a new formation, and seems to be of profound pathological importance, as it not only destroys the anatomical structure of the organ and consequently its physiological functions, but disturbs seriously, and in some instances destroys the health and comfort of the individual.

## TWO CASES OF LARYNGEAL PARALYSIS, WITH A CONSIDERATION OF THE POINTS INVOLVED.

BY JONATHAN WRIGHT, M. D.,  
BROOKLYN.

THE peruser of recent medical literature, especially in the domain of laryngology, must often be struck with the divergence of views and the discrepancies of statement in works on laryngeal paralysis. There is an undoubted tendency toward bewilderment of mind the more one reads and studies the various experiments to settle the nerve supply and the *modus operandi* of the dilators and closers of the glottis with the complicated interrelation of the various contributory muscles. The laryngologist himself, if his experience is large, must from time to time see certain laryngeal paralyses whose aetiology, after the most exhaustive local and general examination, is a mystery. All other muscular groups are normal, and the patient may otherwise be in good health. Ascribing them to some pre-existing laryngitis or to rheumatism or gout is far from satisfactory without an explanation of how these very common affections, in particular cases, can bring about such results. It has been the lot of the writer to see several such cases when the most careful local inspection and the most painstaking physical examination of the chest failed to disclose the cause. In most of these cases (all, I think) the immobile vocal cord was in the median line. The chagrin which they have caused has led me to study the two cases presented in this paper with more interest than they would have otherwise excited. They, of course, do not belong to the group of puzzling cases just mentioned:

*CASE I. Left Lingual and Laryngeal Paralysis; Atrophy of the Left Side of the Tongue.*—G. K., aged twenty-nine, a German shoemaker, came to the throat department of the Roosevelt Hospital on July 20, 1887. His family history is good. He had typhoid fever when twelve years old; otherwise he has never been sick, though always delicate as a child. He

is a moderate drinker of malt liquors. Nine years ago the patient had gonorrhœa and a chancre. He took medicine only four weeks, and had no secondary symptoms nor any trouble attributable to syphilis until four years ago. At that time he began to feel quite weak, but could go on with his work. He states that at that time he was treated for syphilis, but since then has never felt entirely well.

The weak feelings continue and he suffers often from pain in the back of the head and neck, which occasionally extends to the vertex. Last January (1887) he began feeling very much weaker, and noticed that he reeled to the left side when walking in the dark, and felt dizzy. He says his arms and legs felt as though asleep. These symptoms have grown gradually worse. Five weeks ago he suddenly noticed an impediment in his speech. He also began to swallow with difficulty, though he seems undecided as to the time at which this began. He says that when he drinks, the fluids come out of his nose. The patient has a cachectic appearance. His voice is nasal in tone, and he articulates indistinctly. His mental faculties seem normal. There is a slight paresis of the left side of the face, noticeable both in quiescence and when attempting to smile. He can, however, whistle fairly well. His general muscular power seems to be much less than one would expect from his appearance. When he closes his eyes and attempts to walk he falls to the left. On protruding the tongue it is seen to deviate markedly to the left side. There is considerable atrophy of the left side of it, apparent to the eye and appreciated by the finger.\* No loss of taste or of tactile sense can be made out. There is no sensory paralysis anywhere. The left palatine arch is completely paralyzed. On laryngoscopic examination, the left vocal cord is seen immovably fixed in the median line. It seems loose and the edge rises slightly with expiration. The right vocal cord overrides it somewhat on phonation.† The cords are both congested. There is abundant muco-purulent secretion on the left side of the naso-pharynx and in the left nostril. There is no sterno-mastoid or trapezius paralysis.

Dr. T. T. Janeway, of this city, kindly made an examination of the patient's vision and of his hearing with the following results:

R. V.,  $\frac{2}{10}$ ; with  $\frac{1}{5} = \frac{2}{5}$ . L. V.,  $\frac{2}{20}$ ; with  $\frac{1}{5} = \frac{2}{5}$ . Ophthalm.: R.  $\frac{1}{5}$ , L.  $\frac{1}{5}$ .

H. D. R. W. = 18". H. D. L. W. = 1". After inflation, H. D. R. W. = 18". H. D. L. W. = C.

Aerial sound conduction better in both ears than bone.

Aerial and bone conduction both more reduced in left than in right ear. Tuning-fork in median line heard better in the right ear.

T. F. R., aerial, 19"; bone, 8". L., aerial, 4"; bone, 3". After inflation no improvement.

*Urinary Examination.*—Negative. No sugar. There is no appreciable lung lesion.

*Treatment.*—The patient was put on large doses of the iodide of potassium. The limit of tolerance seemed to be about half an ounce daily. During intermissions and along with it were given from time to time arsenic and the syrup of the iodide of iron.

The patient was under observation for about a year. Shortly after his first presentation he had three attacks of inspiratory dyspnoea, probably each time from food or drink dropping into the larynx. He also had a quite severe attack from an application of the solution of the chloride of iron to the congested

\* The appearance was similar to the case represented in the "Berl. klin. Woch.", No. 29, 1887, reported by Pel.

† I give here the usual appearance. At times I was in doubt as to these minor appearances which are nevertheless so important.

vocal cords with a brush. At the end of a year, when he passed out of observation, there was the following change in his condition:

The dizziness and reeling to the left ceased soon after the commencement of the iodide treatment. The difficulty in swallowing was also soon overcome entirely. His articulation became distinct, though his voice was husky at times. The slight facial paresis disappeared. There was partial though not complete relief from the palate paralysis. His general muscular weakness was relieved so that he could resume work. There was no improvement in the lingual atrophy and paralysis, and no change in the laryngeal condition.

A second examination was made by Dr. Janeway four months after the first, with these results:

Eyes: R. V.,  $\frac{2}{10}$ ; with  $\frac{1}{6} = \frac{2}{5}$ . L. V.,  $\frac{2}{10}$ ; with  $\frac{1}{6} = \frac{2}{5}$ .  
Ears: H. D. R. W. 12". H. D. L. W. 4".

Aerial conduction better in both than bone.

Bone conduction better in the right than the left.

Tuning-fork gave increase in duration both of bone and aerial conduction, the record being R., aerial, 25"; bone, 10". L., aerial, 17"; bone, 9". No improvement after inflation.

**CASE II. Left Laryngeal and Sterno-mastoid and Trapezius Paralysis.**—M. M., aged twenty-seven, a married woman and a native of Ireland, came to the Dennet Dispensary April 17, 1888. Her mother died of bronchitis (?); one sister died of consumption.

The patient is an exceedingly nervous and excitable person of limited intelligence. When a child she had lumps in her neck which disappeared later. Four years ago the patient "got a wetting." Since then she has not been unwell and has had "the whites." Aleoholic and specific histories are denied. Two years ago her voice began to be husky at times and she had occasional "choking fits." There was no cough at that time. Six weeks ago the patient began to cough and raise a little blood. She had pain in her back and her leucorrhœa increased. She became short of breath and began to have night-sweats with chilly feelings, followed in the afternoon by fever. Her appetite is poor. She has lost flesh and strength.

**Examination.**—Her general appearance is fairly good. The circulation in her extremities is poor. Her voice is exceedingly husky. At the apex of the left lung in front there is dullness on percussion, crepitant and subcrepitant râles, increased vocal fremitus, and roughened breathing. There is great tenderness to pressure and percussion over this area, which extends downward to the upper border of the third rib. Posteriorly the signs are not so marked. There is no other pulmonary change. There are no cardiac or aneurysmal indications.

Her voice is unsteady, at times clear, but usually somewhat husky.

The laryngoscope shows the left vocal cord and arytenoid cartilage immovable in the median line. The cord itself is congested and lax, and there is general laryngeal congestion, but no swelling or infiltration. The right cord moves spasmodically. There is no palate or facial paralysis. There is decided paresis of the upper portions of the left trapezius muscle and almost total paralysis of the left sterno-cleido-mastoid, but no restriction of the movements of the head.

It will be noticed in this history that the symptoms referable to the laryngeal paralysis antedated those assignable to the lung lesion about two years. The case when last seen was running the ordinary course of phthisis in the first stages, with no change in the laryngeal symptoms.

Now, in these two cases we have several points of great interest because of the doubts in which they are involved:

1. The peripheral manifestations of a central or nerve lesion.

a. The median position of the affected vocal cords.

b. The concomitant lingual paralysis and atrophy in one case and the paresis of the sterno-mastoid and trapezius muscles in the other, with other symptoms.

2. The character and situation of the lesions, whether in the cerebral cortex, the medulla oblongata, or at some point of the nerve trunks supplying the various muscles.

In order to make the conclusions arrived at clearer, it will be well to review, as briefly as possible, the literature of the subject bearing upon the salient points, and in the order named. Of course, it must be understood that nothing like completeness is intended or aimed at; that would be tiresome and useless.

We need not go back to Galen or even to Albers in prelaryngoscopic days, but all the information of use is to be found in literature since 1860.

It will be noted that the term laryngeal paralysis is applied to these cases. This is for convenience rather than for exactitude of nomenclature. Until recently median position of the vocal cords was generally supposed to be due to paralysis of the crico-arytenoidæi-posticæ muscles.

As late as 1880 such an authority as Störk (1) said that paralysis of the posticæ was one of the rarest of laryngeal neuroses. A year later Semon (2) showed conclusively that it was by far the most frequent of all partial laryngeal paralyses. Almost simultaneously with the introduction of the laryngoscope into medicine we find an account of a case of median paralysis of one vocal cord. Lewin (3) gave, in 1860, a wonderfully good description of "paresis of the muscle of the right arytenoid cartilage which narrows the glottis and does not produce hoarseness," in a patient suffering from constitutional syphilis. In the same year Türek (4) described a case of right hemiplegia with immobility of the left vocal cord, which was displaced to the right of the median line. Three years later Gerhardt (5), who is usually credited with reporting the first cases, published his classical work on "Laryngeal Paralysis," with what appears to be the first account of the laryngoscopic appearances of a case of *double "posticus paralysis."* He reported eighteen cases of laryngeal paralysis in all, and in regard to a cerebral laryngeal center contents himself with saying: "Physiological data do not go far here. The superior roots of the accessorius, like the neighboring vagus, can be traced to the gray mass on the floor of the fourth ventricle." Many cases were afterward reported, and many theories advanced to account for them.

Bäumler (6) and Johnson (7), in 1872 and 1873, and later McCall Anderson (8) and Whipham (9), reported cases of bilateral paralysis of the vocal cords, some of them in the median position, which were due to pressure on one vagus nerve alone. Johnson (10), in another and a very able paper, explained this phenomenon on the strength of the researches of Rosenthal and Waller and Prevost, which were repeated by Professor Rutherford at Johnson's instance. Pressure on the trunk of the vagus may cause bilateral spasm or bilateral palsy, or spasm of one and palsy of the other side of the larynx, by reflex action due to the

decussation of the nerve fibers in the medulla, since the vagus is made up of both afferent and efferent nerve fibers, while pressure on the recurrent alone can only cause paralysis of the affected side. This he believed to be the cause of many cases of sudden dyspnœa in thoracic aneurysm. Finally he says: "It is probable that the long-continued irritation of the trunk of the vagus may gradually, as in the cases of traumatic tetanus, induce such demonstrable structural changes in the nerve center as will explain the bilateral palsy, which appears to be one of the results of this chronic nerve irritation." We see here a foreshadowing of part of what Krause years later announced as the results of his investigations. Indeed this article, as pointed out by Semon, has not received the attention and consideration it deserves in the history of laryngeal neurosis. Cohen's (11) recent remarkable clinical observation of the stimulation of the peripheral sensitive distribution of the pneumogastric in the larynx, causing temporary relief to a flagging respiration, is in line with this early work of Johnson.

Rosenbach (12), in 1880, called attention to the greater frequency of abductor paralysis, and Semon still further emphasized the point, showing that adductor paralysis from a central or nerve lesion was almost unknown.\* Since then their respective claims to priority on this point have been urged with a persistence and an industry worthy of a better cause and of a more important subject. Various explanations of this preponderance have been advanced. Rosenbach said that "in the inspiratory closing of the glottis following a paralysis of the dilators there is not primarily a spasm of their antagonists, but a rhythmical perverse innervation in one direction only—namely, toward the adductors." This sentence has been widely quoted, probably on account of the obscurity of its meaning. It is needless to say that it has no experimental proof to stand on, and, if I understand it rightly, can necessarily have none, but must always remain a theory. Semon supposed the adductor and abductor filaments existed separately in the recurrent nerve, and advanced three hypotheses to account for the median position of the cords.

1. The abductor nerve fibers may be peripheral, and hence more exposed to external injury.

2. There may be a specific vulnerability of the abductor filaments, or when adductor fibers are partially disabled the other adductor fibers are able to carry all the adductor stimulus.

3. Possibly the nerve fibers receive an increment of nerve force from the superior laryngeal.

McKenzie (13) and Riegel (14) were inclined to accept the first supposition, the former suggesting that the nerve fibers were peripheral, the latter that they were together at one side. Semon himself leaned to the probability of the second hypothesis. It certainly seems to me that claiming a "specific vulnerability" is begging the question and is as unintelligible as Rosenbach's "perverse innervation." It leaves the problem, Why are the abductor filaments singled out for injury? unanswered.

\* It should be remembered that in *complete* one-sided paralysis of the larynx the vocal cord is in the eadaveric position of Ziemssen, or half way between adduction and abduction.

The third hypothesis has received some support from the investigations of Mandelstamm (15) and Exner (16), and in Lennox Browne (17) it has a prominent though not an unreserved supporter. Many years ago Weir Mitchell, as quoted by Johnson, showed that the movements of the glottis in the turtle are due to two sets of muscles, the openers and the closers. The superior laryngeal nerve supplies both, while the inferior supplies only the openers. The superior laryngeal nerves were found to decussate at the base of the brain like the optic chiasm. The superior and inferior laryngeal nerves were separate throughout their course. If all nerves were cut but one superior laryngeal, the larynx movements would still obtain. Schech (18) and Schmidt (19) separately, in 1873, did much to formulate the arrangement of laryngeal innervation and muscular movement given by the text-books and accepted up to a recent date. According to the investigations of Exner and Mandelstamm, the thyro-arytenoid muscle in its internal division receives its innervation almost exclusively from the superior laryngeal through a branch from its pharyngeal division, which they call the middle laryngeal. This muscle is a straightener and tensor of the vocal cord, and is supplied by both nerves on each side equally. The crico-thyroid muscle is also supplied by the superior laryngeal nerve of both sides equally, while the recurrent probably furnishes some fibers also.\*

"The interarytenoid muscle apparently is supplied equally on the two sides by both the inferior and superior laryngeal nerves. It is probable that the other muscles, including the posticus, receive their principal nerve supply from the inferior laryngeal, though some of it from the superior laryngeal. Often the fibers of the superior laryngeal reach over to the other side posteriorly." Some arrangement of this kind was suspected twenty years ago by Türck (*loc. cit.*, p. 440). It has been urged that this arrangement does not in itself explain those cases where there is a bilateral median position with a central lesion, or a lesion in the vagus above the superior laryngeal. Neither does it explain the cases of Baümler and Johnson, nor why section of the recurrent causes total paralysis.

This brings us to a consideration of the theory of a spasmotic action of all the laryngeal muscles, or at least the principal ones.

Although Jeleneff states (*loc. cit.*) that he announced in 1872 that the condition was due to spasm from irritation and not to paralysis, and although the same was hinted at by Johnson, as we have seen, the credit of demonstrating and emphasizing the fact by experiments on animals belongs to Krause (21). The conclusion he arrived at as a result of his very careful experiments was, in a few words, as follows: The irritation of pressure or disease, either along the nerve trunks or in the nerve centers themselves, causes a spasm of all the laryngeal muscles, and the adductor

\* I have now a case under observation in which there was apparently a paralysis of the thyro-arytenoid muscles with a paresis of the crico-thyroid and interarytenoid muscles on both sides. Besides the elliptical opening in the glottis on adduction, the cords had the peculiar rounded outline described by Störk. This latter soon disappeared, but the laxness of the cords still obtains. This condition supervened on the pharyngeal inflammation caused by swallowing carbolic acid. The patient is gradually recovering her voice.

muscles—resembling the flexor muscles of the extremities, to which they have been repeatedly compared—having the greater power, cause the vocal cord of the affected side to assume the median or adducted position. This position may be permanent or it may continue a shorter or longer time, and then, from the progress of the disease and a destruction of the nervous elements, change to one of complete paralysis, when the cords assume the cadaveric position. Of course this is a very crude statement of Krause's very elaborate article, to which reference must be made for the full force of the argument. It may be said here that complete adductor paralysis from a nerve or central lesion is almost or quite unknown, though some good observers have confessed their inability to invariably distinguish between the cadaveric position and complete abduction. Adductor paralysis, usually bilateral, is the rule in the hysterical form, which is never permanent.\*

That Krause's conclusions have been subjected to many and very weighty criticisms can not be denied. His opponents, until lately, if not still, are in the majority, but Jeleneff's work, unless refuted by future investigations, must eventually establish the reality of Krause's conclusions, at least in the main. The former states—and his demonstrations are singularly convincing, at least to the writer—that not only is the crico-arytenoideus posticus an antagonist to the lateralis in its adducting power, but beyond a certain point is in some of its fibers a synergist. It also tends to fix the arytenoid cartilage on the cricoid, and prevents the vocal process from being depressed by the contraction of the lower fibers of the lateralis. By its counteraction it helps the thyreo-arytenoid and the crico-thyroid muscles to stretch and straighten the vocal bands. It assists the interarytenoideus also to approximate the arytenoid cartilages. The original article† must be consulted for an explanation of this somewhat complicated and yet, according to Jeleneff's demonstration, very obvious function of the posticus. Krause does not deny the possibility of the occurrence of posticus paralysis, but a little reflection will convince those who have seen many cases of the permanent median position of the cords that it must be a rare one if the above view of the action of the posticus is a correct one. Dr. Solis-Cohen (*loc. cit.*) seems to have adopted Krause's views at least as explaining the cases where there is lesion of the recurrents.

In 1885 Hooper (22) noticed in the dog that there was forcible abduction of the vocal cord from galvanic stimulation of the corresponding recurrent nerve when the animal was very profoundly anaesthetized, and adduction at other times. Krause noticed something of the same phenomenon. The former, therefore, said that the abductors belong to

organic life, and denied their proclivity to paralysis. Donaldson (23) in the following year said it was only on weak stimulation that the cords were abducted, and that the abduction was not due to the etherization; but he also denied the greater proclivity of the abductors to paralysis. Seimon and Horsley (24), while denying strenuously the validity of Krause's views, confirmed the statements of Hooper in regard to deep etherization, as well as those of Donaldson in regard to weak stimulation of the recurrents, but showed that, in repeating Hooper's experiments, Donaldson did not carry the narcosis far enough.

These authors also stated that in excision of the larynx in the living animal the postici muscles lose their contractility before the other muscles, but Jeleneff (*loc. cit.*) has shown that this is due to their smaller size and their more exposed condition. While the writer is inclined to accept Krause's views in the main, there are some points which are not explained and some which seem to controvert them. When Remak (25) reported his case of lingual and sternomastoid paralysis with immobility of the right vocal cord, from injury to the nerves at the base of the skull, Fraenkel (26) seemed to think that this settled the question, reasoning that because there was paralysis of other muscles, there could not be spasm of the laryngeal group, but the posticus must be paralyzed. Without at all detracting from the force of this objection, which is open to much more serious criticism, it might be said that the history of laryngeal paralyses abounds in such examples, and the case of Remak is not unique. Case II, recorded here, is such an example. Fraenkel (27) himself has elsewhere advanced an objection that appeared much more vital to the spasm theory. It can not be denied that even in the cases where the lesion is central, and hence including the bulbar origin of the superior laryngeal nerve fibers, the vocal cord, although in the median position, is often, if not usually, lax during respiration, and occasionally is made tense only during phonation. It was difficult to see how this could occur during spasm of all the laryngeal muscles.

Jeleneff's article explains how it is that after atrophy due to the continued spasm we obtain a condition which is practically a paralysis of the posticus and thus allows a laxness of the cord to occur from the non-fixation of the arytenoid cartilage and the lack of counteraction to the cricothyroideus and thyreo-arytænoideus internus muscles.

Nevertheless, the objections to the spasm theory are less numerous and weighty than those of paralysis of the posticus alone, since it is supplied by the same nerve as most of the other muscles. This supposition is unsupported by experimental proof, and many well-established facts seem utterly irreconcileable with it. But argument is of little use. Clinical observation can only serve to keep alive the interest in the subject. Physiological experiment and anatomical research, repeated and varied, are the only methods by which the problem will be solved.

The concomitant lingual paralysis and atrophy in Case I is of only contributory interest to us. Although Fairlie Clarke (28), in reporting a case in 1871, declared that he was unable to find any case of lingual atrophy reported in literature, there is at least one by Dupuytren as long ago as 1832

\* I have seen one case in which what was without doubt hysterical closure of the glottis was so persistent and caused such extreme inspiratory dyspnoea that tracheotomy with artificial respiration for half an hour were necessary to save the patient's life. Lately, after the lapse of six years, I have seen the patient, who wore the tube for many months. She still has occasional attacks of typical hysterical aphonia with an increase in other hysterical manifestations, but she has had no return of the nearly fatal dyspnoea.

† See for résumé "N. Y. Med. Journal," Aug. 31, 1889.

referred to by Lendet (29), while Lande (30) in 1870 reported five cases. Since then, and indeed before, many cases have been reported by the French writers.

The other symptoms need only be referred to in speaking of the location of the lesions. In Case II the shoulder paralysis would indicate, as in Remak's case, that we have to do with a lesion of the vagus and accessory immediately after their exit from the skull. This is still further suggested by the history of glandular enlargement in the neck and by the fact that the phthisis of the left pulmonary apex began two years after the laryngeal affection. Moreover, the "choking fits" or "laryngeal crises" to which the patient had been subject, and the spasmody action of the right vocal cord, point to an irritation of the vagus, as in the cases of Bäumler and others mentioned. It is reasonable to suppose that there was pressure exerted by some enlarged cervical gland, although none could be distinguished upon examination.

In Case I, the lesion being evidently an intracranial one, we have two possible locations—a cortical and a bulbar.

The question of a cortical laryngeal center has been the subject of some interesting pathological and physiological investigations. Lewin (31), in 1874, examined a case with left hemiplegia and made out immobility of the left vocal cord in the middle line. There was no autopsy. So scanty are the data upon which to base a reliable localization of a laryngeal center in the cerebral cortex from pathological evidence, that the laryngoscopic appearance of every ease of hemiplegia should be recorded for future reference on autopsy. Seguin's (32) cases which were reported in 1877 tended to show that the lower part of the third frontal convolution of the left side, especially in right-handed people, was the seat not only of speech, but of laryngeal movements. This, however, was far from conclusive, as no laryngoscopic examination was made. Indeed, until very recently, either the laryngoscopic or the post-mortem appearance of these supposed cortical lesions has been lacking in each case. Indeed, the ease of Garel (33), so far as I know, is the only one in which, with a cortical lesion found at autopsy, there had been in life a laryngeal neurosis noted. There was in his ease right hemiplegia with aphasia, and the left vocal cord was paralyzed, thus resembling the ease reported by Türek many years ago and referred to above. Here, however, an autopsy was subsequently obtained, and, besides the ordinary hemorrhagic lesion on the left side of the brain, there was a localized area of softening in the inferior part of the third frontal convolution on the right side. The report is meager in details and no account is given of the microscopic condition of the medulla. Dr. Delavan (34), in a recent paper published in this Journal, sums up the general testimony on this point in cerebral localization:

"1. Unilateral irritation of a given cortical center excites the corresponding bulbar center and causes bilateral movement.

"2. Unilateral destruction of a given cortical center gives no result, as the influence of the opposite cortical center is sufficient to excite the corresponding bulbar center, and thus to cause bilateral movement.

"3. Bilateral destruction of a given cortical center causes paralysis."

Now, from this standpoint we must conclude that there was a corresponding lesion of the same spot on the opposite side. If so, why was there not bilateral paralysis? A lesion on the left side of the medulla, which, without a microscopic examination, might have been overlooked, would be what we should expect. Garel, however, had a physiological basis on which to stand, and this possibly may have caused him to be a little hasty in his conclusions. Krause (35), in 1884, announced his experiments on the brains of dogs. He demonstrated that in these animals there was a center for the laryngeal adductors in the gyrus praefrontalis, the third frontal or Broca's convolution, near its anterior and descending end. In the neighborhood were also areas for the muscles of deglutition and of the neck. The channel of communication from this region to the medulla is probably through the corpus mamillare. These statements have been confirmed by Semon and Horsley (quoted by Delavan, *loc. cit.*). The electrical stimulation of this cortical area causes different laryngeal muscular actions in different animals—adduction in the monkey and dog, abduction in the cat. Dr. Delavan in the same year (1884) read a paper (36) before the International Congress, at Copenhagen, on a cortical localization of a laryngeal center, based on a ease very much resembling Case I of this paper. This case on autopsy, however, showed the causative lesion to be in the medulla. Gottstein, in the last edition of his work on the throat (p. 302), in referring to the ease, pointed out what afterward proved to be the correct situation of the lesion.

There are a sufficient number of carefully reported cases, as well as physiological data, on which to base a diagnosis of and locate a lesion in the medulla oblongata. Hughlings Jackson (37), in reporting some such cases in 1864, which were also seen by Mackenzie (*loc. cit.*), asks the question which now confronts us, "Where is the disease which suddenly produces together paralysis of the tongue, palate, and vocal cord, all on one side?"

His answer was more unsatisfactory than ours should be to-day, for since then a great deal has been done to supplement the work of Claude Bernard, Lockhart Clarke, and others.

Beginning at the widest part of the floor of the fourth ventricle, where the posterior border of the pons Varolii crosses it, we find an irregular mass of gray matter extending backward and downward to the posterior end of this lozenge-shaped space, where it becomes continuous with the gray matter of the spinal cord. Here, from before backward, the root fibers of the facial, acoustic, glosso-pharyngeal, pneumogastric, and the upper roots of the spinal accessory have their origin. This is not only a motor, but a sensitive tract. The latter, known as the sensitive or ventral nucleus of the vagus, is deeper and a little higher than the dorsal or motor nucleus, though they are continuous with one another. The nucleus of the hypoglossus nerve is nearer the median furrow and parallel with the tract of the other. A careful comparison of Case I, with the symptoms noted and the lesions found in the cases of Senator (38) and Eisenlohr (39)

and Delavan (*loc. cit.*), as well as with others, helps us to a diagnosis and location by pathological evidence. It is probable that the lesion was most extended toward the lower and in the superficial parts of the mass on the floor of the fourth ventricle, where it would involve the nucleus of the hypoglossus and the motor nucleus of the vagus, leaving the sensitive tract unininvaded, since there was no sensory paralysis of any kind noted. It must have extended upward along the median furrow on the left side, involving the nucleus of the acousticus and slightly the facial to account for the facial paresis, the marked diminution of hearing on the left side, and the palate paralysis. The deafness, the difficulty of swallowing, and the tendency to fall to the left we saw improve under treatment. The lingual and laryngeal paralysis remained unchanged, as it usually does. To account for the giddiness, we have either to imagine that it was due to the involvement of the acousticus or to some interference with the blood-supply of the cerebellum. When we come to consider the cause and the nature of the lesion, it is probable, in view of the specific history and the result of treatment, that the patient had areas of softening and congestion due to disease of the coats of the left vertebral artery or its branches, the posterior spinal and the inferior cerebellar. The iodide of potassium relieved the areas where actual tissue necrosis had not taken place, and produced some amelioration of the symptoms, while further improvement could not be expected. It is a singular fact, noticed by Elsberg (40), that, although other muscular groups may recover with varying rapidity and completeness from paralysis, the power of the laryngeal muscles rarely returns. This may be due to the rapidity with which they atrophy on account of their small size.

## THE USE OF ALCOHOL IN MEDICINE.\*

BY J. M. FARRINGTON, M. D.,  
BINGHAMTON, N. Y.

THE subject of this paper is probably the oldest and most conspicuous article that has a place in the history of medicine. We read of it early both in sacred and secular history, not so much as a remedy in the treatment of disease, but as a beverage that, from those early periods of the world's history down all along these ages to the present time, has had more influence in the events chronicled by historians than have any or possibly all other causes combined. Noah planted a vineyard, and got drunk from his home-made wine and notoriously disgraced himself. Alexander the Great, the most illustrious general the world ever saw, died a delirious sot at the age of thirty-three. The wine indulged in by kings, statesmen, and generals has been productive of many wars that have cost millions of lives and the destruction of untold treasures, and have changed the boundaries of many of the nations of our world. In the domain of private and social life its power has been no less marked. The effects of alcohol upon the physical, mental, and moral powers of man are beyond estimation or computation. The flood-tide of evils that flow from its use has long been recognized and acknowledged by every unprejudiced observer. In fact, alcohol is to-day the greatest power known to the world that is constantly operating to dethrone reason, shatter the physical system, and bring on moral and financial ruin. The amount of alcohol consumed by the civilized nations of the world is almost beyond computation, and the avarice of man is introducing it into heathen and barbarous regions as rapidly as commerce and the work

\* Read before the Medical Society of the County of Broome, N. Y., April 2, 1889.

of explorers will permit. It has grown to be such an important article of commerce that its manufacturers and dealers are now an important factor in the political and law-making power of not only our commonwealth, but of every nation under the sun. The liquor oligarchy are dictators in many matters of political policy.

Thus much as a brief introduction to the power and influence of the subject of this essay. As conservators of the lives of our fellow-men, it behooves us to most seriously consider an agent capable of producing such devastating results before we "unchain the tiger," who, when once upon his victim, may never relinquish his grasp until all that is pure and noble, all that is wise and good, all that is lovely and desirable, has been drained from our brother-man, leaving only a bloated carcass and a curse, whose friends painfully endure until death comes to rid them of the living shame, when his poor, debased body has been buried from their sight, and their hearts are torn by the solemn thought that "no drunkard can inherit the kingdom of heaven."

Before beginning this paper I most carefully read the views of those authors who furnish the text-books on materia medica and therapeutics for the medical students of today, and then I did not wonder why it was that alcohol still held such a sway in our profession and among the laity, who naturally look to us as authority in this matter of the value of alcohol. For one, who has witnessed the action of this agent on the human system for thirty-two years in the practice of medicine, I earnestly protest against the teachings of most of our recognized authorities on this subject; to me their language and inferences are more befitting circulars issued by liquor dealers and manufacturers to advertise and recommend the great value of their products to enfeebled and diseased humanity. I quote first from Bartholow: "Alcohol is a useful food in the small quantity which increases but does not impair digestion, which quickens the circulation and gland secretion, but does not overstimulate, and which is within the limit of the power of the organism to dispose of by the oxidation processes." Oh, how habitual and so-called "moderate drinkers" will applaud this language, and how grateful perhaps we ought to be that there is one so wise as to state just how much and how often we should use this valuable and health-giving medicine! Hear our author still further: "This amount has been pretty accurately shown," says Bartholow, "to be one ounce to one ounce and a half of absolute alcohol for a healthy adult in twenty-four hours. All excess is injurious. . . . It is equally true that alcohol is, within certain limits, a food, and that the organism may subsist for a variable period on it exclusively." I take exceptions to all of these statements by this eminent author, and I can sustain my position by Dr. Benjamin W. Richardson, the eminent physician and author of London, who has been a close and able observer and scientific investigator of the influence and effects of alcohol. The results of the scrutinizing investigations of this distinguished physiologist and physician (though in some quarters disputed and their resultant teachings disregarded) have shown that the allegation that "alcohol is food" is not a fact, that it contains no element to nourish or repair the physical organism, and that the impression that

formerly existed—that it was of value to burn in the body and increase the temperature of the body when below par—is likewise a great delusion, for it has been proved again and again that the body will withstand cold and exposure far better without the alcohol than with it. We know that the first effect of alcohol is to increase the action of the heart and elevate the temperature, but that subsequently the temperature of the body falls lower than it was at first, and that the ultimate result is to lower the temperature—a reaction from the perturbing action produced by the stimulant—and that is why a drunken man freezes quickly when falling by the wayside undiscovered until too late to save him. We now turn to Bartholow again; we quote as follows: "Alcohol in small doses is a useful *stomachic tonic*. It is best taken for this purpose after or with meals. It is especially serviceable in the feeble digestion of old people, the atonic dyspepsia of the sedentary, and in the slow and inefficient digestion of convalescence from acute disease." Against all this, with due respect for our truly illustrious author, I take positive and decided issue. They are, in my humble judgment, utter fallacies. Alcohol gives no power; it only stimulates the natural processes, which need rest and carefully selected nutrients, and not the lash of alcoholic stimulants to goad them on to do a work they are unfitted to perform, and thus ultimately do harm instead of good. I quote again: "As alcohol stops waste, promotes constructive metamorphosis by increasing the appetite and the digestive power, and favors the deposition of fat, it is directly indicated in chronic wasting diseases, especially in phthisis. Clinical experience is in accord with physiological data; alcohol is an important remedy in the various forms of pulmonary phthisis." Again I say that Bartholow is in error. Clinical experience has failed to establish the value of alcohol in cases of phthisis for the reasons heretofore given. It retards the normal processes of waste and thereby induces a pathological fatty condition that life-insurance companies have learned to steer clear of. I am here reminded of an old epitaph that I have seen quoted, said to have been upon a tombstone in an old English burying-ground. The man was a tallow chandler by profession, but became so obese, probably from drinking ale, that he died, and this was the inscription on his head-stone:

"Here lies poor Marks, an honest fellow,  
Who died by fat but lived by tallow."

To give you a variety, I will now quote from another eminent author, Ringer, on "Therapeutics." After commanding the use of alcohol to restore "appetite and digestion," he says: "Strength, no doubt, is best supported by food"—to which I say Amen!—"yet," he continues, "the weakened stomach can digest but sparingly, but at the critical juncture alcohol spurs the flagging digestion and enables the patient to take and assimilate more food." I think it fitting to introduce a comparison here which, though it may appear crude, will illustrate my views upon the paragraph quoted. A teamster has a horse that by hard work and a long and continuous draught has become exhausted and unable to pull his load. The driver, whose name is Ringer, would rise upon his feet and, with ejaculations more forcible than rev-

erent, would, with threatening shouts and a vigorous application of the whip, so excite the nervous power of the poor animal that he would pull the load through though he might fall exhausted or dead when the struggle was over. That is the effect of alcohol; it lashes the nervous system and makes a show of strength, but it is only a *show*, that is followed *always* by a corresponding depression. How would driver Richardson manage that beast had he been in charge? Like a man of sagacity, he would spare the horse, if not from humane impulses; he would have a better way. The horse would be unhitched from the load, his harness removed, his limbs bathed, his whole system refreshed by a period of rest and a bountiful supply of nutritious food and water. Then, after a brief period, he would resume his load and take it easily to the desired point and be ready for further duties as usual the next day. Man is an animal that requires rest, pure water, and good food in health, and the conditions do not change when he is sick; and he who in his wisdom believes that he can improve upon the elements needed for man's sustenance in his extremity by substituting alcohol for water or milk and drugs for food is wise only in his own conceit, and has yet to learn the alphabet of physiological science.

But Ringer says some things that I heartily indorse, for example: "After a variable time the prolonged indulgence in alcoholic drinks seriously damages the stomach by producing chronic catarrh." While advocating its use in many conditions of the system and as a cardiac tonic, he is willing to state that "great as are the beneficial effects of alcohol in disease, yet it may do harm as well as good; . . . that, while alcohol may benefit *one* part of the system, it may injure *another*, doing good in one respect, yet on the whole inflicting more harm." Again he says: "In my judgment, there can be no doubt that alcohol is not required in all febrile diseases; on the contrary, many cases are best treated without it; and in no instance should it be given unless special indications arise." That certainly is very conservative advice. Again he writes: "A large dose at one time largely stimulates the heart; then, as the alcohol is decomposed or eliminated, the heart is left unsustained, when great weakness may set in; whereas, the frequent administration of small quantities keeps the heart more uniformly supported." I would ask, Is not the same kind of result produced no matter what the size of the dose? The heart is left weaker in consequence of its unnatural and stimulated activity. To me this appears good logic. I am sorry that Ringer was led to write what I am now about to quote; how old topers must relish such a declaration! "The good old-fashioned remedy—rum or brandy and milk taken before breakfast—is useful in phthisis and exhausting diseases. A little rum and milk an hour before rising is a good prop to town-living women, to whom dressing is a great fatigue, who, without appetite for breakfast, suffer from morning languor and exhaustion, often lasting till midday; and to convalescents from acute diseases." These same persons the good doctor, to be consistent, would have take a little before dinner and tea to help the digestion, and again more at bed-time as a "night-cap" to induce sleep, and, if his practice was exten-

sive, he would furnish business for a wholesale liquor-store by his generous prescriptions for the various kinds of spirituous and malt liquors.

We now turn to Bidwell's "Materia Medica." He says, in brief and concise language, that "alcohol in the form of vinous and spirituous liquors *is employed*" (the Italics are mine; you will notice that he fails to commend, but simply states the facts, which we can not complain of or criticise) "to rouse and support the system in debility, asphyxia, syncope, the latter stages of acute attacks, typhoid and typhus fever, asthenic and malignant diseases, exhausting haemorrhages and suppuration, gangrene, to counteract the effects of bites of venomous reptiles, in *mania a potu*, and in poisoning from digitalis, tobacco, and other narcotics; also as a stomachic in colic, flatulence, indigestion, nausea, etc." Had Bidwell stopped here we would have had no controversy with him, but, alas! he closes by this wholesale commendation, as follows: "The early administration of the preparations containing alcohol furnishes our best means of counteracting the depressing action of disease in general."

I pass to our next author, only remarking that the preceding is a statement entirely unsustained by experience. In the "Annual of the Universal Medical Sciences" for 1888 I find this sentence: "As to the employment of alcohol at all even in disease, the majority of writers seem to believe that it may be a most useful agent." I commend the compilers for their candor in making such a statement, though they rank themselves with the majority, for it reveals the fact (nevertheless, well known for several years) that there is a minority, respectable in numbers and character, that are steadily and conscientiously and scientifically at work to undermine the position that alcohol still holds in the list of remedies for the treatment of disease. I contend that its use as medicine in disease generally is as unwise and delusive as its use as a beverage in health. I am encouraged in this work to know that, from being the universal and infallible remedy it was once assumed to be, and fitted to meet all of the ills to which our poor humanity is heir, it has fallen into disrepute, and there are many sound practitioners of medicine who rarely or never use it.

I now turn to the "National Dispensatory." Hear what that announces: "The use of alcohol in every age and by every nation in the world demonstrates that it satisfies a natural instinct, that it literally refreshes the system exhausted by physical or mental labor, and that it not only quickens the appetite for food and aids in its digestion, but that it spares the digestive organs by limiting the amount of solid food which would otherwise be required. But in accomplishing this salutary end it does not act as a mere condiment. It is also food—in this sense at least, that it offers itself in the blood as a substitute for the tissues which would otherwise be destroyed." The writer quotes from Moleschott, who says: "Alcohol is the savings-bank of the tissues. He who eats little and drinks alcohol in moderation retains as much in his blood and tissues as he who eats more and drinks no alcohol." I wonder he don't go further and state that he might also save expenditure for clothing and coal, for he could fire up with alcohol and keep himself

warm and save his coal-dealer's and tailor's bills. I remember hearing when I was a boy that "rum was a drunkard's lodging, meat, and drink"; it filled all the requirements of his system; but I was not prepared to read in this day and age from a book that is published and received as authority that man had a *natural* instinct for whisky, and that it was "the savings-bank of his tissues." I know a barrel of alcohol will keep a dead man if he is plunged into it and the barrel sealed up, but a *live* man could not long be preserved in it, even if he took to it as naturally as a duck does to water; and if alcohol is his savings-bank, I doubt if he ever has any deposits in any other bank. But I must not descend to the humorous. I had made copious selections from this "Dispensatory," but will forbear to add more save this: "In the form of wine or distilled spirits, alcohol is the universal and familiar remedy for debility of every kind."

I now turn from this undue laudation of alcohol to the more conservative "United States Dispensatory": "Alcohol is a very powerful diffusible stimulant. . . . In a dilute state it excites the system, renders the pulse full, and gives additional energy to the muscles and temporary exaltation to the mental faculties. It is found to lessen the amount of the excretions, from which fact some physiologists have inferred that it diminishes the disintegration of the tissues. . . . In some cases of acute disease, characterized by excessive debility, alcohol is a valuable remedy. In chronic diseases physicians should be cautious in prescribing liquids containing it for fear of begetting intemperate habits. . . . As an article of daily use, alcoholic liquors produce the most deplorable consequences. Besides the moral degradation, their habitual use gives rise to dyspepsia, hypochondriasis, visceral obstructions, dropsy, paralysis, and not infrequently mania."

These conclude my quotations from our standard textbooks in medicine. I now desire to quote from the eminent Dr. Richardson, who, in an address delivered to physicians perhaps fifteen years ago, used these words:

"We offer no reflection on the past, for we admit that in the past there was a common error pervading medicine in relation to the physiological action of alcohol, a common blindness as to the pathological evils springing from it, and a common misunderstanding or ignorance as to the extent of the evils. We remember how, in our pathological studies, our masters indifferently noticed the lesions admittedly produced by alcohol as they were observed in the dead, while they devoted their energies to define with the utmost nicety the lesions which immediately caused death. I recall one of those devoted teachers, whose memory I shall ever cherish, who, at nearly every research in the dead-house, would end the most careful description of the conditions that were the actual cause of the fatal disease with, 'Gentlemen, there are the usually known other lesions with which I need not trouble you, because they come under one head—whisky.' We admit all these past mistakes; we know how blind, not we alone, but all the world has been, and we come at present purely to review the past with the intention of improving the future."

The words of Dr. Richardson express my sentiments, and have ever since they were uttered by him or before I had the privilege of reading them. I feel, as I stated

at our last meeting, that the time has arrived when we should carefully review our practice in the use of alcohol. When I began the practice of medicine, thirty-two years ago, I used whisky by the gallon in my treatment of typhoid fever and other exhausting diseases, because I was taught thus to do, not only by our authors, but by the medical teachers of those times. But I was too much of a Yankee to blindly follow ever in a beaten path, and, using my own eyes of observation, I gradually arrived at positive convictions that the value ascribed to alcohol in the treatment of such cases was a delusion, and cautiously I gradually withdrew the use of stimulants, until at last I found myself successfully managing typhoid cases without the use of a drop of stimulants, and my patients recovered more promptly, I believe, as the result of dispensing with alcohol.

Dr. Richardson goes on to say as follows: "Fifteen or, at the most, twenty years ago (that would be thirty or thirty-five years from this time) the true physiological action of alcohol was a speculative discussion unsupported by any reliable experiment, and therefore of the most contradictory character. Now there is so much evidence of its mode of action that dispute gives way to accepted facts. That the ultimate action of alcohol in the animal temperature is to reduce the temperature; that alcohol relaxes organic muscular fiber; that alcohol produces four destructive physiological states of the body; that alcohol reduces oxidation; that alcohol interferes with natural dialysis; that alcohol induces, even in small quantities, a series of morbid changes and diseases which were not formerly attributed to it; that alcohol prepares the body for destruction by external shocks and depressions which are thus made more fatal; that alcohol belongs to the same class of chemical substances as chloroform, ether, and the anæsthetic family—all this is now on the accepted record, with the final admission, when we are speaking and thinking seriously, that man, like his lower earth-mates and like his own children, can in health live and work and play as well—not to put a fine point on it—without a trace of alcohol as he can with it."

I am confident that were Dr. Richardson speaking today upon this topic he would put a finer point upon it; for the steady nerve of the unerring marksman, Dr. Carver, has no trace of alcohol to influence it, and no one can live or work or play with the full fruition of life's possibilities if alcohol has a place in his system, for it is a perturbing agent that disturbs the equilibrium of the vital forces and deranges the normal action of man's elaborate mechanism.

Dr. N. S. Davis, of Chicago, has said: "Step by step the progress of science has nullified every theory on which the physician administers alcohol. Every position taken has been disproved until it is narrowed down to this: acute diseases where it is supposed there is danger from extreme weakness." After a further discussion of the subject Dr. Davis adds: "Hence I assume that alcohol neither strengthens nor nourishes nor sustains the heart's action, but diminishes it."

The limits within which I desire to confine my paper will not allow of more extensive quotations, and I will only add a few brief ones from other medical gentlemen whose views accord with my own observation and experience. Dr. R.

Green stated several years ago before the Medical Society of Boston : " Alcohol is neither food nor medicine. It can not add one molecule to the plasm out of which our bodies are daily built up. On the contrary, it exerts upon the whole animal economy a most deleterious influence. It does not supply but diminishes vital force. It weakens the nerves, deadens the sensibilities, lessens the power of the system to resist disease or to recover from its effects. Alcohol can not sustain vital force. It weakens the power of digestion and assimilation and can not be long continued without disastrous effects. There can be no excess in the animal economy without a corresponding loss. The momentary exaltation of the functions of either body or mind produced by alcoholic stimulants is always followed by an increased degree of depression. Alcohol may spur a weary brain or nerve a feeble arm to undue exertion for a time, but its work is *destructive*, not *constructive*; such stimulation means destruction, not added force. It is not stimulus but rest that is required for exhaustion from excessive mental labor. It is a whip, a cruel spur, quickening speed and consuming vitality." " As a result," he adds, " of thirty years of professional experience and practical observation, I feel assured that alcoholic stimulants are not required as medicines, and I believe that many if not a majority of physicians to-day of education and experience are satisfied that alcoholic stimulants as medicines are worse than useless, and physicians generally have only to overcome the prevailing fashion of to-day to find a more excellent way, when they will look back with wonder and surprise that they as individuals, and as members of any honored profession, should have been so far compromised." Dr. Bernard O'Conner testified before the British Medical Association : " During fourteen years of practice I never used alcohol for any patient, and my experience at the Consumption Hospital, to which I have been attached for some years, has been that consumptive patients progress very much more favorably with the absence of any alcoholic liquid than they do when alcohol is administered." I make my last quotation from Dr. N. S. Davis : " I speak the more positively because for thirty years I have faithfully tested the correctness of the sentiments given in relation to the therapeutic effects of alcohol in an ample clinical experience both in hospital and private practice. I have found no case of disease—no emergency arising from accident—that I could not treat more successfully without any form of fermented or distilled liquors. The preparations of ammonia and camphor are far more speedy and efficient remedies for immediately arousing the sensibility, while in caffeine, digitaline, convallaria, etc., I have found the proper cardiac tonics for restoring permanent steadiness and force to the circulation."

Gentlemen, I know and am proud of the fact that our noble profession is a conservative one. We are slow to abandon old remedies and theories for new ones, yet our Creator has endowed us with intelligences to guide us through the great responsibilities that we have to bear; and is it not true wisdom for us to follow the teachings of that great apostle, Paul, who said, " Prove all things; hold fast that which is good," by which he implies that we are to cast overboard those agents that are found wanting? The wisest

man of ancient times said: " Wine is a mocker, strong drink is raging, and whosoever is deceived thereby is not wise." It has deluded the world from the time of Noah until now. Let us, my professional brethren, cast off this great delusion and relegate alcohol to the family of anaesthetics, of which it is the least worthy member, and then we shall rarely or never prescribe or make use of it. The limits of this paper have not allowed an elaborate discussion of the subject, but I trust that I have presented sufficient to answer the requirements of your complimentary resolution and to arouse my professional brethren to renewed investigation on this line, that each of us may be prepared to give a reason for the faith we profess and the practice we follow.

## A CASE OF NUTMEG POISONING.

BY AMOS SAWYER, M. D.,  
HILLSBORO', ILL.

On August 14, 1889, I was called to see a boy aged three. I found my little patient with a normal temperature and respiration; pulse regular, but just a little slow; all the muscles completely relaxed. An attempt to arouse him failed, his head falling in whichever way the body inclined. An examination of the pupils revealed complete dilatation. I felt certain that this condition was the effect of something the child had eaten, and, upon inquiry, was informed that he had, unknown to his mother, appropriated from her spice-box five large nutmegs, which he informed his little sister was his tobacco, and which by noon he had managed to consume, presumably spitting out the bulk of the spice. About 2 p. m. he complained of feeling dizzy and soon fell asleep, and they had been unable to arouse him. He had had one movement from the bowels, and had urinated twice while in this condition. There had been no delirium. He recovered consciousness as if awakening from a natural slumber, but with the greatest dislike for nutmegs, after having slept thirty consecutive hours.

Query, Why would this not be a valuable remedy, where a relaxed sleep was indicated, as an antispasmodic narcotic?

**Treatment of Pneumonia by Application of Ice.**—"Dr. Fieandt, writing in 'Duodecim,' a Finnish medical journal, states that he has now treated no less than 106 cases of pneumonia with ice, and with the best results. Though ten of the cases were of double pneumonia, only three out of the whole number succumbed, notwithstanding that the epidemic was by no means a slight one. The method adopted was to apply over the affected lung an India-rubber bag containing ice continuously for from twelve to twenty-four hours after the crisis. In addition to the local treatment the patients were given such medicines as are usually employed—that is to say, opium, ipecacuanha, digitalis, brandy, etc. The method has, we may remark, received of late some attention in this country."—*Lancet*.

**Pathology of Extensive Burns.**—"Oscar Silbermann, of Breslau, finds that in extensive burns the red corpuscles alter their form, and are able to exert less than their normal resistance to heat, drying, compression, and staining. In consequence of these changes, thrombosis and stasis in different organs are very frequent, especially in the lungs, kidneys, stomach, bowels, spleen, liver, skin, and brain, and most of all in the smaller branches of the pulmonary artery. The stasis in the lungs produces a very considerable impediment to the emptying of the right ventricle, with enormous venous congestion and dangerous arterial anaemia. This again leads to apoplexy and parenchymatous alterations in the above-mentioned organs, also to dyspnoea, cyanosis, coma, a small pulse, angina pectoris, eclampsia, anuria, and to a diminution of the surface temperature."—*Lancet*.

NEW YORK, SATURDAY, SEPTEMBER 28, 1889.

GLANDULAR FEVER.

UNDER this title, in a recent number of the "Centralblatt für klinische Medicin," Dr. E. Pfeiffer describes an acute febrile condition mainly characterized by a swollen state of the lymphatic glands—an affection of frequent occurrence. According to his observations, the temperature rises to about 103° F., the tongue is slightly coated, the tonsils are a little reddened, and there is chilliness with fever, pain in the limbs, great uneasiness, loss of appetite, and vomiting. All the internal organs appear normal, but the lymphatic glands of the sterno-cleido-mastoid and occipital regions are swollen and painful. In moderate cases the fever ceases on the second day, and the glandular swelling subsides gradually. The affection may, however, be prolonged by recrudescences, the implication of the sterno-cleido-mastoid glands passing from one side of the neck to the other, and the lymphatic glands of the whole body may become involved. In such cases the throat symptoms are more pronounced, with slight cough, dysphagia, and hepatic and splenic pain on pressure on the third or fourth day. Another form of glandular fever is that which accompanies swelling of the intestinal glands; the liver and spleen are both tender, and there is diarrhoea with moderate fever, loss of flesh, slight albuminuria, and ascites.

Pfeiffer thinks that the course of the disease and its occurrence in localized epidemics, confined to a house or a family, show it to be infectious. O. Heubner is represented as having made similar observations, except that he has not noticed the implication of the liver and spleen or the occurrence of the disease in the epidemic form. Pfeiffer asks whether the affection is idiopathic, symptomatic, or a mere aggregation of symptoms of various morbid processes. Heubner has always taken the glandular condition as proceeding from infection of a neighboring mucous membrane, and this view is more in harmony than Pfeiffer's with what has previously been held, although the tendency to make glandular swelling an idiopathic disease has been so marked that in the first half of the century Velpeau, among others, protested against it. "Swollen and inflamed," said Velpeau, "the glands may remain for a long time the only sign of disease after the part originally diseased has returned to its normal condition; if there have been no appreciable changes, no signs of lymphangitis, in the course of the intermediate vessels, the patients and even their doctors readily overlook the cause of the adenitis and content themselves with studying the effect."

Sometimes the effect is disproportionately severe, often probably on account of the patient's reduced powers of resistance. Such was the case in a family to which the present

writer was once called. Two of the children were affected in a manner absolutely the same as that described by Pfeiffer. The swelling of the sterno-cleido-mastoid glands was very great, especially on the right side. The tonsils were so slightly reddened that attention was at once called to the disproportion between cause and effect. On inquiry, it was found that the mother, owing to dread of overfeeding her children, had so systematically underfed them that it required but a slight cold to make them very sick. Cod-liver oil and iodide of iron gradually got the upper hand of what might naturally be considered a cultivated weakness—a weakness common enough in poorly nourished children, whether from inherited tendencies or from improper feeding.

In his cases of the second class of glandular fever—those in which the intestinal glands were involved—Pfeiffer used calomel, cold compresses, a strengthening diet, quinine, wine, and iron, and it took at least three months for the patients to be completely restored to health.

AN UNJUST DISCRIMINATION.

MANY of our readers may not be aware that the law forbids the appointment of a physician to the presidency of the City Health Board. The fact has been severely commented upon by the profession, not with the prospect of the candidacy of any individual, but on account of the implied insult flung upon the profession at large. It seems to us preposterous that a board which should be composed of those versed in sanitary matters should be crippled with the condition that its head must not be a physician. The text of the law, however, makes it a mandatory proviso, even to the verge of ostracism. Can it be possible, we ask, that the pains taken to acquire the essential requisites of such an office should be a disqualification? If, indeed, the prospective incumbent were a recluse without the ordinary intelligence of the ordinary business man, unaccustomed to responsibilities, devoid of principle, or lacking in executive ability, there might be some reason in such special legislative discrimination. But, in the majority of instances, the physician has figured very largely and very acceptably in public affairs, even out of his ordinary sphere. Under the Dutch rule and during the colonial period he was a valuable counselor, and helped in no mean degree to shape the destinies of the metropolis. Toner, of Washington, in his "Medical Men of the Revolution," has also offered a tribute in favor of his patriotism, loyalty, self-sacrifice, and integrity. And yet the State of New York, carelessly we hope, has entered upon its statute-book this slur against an honorable profession, which in Europe claims the respect of potentates of almost every degree, particularly in affairs that concern the physical welfare of the people. Surely with a counsel of its own, or a corporation counsel, whose duty it is to advise regarding the limits of power, and with the distribution of funds checked by ample safeguards, there can be no danger in allowing the meager privilege of electing a physician to the presidency of the Health Board if he is qualified. The doctrine of this republic is supposed to be the largest liberty, and yet the member of our guild must necessarily forswear

his allegiance, forget his knowledge, and go into an all-around training, if his ambition happens to be in the direction of the only office in the State placed beyond his reach by self-seeking politicians. We have no candidate for the position, or, if we had, we should not depart from our policy of urging no one's advancement in political matters; we merely wish to rebuke what can be construed into nothing else but an insult or want of confidence. Let the office go, but remove the disqualification.

### MINOR PARAGRAPHS.

#### THE STATE EXAMINATION OF MEDICAL STUDENTS.

THE law, passed last winter, requiring students having no baccalaureate degree to be examined before entering upon medical study, is being put in train for enforcement by the Regents of the University. A circular, dated August 20th, has been sent to the colleges and to individuals giving information respecting the methods of these examinations. The secretary, Professor Melvil Dewey, may be addressed at Albany for copies of the circular. Students who had entered upon a three-years' course prior to June 13, 1889, are not affected by the new law. The earliest date for which an examination has been set down is September 30th, at Buffalo. Hence, we judge, a certain proportion of this year's entries at the colleges will be in the plight of a legal oversight, unless there happens to be some provision that is not explicitly stated in the circular of the Regents. However, as it is not the object of the act to lay a hardship upon the students of the current term, there will probably be no difficulty in obtaining an amendment from the next Legislature by which their cases may be passed upon equitably. It is not generally known that the Regents' certificate is required to be filed with the dean or secretary of the medical school "prior to entering upon the prescribed three-years' course of study of medicine," and without this preliminary filing it is forbidden to the schools to grant the degree of doctor of medicine. The act does not apply to persons who "have already entered upon" the said course of study. The word "already" must be construed to refer to the date of the approval of the act by the Governor, on June 13, 1889.

#### THE AMERICAN PUBLIC HEALTH ASSOCIATION.

ELSEWHERE in this issue we publish the substance of certain announcements indicating that the forthcoming meeting, to be held in Brooklyn, promises to be altogether the most profitable one that the association has ever held. Far too seldom is the Brooklyn profession given an opportunity to show what it can do in connection with the meetings of medical and quasi-medical bodies of more than a local character. The pains that have been taken by the local committee in this instance ought not only to insure the success of the meeting, but also to dispel the illusion that Brooklyn has no title to as much individuality in such matters as is freely accorded to cities of a far smaller population.

#### THE CARBOLIC-ACID TREATMENT OF HÆMORRHODS.

DR. ANDREWS, of Chicago, was one of the first to study the subject of the carbolic-acid treatment of hæmorrhoids, and he has been reverting to it from time to time during the past ten years. According to the "Indianapolis Medical Journal," he states that there have been thirteen deaths following the operation of injecting the acid into piles, out of three thousand cases. This is a mortality far greater than that attendant upon the use

of chloroform as an anaesthetic. The estimated mortality, in the late civil war, following chloroform anaesthesia was about one in three thousand administrations, often undertaken under circumstances of embarrassment and risk. But the chloroform was of the purest that could be found and was scrutinized with care before being accepted in the medical supplies. On the other hand, in regard to the purity of the carbolic acid used by the operators on hæmorrhoids, little if any attention is given to it, it is alleged; generally the first that is offered is accepted without question.

#### THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

DR. C. H. MASTIN, of Mobile, who may be said to be the father of this organization, set a wholesome example in the ground he took, at a recent meeting of the Executive Committee, for declining the nomination to the presidency. He is reported as having said that no member of the Executive Committee ought ever to be elected to the presidency. Thereupon Dr. S. Weir Mitchell, of Philadelphia, was chosen president, and Dr. William H. Carnall, of New Haven, secretary. The next meeting is to be held in Washington, in September, 1891.

#### THE ACADEMY OF MEDICINE'S NEW BUILDING.

IT is announced that the corner-stone of the new building, in West Forty-third Street, will be laid by the president on Wednesday, October 2d. The exercises, which are to begin at 4 o'clock in the afternoon, will include an invocation by the Right Rev. Bishop Potter, an address by Dr. A. Jacobi, and remarks by the Hon. Grover Cleveland. We trust that there will be a full attendance of fellows of the Academy, as well as of members of the profession at large, to add dignity to the occasion and to promote general interest in the Academy's efforts to raise the sum still wanted to complete the amount of money required for the new building.

#### THE OBSTETRIC USES OF CREOLIN.

THE "Medical Press" for September 4th refers to creolin as about the best disinfectant in midwifery. It is not an irritant to the vaginal mucous membrane, like carbolic-acid and sublimate solutions. It does not irritate wounds or abrasions, and will not retard healing. Under the use of creolin mucous membranes become softer and smoother than before its use. Its odor is not disagreeable, especially when brought into comparison with carbolic acid or iodoform. If by accident it is taken internally it is said to be bland and harmless. It does not corrode instruments, but, mixed with water, it forms a non-translucent emulsion, so that instruments may be lost sight of, if not sought for with care. The cost of creolin is not high, being less than that of carbolic acid. The writer recommends Pearson's creolin as being less variable than some others. The uncertainty of its composition has been the chief objectionable feature of creolin.

#### ITEMS, ETC.

THE Shelby County (Indiana) Medical Society will hold its next monthly meeting in Shelbyville, on Monday, October 14th. The programme includes the following titles: "The Management of Normal Labor, with Particular Reference to the Employment of Antiseptics in Midwifery Practice," by Dr. J. W. Green, of Shelbyville; "The Use of Ergot in Labor," by Dr. S. L. Strickler, of Boggstown; "Practical Obstetrics," by

Dr. John Moffett, of Rushville; "Delivery of the Placenta, with Report of Cases of Adherent Placentæ," by Dr. M. R. Gilmore, of Boggstown; "The Management of Shoulder Presentations," by Dr. Edward F. Wells, of Shelbyville; "Post partum Hæmorrhage, with Report of Cases," by Dr. J. W. Bowlby, of Marion; "Puerperal Eclampsia, with Report of Cases," by Dr. T. R. Rubush, of London; "Management of the Perinæum, with Report of a Case of Rupture," by Dr. I. W. Trees, of Smithland.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 24, 1889 :

DISEASES.	Week ending Sept. 17.		Week ending Sept. 24.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	55	14	63	16
Scarlet fever.....	22	2	24	4
Cerebro-spinal meningitis....	1	0	0	0
Measles.....	11	0	9	0
Diphtheria. ....	61	16	55	15

**The Military Service Institution.**—The announcement of the meeting for Friday, the 27th inst., at Governor's Island, New York Harbor, gave the title "Personal Identity as a Means of Recognizing Deserters" as that of a paper to be read by Surgeon Charles R. Greenleaf, of the army.

**The City Health Department.**—Dr. F. Irving Disbrow has resigned his position under the Department, on account of failing health, and resumed private practice.

**Change of Address.**—Dr. George P. Thomas, formerly of Staten Island and late superintendent of the Alameda County Hospital, California, to lock box No. 253, San Leandro, Cal.

**The late Dr. Addinell Hewson,** of Philadelphia, who died on the 11th inst., aged sixty-five years, was of the fourth generation, in direct line, in medicine. He received his preliminary education in the University of Pennsylvania, and was graduated in medicine at the Jefferson Medical College in 1850. He held several hospital appointments in Philadelphia, and was a meritorious writer on surgical subjects.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 15 to September 21, 1889:*

SMITH, ANDREW K., Colonel and Surgeon. By direction of the Acting Secretary of War, leave of absence for fourteen days is granted on surgeon's certificate of disability. Par. 1, S. O. 214, A. G. O., September 14, 1889.

STERNBERG, GEORGE M., Major and Surgeon, having completed the duties assigned him in War Department order dated February 4, S. O. 30, February 5, A. G. O., is, by direction of the Acting Secretary of War, reassigned to duty as attending surgeon and examiner of recruits at Baltimore, Md. Par. 12, S. O. 218, A. G. O., September 19, 1889.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending September 21, 1889:*

BEARDSLEY, G. S., Medical Inspector. Granted six months' leave, with permission to go abroad.

RUTH, M. L., Surgeon. Order granting furlough revoked, and placed on waiting orders.

HUDSON, ADRIAN, Medical Director, Woods, G. W., Medical Inspector, and DICKINSON, DWIGHT, Surgeon, will continue as president and members of an Examining Board for examina-

tion of applicants for the position of assistant surgeon in the navy at San Francisco, Cal., until June 30, 1890.

#### Society Meetings for the Coming Week:

TUESDAY, October 1st: New York Obstetrical Society (private); New York Neurological Society; Elmira Academy of Medicine; Buffalo Medical and Surgical Association; Ogdensburg Medical Association; Medical Societies of the Counties of Broome (annual), Columbia (annual—Hudson), Orange (semi-annual—Goshen), and Schoharie (semi-annual), N. Y.; Medical Association of Northern New York (annual—Malone); Hudson (Jersey City) and Union, N. J. (quarterly), County Medical Societies; Chittenden, Vt., County Medical Society; Androscoggin, Me., County Medical Association (Lewiston); Baltimore Academy of Medicine.

WEDNESDAY, October 2d: Society of the Alumni of Bellevue Hospital; Harlem Medical Association of the City of New York; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond (Stapleton), N. Y.; Penobscot, Me., County Medical Society (Bangor); Philadelphia County Medical Society; Bridgeport, Conn., Medical Association.

THURSDAY, October 3d: New York Academy of Medicine; Society of Physicians of the Village of Canandaigua; Washington, Vt., County Medical Society; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington).

FRIDAY, October 4th: Practitioners' Society of New York (private); Baltimore Clinical Society.

SATURDAY, October 5th: Clinical Society of the New York Post graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

### AMERICAN GYNÆCOLOGICAL SOCIETY.

Fourteenth Annual Meeting, held in Boston, September 17, 18, and 19, 1889.

The President, Dr. H. P. C. WILSON, of Baltimore, in the Chair.

An address of welcome was given by Dr. J. P. REYNOLDS, of Boston.

**The Use and Abuse of Antiseptic Injections in Obstetrical Practice** was the title of a paper by Dr. H. J. GARRIGUES, of New York. If, he said, one was satisfied that puerperal fever in any given case was the result of infection, the use of antiseptic injections was indicated. Like all other useful measures, this had sometimes been carried to extremes. The other extreme was reached by those who discarded injections after labor altogether. Much mischief was undoubtedly done by injections when they were not needed—as, for example, when they were used too frequently, of too great strength, etc. At the Maternity Hospital, at Blackwell's Island, from 1874 to 1885, the mortality had been 4·17 per cent. During the period from 1884 to 1888, in which the author's method of treatment had been followed at the same institution, there had been but two fatal cases, or a mortality of a fraction of one per cent. The morbidity also had been small. Vaginal injections before delivery were believed by the author to be useful, though they were objected to by many writers on the ground that they were

dangerous, that the lubricating mucus of the vagina was removed, etc. In answer to the objections that the bacteria on the surface of the vaginal mucous membrane were harmless, it must be remembered that they would not be harmless if they penetrated the subjacent tissues. They would also constitute an element of danger when carried from the vagina into the womb. If vaginal injections were used prior to labor, the vagina would be dilated and the micro-organisms removed or destroyed. It must not be forgotten, too, that during labor a new supply of mucus was secreted to replace that which might have been washed away. In cases in which, for any cause, frequent examinations were required during labor, vaginal injections should be repeated as often as every three hours, and, if instruments were required or the hand was introduced into the uterus, both uterine and vaginal injections would be required. Such injections were better than intra-uterine applications of antiseptic material with a swab, which was recommended by some. Infection would not occur if the labor had been antiseptic. Subsequent to labor, if the lochial discharge became foetid, another indication for intra-uterine irrigation would exist, likewise if *débris* were left in the uterus, if there had been sloughing as the result of prolonged labor, if the fetus had been macerated, etc. Puerperal peritonitis should be treated with such injections as soon as it was recognized, and such treatment might also be required after abortion. As to the proper material for injections, solutions of bichloride of mercury might be used, but they should be used with great caution. Since 1884 reports of twenty-two fatal cases from the use of such injections had been reported, though it must be admitted that four of this number should not be considered, and in others the solution had been too strong, or had been too frequently used, or had been improper in some other way. The strength of the mercurial solution should not exceed 1 to 5,000, and its use should immediately be withheld if toxic symptoms were apparent. Some of the contra-indications to its use were anaemia, kidney disease, and diarrhoea. Other solutions had also been extensively used for this purpose, especially that of carbolic acid. The objection to this was that its odor was offensive to many, it numbed the hands, and might produce severe results to the patient's entire nervous system. Thymol, salicylic acid, chloride of zinc, hydronaphthol, and various other substances had advocates. The author had made extensive trial of creolin, and had been well pleased with the results. In two-per-cent. solutions it was perhaps as useful and as unobjectionable as anything that had been tried. Objections to its use were that its agreeable odor might mask offensive odors which would lead to the discovery of important conditions; also that, as it formed an opaque emulsion and not a transparent fluid, it might conceal particles the presence of which it would be desirable to ascertain. It had also valuable lubricating and haemostatic properties. If vaginal douches alone were to be given, the author preferred to use a glass vaginal tube six inches long. If the solution was to be carried into the uterus, a single tube was preferable to a double one, and it should be carefully guided into the uterus with the fingers, great pains being necessary to avoid forcing any fluid or uterine *débris* into the Fallopian tubes. The patient, while receiving the injection, should be on the back, on a bed-pan or a rubber cloth so folded that it would catch and carry away all fluid as it returned from the vagina. The tube must not be forced into the uterus, but must be withdrawn and re-introduced if obstruction was encountered. Failure to observe this precaution had resulted in perforation of the uterus and injection of the bichloride solution into the abdominal cavity. The temperature of the uterine douche should not exceed  $110^{\circ}$  to  $115^{\circ}$  F., and the quantity should not be greater than two or three pints. For vaginal douches there would be

no objection to using from two to three quarts. The return fluid should be carefully examined for septic matter, the uterus should be compressed after the irrigation was completed, and no fluid should be allowed to remain in the vagina.

Dr. W. T. LUSK, of New York, agreed entirely to the fundamental principle of the paper, which he understood to mean the advocacy of prophylactic vaginal injections. He also believed that all cases of septic puerperal fever which called for irrigation were the result of insufficient precautions on the part of the attending accoucheur. Of course this did not apply to diseases in which the virus was not introduced through the vagina. The best results from uterine injections were obtainable in cases in which there was infection from putrid matter, decayed blood-clot, etc. In septicæmia, in which round bacteria constituted the infecting agent, injections did no good, and probably did harm if used after the microbes had passed into the lymphatic circulation. In general, he believed that one thorough uterine irrigation, followed by the use of an intra-uterine iodoform pencil, was all that would be serviceable. Injections repeated as often as once in three hours were improper and likely to be injurious. He did not believe that one could depend upon the odor from offensive discharges as a guide for the administration of uterine injections, as had been frequently asserted. In fact, the most offensive discharges might proceed from simple puerperal catarrhal endometritis. In New York practice, he believed, many cases of supposed puerperal fever were in reality cases of typhoid fever proceeding from defective sanitation. Especially was this true in tenement-house practice. The method of treating puerperal fever which was practiced by Doléris and his followers, which consisted in curetting the uterine mucous membrane and then irrigating, was to be recommended in some cases.

Dr. H. C. COE, of New York, had followed the method prescribed by the reader of the paper with satisfactory results. He found it very difficult, however, to distinguish those cases which were suitable for irrigation from those in which it was contra-indicated, in view of the fact already referred to by Dr. Lusk that the infectious elements might have passed beyond the reach of the injection. He had obtained good results from the use of creolin, but had also observed that it sometimes masked the odor of the discharges. He believed that prophylaxis was all-important in the treatment of puerperal cases.

Dr. W. M. POLK, of New York, indorsed the principle advocated by the author, but, as to the details, his custom was somewhat different. He first washed the genitals externally and internally with potash soap and hot water, and then used an injection of bichloride of mercury, 1 to 5,000, or creolin. He had not yet decided which of the two solutions was preferable. He believed it a fact that suppuration in the uterine cavity should be treated in the same manner as suppuration in any other cavity. His habit was to place the patient on the left side, carefully swab out the vagina and uterus with cotton, give the injection, and then introduce iodoform gauze for drainage. There was usually no necessity of repeating the irrigation—certainly not within a day or two.

Dr. P. F. MUNDÉ, of New York, thought it had not been stated that a prime condition was to find the absolute cause of sepsis. This implied a careful examination of the uterus with the finger after the chill or high temperature had appeared and before irrigation had been practiced. If septic matter was discovered it should always be removed with the curette, this being followed by irrigation. Subsequently ergot might be administered, the ice-bag or cold-water coil applied, and an antiseptic pad placed at the vulva. He agreed to the statement that one should not depend upon the odor of discharges as a guide to irrigation, and even the finger could not

be relied upon in all cases—notably in those cases in which the infecting bacteria had passed into the circulation. A chill might follow irrigation, the temperature reaching from 104° to 105° F. This need not cause alarm. Intra-uterine injections after normal labor were entirely uncalled for. He agreed to the statement that the fault was that of the attending accoucheur if a puerperal woman became septic.

Dr. H. J. BOLDT, of New York, showed an intra-uterine catheter which was a modification of the Bozeman-Fritsch instrument. He admitted the difficulty of cleansing it, and stated that it should always be boiled immediately before being used.

Dr. A. P. DUDLEY, of New York, believed that there were cases of puerperal fever which were due to infection from pyosalpinx of one side, infection of the uterus not occurring until labor had been concluded.

Dr. HOWARD KELLY, of Philadelphia, believed that the vagina should always be washed out in cases in which there was any suspicion of infection. In tenement-house practice, in which the surroundings were very unhygienic, he had derived great benefit from the use of a device of his own by which means injections could be given and the fluid be carried off without wetting the clothes of the patient or the bedding.

Dr. E. C. GEHEUNG, of St. Louis, thought that septicæmia might be produced by the use of uterine injections, *débris* being propelled by the current farther into the uterus. Suction or aspiration was more successful in the treatment of puerperal cases than propulsion.

Dr. W. G. WYLIE, of New York, believed that in many cases of puerperal fever the source of the trouble was not in the uterus, but in the broad ligaments or other pelvic tissues. He had long since advocated intra-uterine irrigation if the disease was in the uterus, and believed that, if used at all, injections should be used frequently—as often as once an hour. If the disease was in the broad ligament, his plan was to make an opening in the vagina, remove the septic matter, and drain. In many cases general peritonitis would result, but even this might be cured by timely laparotomy.

Dr. GARRIGUES warned against depending solely upon temperature as an indication for uterine irrigation. The uterus should be carefully examined for septic matter; if any was found, it should be removed with the curette, and irrigation practiced. If these conditions did not exist, irrigation was not called for. He approved of the preliminary use of soap and water recommended by Dr. Polk, but saw no necessity for gauze or other means of drainage in the uterus, the natural conditions of the organ favoring drainage. A chill after irrigation was not usual, but, should it occur, the irrigation should not be repeated. Laparotomy would seldom be appropriate; indeed, the patients or their friends would seldom allow it. Frequent irrigations might not be harmful if properly given, but he thought that equally good results could be obtained by using powerful vaginal suppositories.

**A Digest of Twenty Years' Experience in the Treatment of Cancer of the Uterus by the Galvano-cautery.—**A paper with this title was read by Dr. JOHN BYRNE, of Brooklyn.

One reason, the author said, why a knowledge of the value of the galvano-cautery was diffused to so small a degree among gynaecologists consisted in the great popularity of the thermo-cautery, which, however, could not occupy the same field with the former. His first series of cases of cancer of the uterus treated with the galvano-cautery had been published in 1872. He had tried to demonstrate at that early day that this means of treatment was less dangerous than any other, and that it was the most useful for the treatment of uterine cancer. Even at that time he had stated that it was necessary in all cases to re-

move tissue quite beyond the apparent seat of the disease, if one would obtain permanent results. Prior to 1872 there had been few who had made use of the galvano-cautery, one great obstacle being the difficulty of obtaining a battery of the requisite power. He had finally succeeded in overcoming this difficulty, and the battery which he had devised had been in constant use in all his work during the past fifteen years. The Paquelin thermo-cautery was much inferior to the galvano-cautery in the treatment of uterine cancer, because of its great radiation of heat, and he believed that its value was greatly overestimated. Whatever instrument was used, it was essential that all the diseased tissues should be thoroughly burned. Chloride of zinc had been used for many years, and was an inferior substitute for the cautery when the latter was not attainable.

The author's patients numbered 367. Of these, 121 had been lost sight of within a year after the operation; his statistics were, therefore, necessarily incomplete. Of those cases which he had been able to follow up, in 59 the disease had been limited to the portio vaginalis, in 81 to the entire cervix, and in 8 to the corpus; in 219 the entire organ had been involved. In the first class, 36 had exemption from recurrence for from one to fifteen years, the average period being eight years and a half. In the second class, there were 35 in which the average period of exemption was five years and a half. In the third class, 4 had an average period of relief for two years. In the fourth class, 78 were exempt for nearly three years. Though the relief in many cases was only temporary, all palliative means in so terrible a disease should be considered useful. In using the cautery the greatest care and thoroughness were necessary, and the current should not be passed until the wire had been secured upon the tissues which were to be burned. Care must also be taken to avoid burning the healthy vaginal tissue at a distance from the disease.

Dr. A. REEVES JACKSON, of Chicago, eulogized the pains-taking and laborious efforts of the reader of the paper, and considered its statements as forming a striking contrast to most of the recent contributions to the treatment of cancer, in which serious cutting operations upon the uterus or its adjacent organs were advocated. Such contributions showed results which were far inferior to those which had been published by Pawlik and the reader, by both of whom the galvano-cautery had been used. Those who performed hysterectomy admitted that the death-rate from that operation was high, but as an offset they maintained that those who recovered from the operation were likely to be free from recurrence of the disease. Reference to recent German statistics showed that such a statement was fallacious.

Dr. T. A. REAMY, of Cincinnati, thought the author of the paper too sanguine in regard to the possible results to be obtained by the use of the cautery. In his own series of fifty-seven cases of operations for cancer of the cervix, in which twenty-two patients had apparently recovered, he doubted whether the results would have been much better if the cautery had been used, as the reader of the paper had seemed to imply. The result in all cases must depend upon the stage of invasion of the cancer at the time of the operation, rather than upon the method or form of the operation. He believed that hysterectomy had a field, though it might be a narrow one, and did not agree with the two previous speakers that such operations should never be performed.

Dr. BYRNE thought it impossible to define the limits of cancer in any given case, and believed that after all tissue that could be reached by the knife or scissors had been removed the cautery would reach diseased cells which were otherwise inaccessible. He had avoided the use of the word *cure* in the relation of his cases, preferring to use the word *relief* as more

appropriate, for no one could say that an absolute cure was obtained in any case. Even in those cases in which relief had continued the longest the disease might reappear in the ovaries or elsewhere. With reference to hysterectomy, he was totally opposed to it, and was certain that the statistics were even much worse than had been reported.

Dr. H. C. COE, of New York, read a memorial of the late Dr. James B. Hunter.

**The Nature and Limitation of Treatment for Uterine Fibroids** was the title of a paper read by Dr. P. F. MUNDE, of New York. There were many cases of uterine tumor in which no treatment was required. Referring to the usual classification of uterine tumors, it was noticeable that those of the sub-peritoneal variety were seldom accompanied by haemorrhage; those of the submucous and interstitial varieties frequently were. The treatment for the subperitoneal variety, in cases in which treatment of a surgical character was required, would consist in removal of the uterus with the tumor, or in removal of the ovaries alone. In the interstitial variety the tumor could often be removed without removing the uterus; in the submucous variety the tumor alone would require removal. If the tumor was not removed, ergot or electricity might be substituted, the object being to force the tumor as far as possible into the pelvis. The greatest difficulty was to be expected in attempting to remove sessile fibroids seated near the fundus through the undilated utero-vaginal canal. The German method, of performing laparotomy and removing the tumor through the opened uterus, was perhaps preferable in such cases. Haemorrhage accompanying uterine tumors might be treated with the curette or by electro-puncture through the vagina. It was maintained for the latter, which was Apostoli's method, that it would cause the tumors to cease growing, but this cessation was not permanent. In the three cases in which the author had performed oophorectomy for the relief of uterine tumors the results had been satisfactory. In six cases in which subperitoneal tumors had been removed through the abdomen recovery had taken place in four; in all cases the pedicle had been treated by the extra-peritoneal method. Tumors which were seated near the os internum tended to dilate the os, and in many cases no treatment would be required. In some cases in which operation was indicated they could be enucleated and drawn out after the capsule had been split. Laparotomy should not be performed if a tumor was causing no serious trouble, and no operation was indicated in most cases in which the menopause was imminent.

**The Nature and Treatment of Fibroid Tumors.**—Dr. W. G. WYLIE, of New York, in a paper on this subject, said that he had observed that in tumors which were slow in growth uterine symptoms were equally absent, and that, if pain and general discomfort were present, the endometrium or the tubes and ovaries were usually involved. In women forty years of age and upward small tumors of the uterus were not usually significant, though they might delay the menopause. If there were pain and failing health about the time of the menopause, it was usually an indication that degeneration was taking place, and hysterectomy would probably be indicated. Fibroid tumors were like all organic matter, and had their periods of growth and decay. He could not speak with accuracy, but believed that the life of a tumor would usually be from two to eight years. Should it cease growing, and after a time begin again, its removal might be required. A tumor might be quite large and give rise to no symptoms; the patient might even be unconscious of its existence. Should complications occur, such as cystic degeneration or suppuration, an indication for removal would then be furnished. If only the lining membrane of the uterus was diseased, curetting might control haemorrhage for a year or more, but in case it did not, the tubes and ovaries

should be removed. If this was done thoroughly, all bleeding would probably cease. He believed that it was possible to do hysterectomy with comparative safety. His own death-rate was now but ten per cent., and he thought it could be lowered. He had experimented with Apostoli's method of treating fibroids for two years, and believed that its value had been overestimated. If it did no harm, it would at least cause delay, and thus might remove a patient's only chance for relief by operation. With women of the child-bearing period strong currents of electricity were inadvisable. Electricity would doubtless stop bleeding from fungous growths of the uterus, but it might also cause damage, and was no safer than the curette. In fact, the use of the latter had been absolutely safe in his experience. His opinion as to the value of electricity was admitted to be provisional, as he considered his experience still insufficient.

Dr. REAMY approved of the conservative tone of both the papers which had been read, especially in view of certain radical views that had recently been enunciated in certain parts of our country. Cases were innumerable in which autopsies revealed the presence of uterine tumors the existence of which had never been suspected during life. Such a fact was fundamental in the consideration of any method of treatment. Martin had recently stated that in 205 cases in which uterine myomata had been removed by him, fatty and other degenerative changes were found in 70; hence spontaneous cure might occur. It was even possible in cases in which changes of an inflammatory character had taken place, as he had twice witnessed. The low vascularity of most of these growths also taught us that severe measures were not always necessary. Many might be cured by ergot without the aid of knife or electricity. The speaker was of the opinion that Apostoli had not been fairly dealt with in this discussion. He knew from personal experience that tumors were curable by Apostoli's method. Curetting had not been absolutely safe in his hands, and if, as was asserted, electricity caused stenosis of the uterine canal, it could not destroy the possibility of pregnancy more effectually than removal of the tubes and ovaries, which had been so freely advocated. In his experience oophorectomy would not always stop the haemorrhage caused by uterine tumors. For the severest cases he conceded the propriety of hysterectomy.

Dr. G. J. ENGELMANN, of St. Louis, admitted that his results in the treatment of uterine fibroids by electricity had not come up to his expectations. The results were excellent in cases in which the uterus was surrounded by hard masses of exudate. The same was true in the treatment of both profuse and scanty menstruation. In most cases in which electricity had been used by him the patients had become more comfortable, and with poor working women that was of great consequence. No single method of treatment was applicable to all cases of uterine tumor. There was a field for ergot, for the knife, and for electricity.

Dr. J. R. CHADWICK, of Boston, was entirely opposed to Apostoli's method. He had followed Apostoli's directions carefully in twenty-four cases, and had seen improvement in but one. In that case the haemorrhage was checked for three years. In none of them had the tumors been reduced in size. In two cases death had resulted, and two others had been nearly fatal. Apostoli alleged much for his method; he was therefore a fair object for the most searching criticism.

Dr. ELY VAN DE WARKER, of Syracuse, N. Y., believed that Apostoli's method had produced positive scientific results, and objected to such sweeping denunciation of it. Electricity might result in cystic degeneration in tumors or intensify such a condition if already existing. It might also be followed by high temperature, and these results might be caused by the intra-uterine use of electricity as well as by galvano-puncture. But

such results were exceptional. On the other hand, it would cause tumors to become movable and smaller, and would stop haemorrhage.

Dr. M. D. MANN, of Buffalo, N. Y., had used electricity with success in all cases in which tumors had been treated, but this statement did not apply to galvano-puncture.

Dr. MUNDÉ stated that he had seen three tumors disappear after galvano-puncture, but still believed that Apostoli's statements were extravagant.

Dr. WYLIE reiterated his opinions concerning the value of the curette and the extravagance of Apostoli's assertions.

(To be concluded.)

#### MEDICAL SOCIETY OF VIRGINIA.

*Twentieth Annual Meeting, held in Roanoke, on Tuesday, Wednesday, and Thursday, September 3, 4, and 5, 1889.*

The President, Dr. E. W. Row, of Orange, in the Chair.

(Concluded from page 329.)

**Some Practical Points in the Treatment of Hip Disease with Special Reference to the Use of Thomas's Splint.**—In a paper with this title, by Dr. JOHN RIDLON, of New York (present by invitation), the management of hip disease in a mechanical way was considered from the standpoint of the general practitioner. The difficulties in the way of the use of the various forms of traction splints were considered. The use of plaster of Paris was dwelt upon, and its advantages and disadvantages were pointed out. Traction in bed, after the manner of Howard Marsh, was described and commended for those cases where traction was indicated, and where there was no contra-indication to prolonged rest in bed. To one, however, who was satisfied to treat tubercular joint disease in any part of its course without traction, or who was so circumstanced, as the general practitioner was, that he must treat all walking patients without traction, and to one who believed that immobilization, and not traction, was chiefly indicated in the management of these cases, Thomas's splint would prove of great service, as it could be made by a blacksmith and a harness-maker at a cost of not more than \$2.50. Splints were exhibited, their construction was described, and their application was shown according to Mr. Thomas's latest methods. It was urged that the splint should not be considered as essentially a walking-splint, but that it should be applied to the patient while he was still in bed, and that he should be kept in the horizontal posture, though not necessarily in bed, till all involuntary muscular spasm subsided. Then he should be allowed to go about on crutches and a patten (on the sound limb). When it appeared that he was cured, the crutches and patten should be dispensed with and the splint shortened so as to reach only to the knee, and so continue for several months. The importance of not once removing the splint, to test the joint motion, was insisted upon as likely to prolong the disease and lead to ankylosis.

A Report on Advances in Ophthalmology, Otology, and Laryngology was read by Dr. JOSEPH A. WHITE, of Richmond.

**Primary Iritis, its Diagnosis and Treatment,** was the title of a paper by Dr. J. HERBERT CLAIBORNE, Jr., of New York (present by invitation). After an anatomical description of the iris and contiguous parts, he remarked that it was important to remember that, in a condition of health, the edge of the pupil rested on the anterior surface of the lens in moderate dilatation. The diagnosis was to be made by the signs rather than the symptoms of the disease. The chief signs were circumcorneal redness, steamy cornea, clouded aqueous, discolored iris, small pupil, irregular and puckered edges of the pupil, etc. Tenderness on pressure in the ciliary region was the symptom

indicating a high stage of ciliary congestion, but not necessarily of cyclitis. Treatment was comprised under the great "therapeutic trilogy"—local depletion, dilatation of the pupil, and systemic treatment. Local depletion was best obtained by that leech that took deepest hold, sucked the longest, and drew the most blood. Bleeding should be encouraged by hot applications to the bites. The position for the leeches was in the temporal fossa, in a horizontal line with the outer canthus of the eye, to drain the temporo-malar branches of the lacrimal arteries. He preferred to combine cocaine with mydriatics, on account of the greater mydriatic power of such a combination, and the analgesic effect of cocaine. He preferred duoboisine combined with cocaine. With regard to systemic medication, he used blue ointment, salicylate of sodium, iodide of potassium, the iodide combined with bichloride or biniodide of mercury, antipyrine, Russian or Turkish baths, and quinine for its general tonic effect. He laid much stress on the value of salicylate of sodium, especially in rheumatic iritis. It was also of great value in the specific forms of the disease, as assisting the action of the other agents. There was no need of opium or morphine in iritis. If the pupil could be dilated, pain would cease; if it could not, antipyrine was a good substitute for morphine. Too much stress could not be laid on the importance of the early treatment of iritis with regard to preserving the sight. The responsibility of treatment rested on him who saw the case first.

**Neurectomy for Facial Neuralgia.**—Dr. E. M. MAGRUDER, of Charlottesville, read a paper reporting two cases. The first was that of a gentleman, aged seventy-one, who had had persistent neuralgia for fourteen years that no medicine cured, although he had consulted eminent specialists. Seven drops of fluid extract of gelsemium, every three hours, gave greater relief than any other medicine except morphine. But, all medicines failing, the patient was chloroformed, and, with strict antisepsis, an incision was begun just below the lower orbital margin, over the infra-orbital foramen, and carried straight downward, parallel with the nose, toward the lip, ending on a level with the lower border of the ala nasi—about an inch long. The fascia and fibers of the levator labii superioris were torn through with the handle of the scalpel, and the nerve was exposed at its exit where it divided into its branches. Each branch—the palpebral, the nasal, and the labial—spreading into a fan-shape as it neared its destination, was dissected out as far as it could be followed without mutilating the face too much. The main trunk was then seized with a forceps at the foramen, drawn out as far as possible without breaking it, and cut off close to the bone, after which the various branches were divided at their farthest point of dissection. The wound was closed with fine silk sutures. There was at first considerable paralysis of the side of the face, with loss of sensation, but these had now disappeared except from the right half of the upper lip, which was still without motion or sensation. There had been no recurrence of the neuralgia. The patient felt like a new man.

The second patient was a lady, aged fifty-eight, who had had facial neuralgia for ten years. At first it was confined to the left lower jaw, never passing the middle line of the chin, but afterward extended to the left external ear, the temple and the side of the head above and behind the ear, the left side of the tongue, and then the left side of the floor of the mouth. The diagnosis was that of neuralgia of the inferior dental nerve, with reflex and sympathetic phenomena exhibited by the auriculo-temporal, gustatory, and mylo-hyoid nerves. As to treatment, teeth had been extracted, analgesics had been used, etc., and finally total neurectomy of the inferior dental nerve—including its branches—was done. In the operation, to avoid injury to the facial artery and Stenson's duct, the scalpel was inserted just in front of the posterior border of the ramus and

just below the parotid duct and lobe of the ear, and a curvilinear incision was made downward, half an inch in front of the inferior maxillary angle, then carried forward a little above the lower border of the ramus, and upward just behind and avoiding the facial artery, stopping short of the line of Stenson's duct above. The flap thus shaped was raised by shaving the masseter muscle from its attachment to the outer surface of the ramus, and the bone laid bare. With a half-inch trephine he cut out a button of bone from the center of the outer plate of the ramus, exposing the nerve in its bony canal. Seizing the proximal end of the nerve with a forceps, he made strong traction away from its origin; it was then cut off with scissors close to the bone as it entered the circular cavity made by the trephine. Then, the wound being stuffed with moist antiseptic cotton and the hemorrhage stopped with pressure, a second incision was made, an inch long, horizontal in direction, over the mental foramen (below the root of the second bicuspid tooth), beneath the depressor anguli oris, disclosing the mental nerve and its branches beneath the last-named muscle. The nerve was grasped with a forceps and pulled upon, but broke off at its point of exit. The branches were then dissected out and cut off as far as possible from the foramen. Then, returning to the first wound over the ramus, and chiseling away the wall of the dental canal for an eighth of an inch from the circular cavity in the ramus, so as to expose this end of the nerve, which had been divided by the distal side of the trephine, he drew it out of the dental canal with the forceps, in its entire length from the ramus to the mental foramen. In all, three inches and three eighths of nerve structure were removed. The wounds were closed, the patient was perfectly relieved, and there had been no return of neuralgia since. The paralysis of the left side of the face disappeared in about two weeks.

The lesson to be learned was that in all operations for facial neuralgia, as much of the troublesome nerve and its branches as the anatomical formation of the parts would allow of, without rendering the procedure too grave, was to be removed.

A Report on Advances in Neurology and Psychology was read by Dr. LEWIS G. PEDIGO, of Roanoke.

A paper on "Railroad Injuries" was read by Dr. C. R. CULLEN, of Waldo, Florida (present by invitation).

A paper on "Diagnosis by Means of Urinary Analysis" was read by Mr. HUGH BLAIR, of Richmond, a delegate from the Virginia Pharmaceutical Association.

Dr. A. F. KERR, of Williamsville, reported a case of external glanders in man.

Dr. W. W. PARKER, of Richmond, read a paper entitled "A Few Original Observations on Blood Gravitation in Health and Disease."

**Outline Tests for Muscular Insufficiencies of the Eye.**—Dr. A. C. PALMER, of Norfolk, read a paper on this subject. Leaving out of consideration cases of strabismus, etc., he confined his attention to the more minute forms of insufficiency known by the term heterophoria. In strabismus one eye soon accustomed itself to see the object looked at while the other was idle. In heterophoria there was acute normal vision, in which every detail of an object was seen; but the external rectus of one or both eyes was too weak to prevent the internal rectus muscle from turning the ball in just past the normal axis. Eyes such as these had to swing a very little way to make the image seen with one eye a little to one side of that seen with the other; and the confusion resulting was all the worse from the very fact that each eye saw so clearly that neither image could be ignored. The patient had before him two similar images, which were continually receding from and blending with one another. But he would involuntarily overcome this blurring of outlines if he could possibly spur up the externus insuffi-

cient to pull the eye out to its proper place. Just these insufficiencies or strains produced more mischief than true strabismus. Prisms deflected an image toward their apices or their edges. The relative strength of each of the four recti muscles in their normal conditions was presumed to be first ascertained. Thus the externi should diverge the eyes sufficiently to make the image single when prisms of  $8^{\circ}$  were placed before them with their bases in. The interni, after a little trying, should converge sufficiently to produce single images when prisms of  $50^{\circ}$  were placed before them bases out. If a patient with neurasthenia presented himself he should stand erect and direct his vision on a lighted candle twenty feet off. Then each eye should be covered alternately, and notice taken as to whether the light seemed to move up or down or to the right or left. This parallax test, introduced by Dr. Alexander Duane, of New York, often established at once the form of insufficiency. But, should it not do so, then the prism test should be used, which the author described in detail. He then explained the application of glasses to overcome each of the insufficiencies.

**Therapeutic Position in Sexual Congress** was the title of a paper by Dr. HENRY V. GRAY, of Roanoke, who recommended that, in cases of pelvic inflammatory troubles that were aggravated by coitus in the ordinary fashion, the woman should assume Sims's posture, and the man approach her from behind. He referred to several cases in which this device had relieved the pain of intercourse.

A paper on "The Use and Abuse of the Obstetric Forceps" was read by Dr. D. MAYER, of Charleston, W. Va., a delegate from the Medical Society of West Virginia.

Dr. L. B. ANDERSON, of Norfolk, presented a Report on Hygiene and Public Health.

Dr. J. G. WILTSHIRE, of Baltimore (present by invitation), read a paper on "Anæsthetics."

## Book Notices.

*College Botany*, including Organography, Vegetable Histology, Vegetable Physiology, and Vegetable Taxonomy, with a Brief Account of the Succession of Plants in Geological Time, and a Glossary of Botanical Terms; being a Revised and Enlarged Edition of the "Elements of Botany." With nearly Six Hundred Illustrations, largely from Drawings by the Author. By EDSON S. BASTIN, A. M., F. R. M. S., Professor of Botany, Materia Medica, and Microscopy in the Chicago College of Pharmacy. Chicago: G. P. Englehard & Co., 1889. Pp. 15-451. [Price, \$8.]

This work, compiled, as the author states, chiefly as an introductory text-book for use in our higher academies and colleges, we take pleasure in recommending, after a somewhat careful examination, as one of the best aids to the study of the interesting topic of which it treats that have appeared. The author has succeeded, by the logical arrangement of his subject, the lucid, simple, non-technical language of the text, and the copious, well-executed illustrations, in bringing our knowledge of the life-history of plants within the comprehension of any student of average intelligence, and the plan he has adopted of giving practical exercises at the close of each chapter, directing the student how to verify the previous lesson by his own experiments, adds great value to the work, and tends to make the study a pleasant recreation instead of a dry task. The execution of the wood-cuts is very creditable to the engraver, and the printing is all we could desire.

## BOOKS AND PAMPHLETS RECEIVED.

Die allgemeine Pathologie, oder die Lehre von den Ursachen und dem Wesen der Krankheitsprocesse. Von Dr. Edwin Klebs, O. Ö. Professor der allgemeinen Pathologie und der path. Anatomie an der Universität Zürich. Zweiter Theil. Störungen des Baues und der Zusammensetzung. (Allgemeine path. Morphologie.) Mit 79 farbigen Abbildungen in Text und 47 Farbentafeln. Jena; Gustav Fischer, 1889. Pp. xviii-836. [Price, 30 Marks.]

The Diseases of Children, Medical and Surgical. By Henry Ashby, M. D. Lond., M. R. C. P., Physician to the General Hospital for Sick Children, Manchester, etc., and G. A. Wright, B. A., M. B. Oxon., F. R. C. S. Eng., Assistant Surgeon to the Manchester Royal Infirmary, etc. London and New York: Longmans, Green, & Co, 1889. Pp. xix-681. [Price, \$6.]

Mother, Nurse, and Infant: a Manual especially adapted for the Guidance of Mothers and Monthly Nurses, comprising Full Instruction in regard to Pregnancy, Preparation for Childbirth, and the Care of Mother and Child, and designed to impart so much Knowledge of Anatomy, Physiology, Midwifery, and the Proper Use of Medicines as will serve intelligently to direct the Wife, Mother, and Nurse in all Emergencies. By S. P. Sackett, M. D. New York: H. Campbell & Co., 1889. Pp. viii-13 to 387.

Syphilis of the Nervous System. By H. C. Wood, M. D., LL. D. Detroit: George S. Davis, 1889. [The Physicians' Leisure Library.]

Fourth Annual Report of the State Board of Health of the State of Maine. For the Fiscal Year ending December 31, 1888.

Seventh Annual Report of the Provincial Board of Health of Ontario, being for the Year 1888.

An Experimental Study of Intestinal Anastomosis, with some Practical Suggestions as to a Modified Technique. By A. V. L. Brokaw, M. D., St. Louis, Mo. [Reprinted from the "Weekly Medical Review."]

Syrone: A Consideration of its Value as an Antiseptic. Copia in Surgery. By H. H. A. Beach, M. D., Visiting Surgeon to the Massachusetts General Hospital. [Reprinted from the "Boston Medical and Surgical Journal."]

Dress Reform and its Relation to Medicine. By S. Knopf, M. D., Los Angeles, Cal. [Reprinted from the "Southern California Practitioner."]

Light Gymnastics for Schools. By F. N. Whittier A. M., M. D., Director of Sargent Gymnasium, Bowdoin College, Brunswick, Me. [Reprinted from the "Fourth Annual Report of the State Board of Health of Maine."]

The Hydro-therapeutic Treatment of Typhoid Fever. By G. C. Smythe, A. M., M. D., Greencastle, Ind. [Reprinted from the "Transactions of the Indiana State Medical Society."]

Notes on the Electro-Magnet in Ophthalmology, with a Report of Nine Cases. By William Ellery Briggs, M. D., Sacramento, Cal. [Reprinted from the "Occidental Medical Times."]

A Few Observations on the Aëtiology, Prognosis, and Cure of Incipient Cataract without Operative Interference. By A. R. Baker, M. D., Cleveland, O. [Reprinted from the "Transactions of the Ohio State Medical Society."]

The Treatment of Typhoid Fever. By William G. Daggett, A. B., M. D., New Haven, Conn. [Reprinted from the "Proceedings of the Connecticut Medical Society."]

The Treatment of Fractures of the Neck of the Femur by Immediate Reduction and Permanent Fixation. By N. Senn, M. D., Ph. D., of Milwaukee, Wis. [Reprinted from the "Journal of the American Medical Association."]

Du traitement des fibromes utérins, par la méthode d'Apostoli (l'électrolyse utérine), avec une lettre-préface du Dr. Apostoli. Par le Dr. Delétang (des Nantes), chargé du service d'électrothérapie des hôpitaux de Nantes. Paris: O. Doin, 1889.

The Nervo-vascular System. [Three charts.] Arranged by W. Henry Price and S. Potts Eagleton. Philadelphia: F. A. Davis. [Price, 50 cents.]

Fibromes utérins, leur traitement par l'électrolyse (méthode Apostoli) et leur élimination fréquente sous-muqueuse par l'action de l'élec-

tricité. Par le Docteur La Torre (de Rome), etc. [Extrait, revu et augmenté des "Archives de tocologie."] Paris: O. Doin, 1889.

Some Uterine Displacements not Curable. What shall we do with them? By W. F. Rochelle, M. D., Jackson. (Read before the Tennessee State Medical Society at its Fifty-sixth Annual Meeting.)

## Miscellany.

**The American Public Health Association.**—The seventeenth annual meeting will be held in the hall of the Brooklyn Institute, Washington and Concord Streets, Brooklyn, on October 22d, 23d, 24th, and 25th. Addresses of welcome will be delivered by the Hon. Alfred C. Chapin, Mayor, on behalf of the city, and by Dr. Alexander Hutchins, on behalf of the medical profession. The following topics have been selected for consideration at the meeting: "The Causes and Prevention of Infant Mortality"; "Railway Sanitation" (heating and ventilation of railway passenger coaches; water-supply, water-closets, etc.; carrying passengers infected with communicable diseases); "Steamship Sanitation"; "Methods of Scientific Cooking"; "Yellow Fever" (the unprotected avenues through which yellow fever is liable to be brought into the United States; the sanitary requirements necessary to render a town or city proof against an epidemic of yellow fever; the course to be taken by local health authorities upon the outbreak of yellow fever); "The Prevention and Restriction of Tuberculosis in Man"; "Methods of Prevention of Diphtheria, with Results of such Methods"; "How far should Health Authorities be permitted to apply known Preventive Measures for the Control of Diphtheria?" "Compulsory Vaccination"; "Sanitation of Asylums, Prisons, Jails, and other Eleemosynary Institutions."

It is the purpose of the association to provide an exhibition of everything available adapted to the promotion of health. The exhibits will be classified as follows: I.—*The Dwelling*: 1. Dwellings; models and designs for sanitary dwellings. 2. Treatment of the site; foundations, drainage, drainage-tiles, etc. 3. Materials for construction; bricks, tiles, floors, cements, etc. 4. Heating; devices and appliances for furnaces, stoves, and water and steam heating apparatus. 5. Ventilation. 6. Lighting. 7. Domestic water supply, purification, filters, water fittings, etc. 8. Plumbing; traps, sinks, water-closets, baths, etc. 9. Disposal of waste; domestic garbage destructors, garbage receptacles, etc. 10. Sanitary furniture, refrigerators, wall-paper (non-arsenical), floor-coverings, etc. II.—*Schools and Education*: 11. Plans and models for improved school buildings. 12. Heating, ventilation, lighting. 13. Furniture and fittings. 14. Improved books, printing, etc. 15. Gymnastic apparatus. 16. Works on sanitary topics. III.—*Factories and Workshops*: 17. Designs and models for improvements in factories and workshops. 18. Life- and health-saving devices. 19. Special devices for removing dust and effluvia and preventing injuries from the same. IV.—*Clothing and Dress*: 20. Improved materials and garments, etc. V.—*Food*: 21. Selected displays of unprepared animal and vegetable substances used as food or in the preparation of food. 22. Prepared vegetable substances used as food, including canned and prepared and preserved fruits and vegetables; prepared cereals, meals, flour, biscuits, bread, etc.; syrups, sugars, etc. 23. Prepared animal substances used as food; canned, smoked, salted, preserved, and prepared animal foods, including honey. 24. Products of the dairy. 25. Beverages of all kinds; alcoholic, non-alcoholic, tea, coffee, cocoa, chocolate, etc. 26. New varieties of food; food for infants and invalids. 27. Articles and devices used in the preparation of food; cooking stoves, ranges, etc.; vessels for preserving food, etc. 28. Adulterants and adulteration. VI.—*Sanitary Engineering*: 29. Plans for sewerage and sewage disposal. 30. Plans for drainage. 31. Plans for water-supply, including purification, filtration, etc. VII.—*Public Health Administration in Cities and Towns*: 32. Treatment of contagious diseases, including plans for hospitals for the same. 33. Vital statistics, blanks, etc. 34. Disposal of waste, garbage destructors, odorless apparatus. 35. Anti-

septics, disinfectants, and disinfection. 36. Reports of local and State boards of health. VIII.—*The Laboratory*: 37. Instruments of precision in meteorology, thermometers, barometers, hygrometers, etc. 38. General chemical apparatus for a health laboratory. 39. Microscopes, etc. 40. Biological apparatus, cultivations, etc. IX.—*Red Cross Section*. The exhibition will be held in the hall at the northwest corner of Fulton and Pineapple Streets, one block from the Brooklyn Institute, where the sessions of the association will be held, and but three blocks from the bridge. It will be opened to the public on October 22d, at 1 p.m., and will continue open until December 1st. Admission free. Applications for space may be made to any member of the Committee on Exhibits, accompanied with details as to name and character of articles proposed, space required, and the name and address of the applicant. To cover the necessary expenses of the exhibition, each exhibitor will be charged ten dollars, allowing him twenty square feet of floor space, and thirty cents a square foot for additional space, to be paid on the second day of the exhibition. All proposals for exhibition and applications for space are subject to the approval of the Committee on Exhibits, and should, therefore, be made as promptly as practicable. At the close of the exhibition the association will award diplomas to exhibitors of specially meritorious articles, based upon the judgment of experts.

The chairman of the Committee on Exhibits is Dr. A. N. Bell, No. 113a Second Place, Brooklyn; its secretary is Dr. E. H. Bartley, 21 Lafayette Avenue, Brooklyn.

**The Health of Connecticut.**—According to the State Board of Health's "Monthly Bulletin," the total number of deaths reported from 167 towns during the month of August was 1,190, including 5 from scarlet fever, 15 from cerebro-spinal meningitis, 46 from diphtheria and eroup, 15 from whooping-cough, 3 from erysipelas, 45 from typhoid fever, 9 from malarial fever, and 12 from typho-malarial fever. There were also 120 deaths from consumption, 25 from pneumonia, and 13 from bronchitis.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the abstract of sanitary reports received by him during the week ending September 20th:

CITIES.	Week ending—	Estimated population.	Total deaths from all causes.	DEATHS FROM—										
				Cholera.	Yellow fever.	Small-pox.	Varioloid.	Variola.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Measles.	Whooping-cough.
New York, N. Y.	Sept. 14.	1,581,179	624						15	2	19	1	8	
Chicago, Ill.	Sept. 14.	1,100,000	360						9	2	17		4	
Philadelphia, Pa.	Sept. 14.	1,040,245	352						19	4	1		5	
Brooklyn, N. Y.	Sept. 14.	834,607	323						5	1	13		2	
Baltimore, Md.	Sept. 14.	500,343	164						6	1	5		2	
St. Louis, Mo.	Sept. 14.	450,000	165						5	2	5		1	
Cincinnati, Ohio	Sept. 14.	325,000	108						3	4	2		1	
New Orleans, La.	Sept. 7.	254,000	113						1	4			1	
Washington, D. C.	Sept. 14.	250,000	101						6	9			1	
Detroit, Mich.	Aug. 31.	250,000	79						22	2			1	
Detroit, Mich.	Sept. 7.	250,000	67						3	2	2		2

**Parasitic Fœtus in a Multiparous Woman.**—Early in 1888 we published an account of Laloo, the Indian boy, who bears a parasitic fœtus

attached to his epigastrium, consisting chiefly of the four extremities and nates. Messrs. Sutton and Shattock reported the case in the "Pathological Transactions" for the same year. Another case of parasitic fœtus is described by Dr. E. Bugnion in the "Revue médicale de la Suisse Romande" for June, 1889. The patient, whose photogravure adorns the paper, is a well-developed young woman with regular features. She was born in 1869. In front of the pubes is attached a rudimentary pelvis bearing two long, deformed, and partly atrophied lower extremities. Rudimentary nipples were found in the integument of the autosite's groin on each side of the attachment of the pedicle of the parasite. There were no signs of any external genitals on the parasite. The vulvar orifice of the autosite is anteriorly encroached upon by the parasite, and is pushed backward so that the perineum is reduced to a thin septum. The autosite, Louise L., of Reims, walks well; the monstrosity shows but little. She married three months before her fifteenth birthday. In March, 1885, her first, and in December, 1888, her second, child was born. She was suckling the latter when Dr. Bugnion examined her. He describes her as a dipygus parasiticus, or more strictly as a *pumbimèle* or *pygymèle pubien*. She is known as the *dame à quatre jambes*, and has been on show for some time, after the fashion of most monsters.—*Brit. Med. Jour.*

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

## Lectures and Addresses.

### AN ADDRESS,

DELIVERED ON THE OCCASION OF THE  
LAYING OF THE CORNER-STONE OF THE NEW BUILDING OF  
THE NEW YORK ACADEMY OF MEDICINE,

*On Wednesday, October 2, 1889.*

BY ABRAHAM JACOBI, M. D.

THE New York Academy of Medicine has called upon the profession and the public alike to assist it in this ceremony of laying a corner-stone. Where we are now standing there will be the home of the Academy, we believe, for generations to come. If we are mistaken, if this large building is too small before long, it will be the pleasant duty of our successors to provide for their wants. That this may become necessary is possible, for the Academy has experienced a development rapid beyond expectation. Forty-three years ago it was founded; for dozens of years it held its meetings in hired quarters; ten years ago it occupied its own building, No. 12 West Thirty-first Street; today we are preparing accommodations such as the profession of New York, or any other city of the country, has never possessed. Meanwhile, however, the spirit and the aims of the Academy have remained intact. Among these aims are the cultivation of the science of medicine and the promotion of public health.

In the words of a circular published nearly two years ago in behalf of our building fund, "these purposes are accomplished by lectures and discussions in the stated meetings of the Academy and its numerous sections; by maintaining reading-rooms which furnish nearly all the medical journals of the world, and by collecting a library containing about sixty thousand books and pamphlets, which are free both to the medical profession and the public." The number of its fellows is nearly six hundred. They have been selected from among those who have practiced medicine in New York city or its vicinity three or more years. Some time ago fellowship was extended to those residing in the State.

In its composition the Academy participates in many of the peculiar features of our political organization, which means to benefit all through the co-operation, if not of all, still of the best. In Europe an academy of medicine means a small body comprising a few select men only, appointed by the body itself when there is a vacancy, or by the political rulers. Thus the academies form an aristocracy of the mind parallel to the aristocracy of birth, with all its exclusiveness and real or assumed superiority. They are representative bodies only in this, that the best minds and most scientific workers are expected or believed to fill the seats.

The New York Academy of Medicine, however, is a democratic institution. It is not limited in numbers; on the contrary, it is desirable that the many respectable physicians should gather round its flag. Like our political commonwealth, it must look for its development and success in the co-operation of the competent and cultured

masses. Like the Union, it is a voluntary confederation of peers who make their own laws and obey them because they are of their own making.

The members have common interests both scientific and professional. Since its foundation, with the changes for good and bad appertaining to everything organic, the Academy has prospered constantly, in spite of, or, as I am more inclined to say, in consequence of its very constitution as an independent and democratic body. In the words of the same circular alluded to before, "the Academy is not connected with any school or college. It is self-supporting and is carried on in the interest of the whole profession. There are no fees nor emoluments of a private or individual nature. It is not supported nor subsidized by the State or municipality." Whatever has been accomplished by it: its scientific labors, most of which are laid down in its "Bulletins" and "Transactions," and in the medical journals of the country; the hall in West Thirty-first Street; the library and reading-rooms in the upper stories; the wealth of books and journals at the disposal of those eager to learn, and so numerous that they alone compelled us to look for more appropriate quarters—all of that has been created, with few exceptions, by the exertions and pecuniary sacrifices of the medical men themselves.

All classes of these are represented in the Academy. It shows you the choice of those who are interested and active in the promotion of medical science and art; those who have earned an international reputation; those who have deserved well of the community by a life filled with services rendered to the public; and those who look forward for the fulfilling of their dreams and the reaching of their aims through coming years of honest labor spent on theoretical study and practical work. In this co-operation of the old and young, the illustrious and those yet unknown, but promising or anxious to earn renown, the mature and the maturing, you have one of the features of a unity of the profession.

Another feature of unity, which, moreover, ties the profession indissolubly to the community at large, is the labor performed in the service of one and all. It is in these labors and their results that the community at large ought to take a deep interest. Modern medicine is probably the greatest benefactor of mankind. The more medicine has been founded on the study of the exact sciences, chemistry, physics, and physiology with mathematics, the more has its field of usefulness enlarged. The more theoretical it appeared to become, the more did it develop practical usefulness and dignity. Indeed, the dignity of a science or study rises with its capability of being utilized in the service of mankind. Now, the promotion of medical science and art does not mean only the improvement in diagnosis and in the administration of drugs and remedies, but the discovery of the best means of placing the human being in the best possible condition. The labor of the physician is not exhausted by carrying you through a severe case of illness; he renders you the greater service, less remunerative to him though, of preventing you from falling sick.

The peculiar relations of the individual physician to his

patient or the family intrusted to his care are widened in the relations of the profession to the public. Great epidemics take the place of a single case, the protection of a community that of guarding a person, the hygiene of schools that of a dwelling, the sanitation of a large city that of inspecting a suspicious trap or sewer in a private domicile. The more in your health department the medical element predominates over the military and political, the more actual benefit will the people derive from it. The hygiene of the whole population—the superintendence of public buildings in which many people, old or young, are gathered, public hospitals, quarantine stations; the questions of physical and mental elevation, of legal responsibility, of the State care of the insane—they all belong to the domain of the profession. This is not theory only. No grave question of the kind has come up without the gratuitous and spontaneous aid of medical men. The health board of the city has long appreciated that. The Academy has furnished a consulting board to all the health department's hospitals. A committee of the Academy was intrusted with the inquiry into and the report on the condition of Quarantine. It is to its report that the first appropriation for the rebuilding of the Quarantine Station was due, and to its recommendations that improvements are being carried out at the present time. In this way the medical profession excludes epidemics, and guards both the physical health and the economic interests of the city. Imagine the pecuniary loss to the city if the cholera and the yellow-fever scare of a year and two years ago had not been prevented by the profession, as indeed it was. A week's panic would have been a pecuniary calamity amounting to the loss of a good many millions.

These are but a few examples of the value of medical services, both paid and unpaid ones, to the public. The health of the city is the foundation of its prosperity. Let epidemics prevail, and not only will your children die, your families be decimated, and the graveyards fill with places where flowers and tears mingle, but your commerce will be drawn to other ports. It is due to increased knowledge and activity on the part of the profession, both official and unofficial, that, in spite of the unchanged severity of the epidemics and the rapidly increasing population of the city, the number of cases of diphtheria shows an absolute diminution.

Such among many are the services of the profession, not to speak of the gratuitous daily work of hundreds of medical men in the hospitals and dispensaries. Nobody can count or calculate, but everybody can appreciate, how many lives are preserved, how many millions are saved for the poor and rich alike. From that point of view a whole-souled, generous woman presented to the Academy twenty-five thousand dollars, in recognition of the services to the public on the part of the profession, and in accordance with the esteem her husband had held the profession in while he was alive. To this consideration we owe the bequest of seventy thousand dollars, coming to us under the will of Mrs. Alexander Hosack, who had spent a large part of her valuable life with illustrious examples of professional worth. All we require now is fifty thousand dollars to complete

this building. There must be many who have that sum or a part of it to spare in the interest of the profession; perhaps to commemorate the name of a dear one who has passed away, or to imprint his or her name—and a legitimate ambition it is—on one of the halls of the new building, or to perpetuate the memory of one who has been saved from a premature grave by the endeavors of one of those who are now striving to erect a home for the most practical and beneficent of all sciences and arts.

It is a home we want, more than merely a house. To make the house of the medical profession a home, it requires a library. This is to the profession what a tool is to the mechanic, an engine to the engineer, a telescope to the astronomer. A complete library represents the thoughts, experience, genius, and discoveries both of all previous centuries and of the present time. All these treasures must be accessible to the profession whose knowledge and skill is to be the safeguard of the public's best interests. To accomplish that end, the whole medical literature of all countries must contribute. New York has never been satisfied with anything that is second class; it can not afford to trust itself to a profession without the first order of learning and erudition.

Why do we insist upon physicians being erudite? Do I ask, Why do you apply to a particular watchmaker, an engineer, an architect, a milliner? You select him because you believe or know him to be well informed or skillful. And the physician? His practice is the application of knowledge acquired by hard brain work spent on all the learning and practice which have been evolved out of the labor and efforts of thirty centuries. A learned doctor may happen to be an unsuccessful practitioner, for more reasons than one; but among those reasons erudition is not. An uninformed man is never a good practitioner; under equal circumstances, the more learned man is the better man in practice. Practice and learning do not exclude each other; on the contrary, the former depends on the latter. It ought not to suffice for your selection of a doctor that you met him at a bar, or a ball, or at a church meeting, or at whist, in a concert, or on a hotel piazza, or that he is well dressed, pleasant, and tells you he is your "friend"; all these are fine opportunities and agreeable social and personal qualities which may also be considered when you are credibly informed that he burns midnight oil over medical literature and that his professional brethren speak well of his abilities and achievements. And as far as medical friendships are concerned, your best friend is he who knows best how to protect you and your children and your parents from disease, and to cure them when they are sick.

The erudition we claim for the profession demands a large library of constant growth. A fund of one hundred thousand dollars will enable us to keep abreast with any similar institution. The library of the Surgeon-General's Office in Washington, which contains at present seventy thousand volumes and one hundred and thirty thousand pamphlets, is the result of industrious and systematic collections. It is not much over twenty years old, but it is the richest and most complete medical library in the world. Still its annual appropriations for the purchase of books

have seldom exceeded five thousand dollars. Thus a fund of a hundred thousand dollars will enable us to procure nearly everything medical that appears in any land. Of that sum we have only ten thousand dollars. One half of that sum was set aside by the Academy, the other half is a donation separately administered in perpetual honor of a departed one. Such special funds, or additions to our general library fund, are urgently requested. The citizens of New York have developed a metropolis of large size and commercial power; they can well afford to tax themselves in the interest of medical science, than which there is none more cosmopolitan and humanitarian.

But it is not the medical profession only which will be directly benefited by the endowment of a large and complete library. Our library is a public one, free to the profession and the public. Now, there is a class of literature which in a free and public library like ours ought to be well represented. Laymen intending to avail themselves of it expect to find mental food adapted to their comprehension and taste. That sort of literature is by no means scarce. Much of it is of fair quality, some of it surpassingly good. Books on anatomical and physiological topics, those on subjects connected with natural history, hygiene, and statistics, will always be found interesting and instructive. They ought to be well represented in our library, for they can not be found in large numbers in the public and circulating libraries. Indeed, the frequenters of the latter differ much from the class of readers consulting ours.

The additional knowledge acquired in this matter will not only improve a man's ability to protect himself and his family; it will also facilitate the work of his doctor. A person who has filled his mind with comprehensible ideas and sound facts will no longer study quack advertisements. He who has learned something about the functions of his body, and been taught to consider the correlation of causes and effects, can appreciate a disease to be the result of either a preventable or an unavoidable cause, and recognize that whatever disease was not the result of faith can not be cured by faith, not even by faith in panaceas. The business of the quack may thus cease, the nostrum-mixers may suffer, but individual and public health will be the gainers. There is less sickness in a man who has some knowledge of his body and its requirements; and when he falls sick he expects relief from natural and intelligible sources only. That man is a better patient, more accessible to reasoning, more obedient to the rules imposed in the interest of recovery. If he knows enough to recognize the superiority or inferiority of his physician, so much the better. To-day most people have not a sufficient knowledge to guide them in their selection; there are many who are so little informed that they do not so much as care. If in a matter ever so trifling a medical man is called as a witness before a court of justice, the first question he is asked refers to his membership in a medical society. The uninformed public, however, often select their doctor for reasons known to nobody, least perhaps to themselves. All this would be changed if a small part of what is the basis of a physician's thinking and knowing were made accessible and intelligible to every man and woman. A library like that which we

intend to establish is destined not only to supply the professional man, but to furnish healthy mental food to all those who are thirsty for knowledge. Those who have means to spare in the interest of public education, hygiene, and health, can not possibly apply them better than by providing for a library fund sufficient for the gradual accumulation, from year to year, under the supervision of experts, of all the good popular literature on the subjects of anatomy, physiology, hygiene, dietetics, and statistics.

May all this become true. We are preparing this edifice to be the head-center of medical study in the city, an example to the profession of the country, and a resort for the brethren who come to us from near or distant parts. This building when completed will be an ornament to the metropolis. What is still more important is that we mean it to become, and feel assured that it will be, an additional element of intellectual and ethical power, and in its results a blessing to the commonwealth.

### ANGULAR CURVATURE.

NATURE OF THE PHYSIOLOGICAL FAILURES WHICH SUPERINDUCE VERTEBRAL DEFORMITY.

BY GEORGE H. TAYLOR, M. D.

WE are now in a position to understand more fully the nature, kind, and degree of the several physiological defects which culminate in posterior deviation of form of the spinal column and the morbid changes of figure associated therewith.

Since the spinal muscles are charged with the duty of maintaining the erect position and of executing the motions of the column, these muscles are necessarily associated with its functions of elasticity and flexibility, on which, as has been shown, its nutrition and therefore its health depend. The columnar functions are consequently in a sense derived, inasmuch as the force required in the execution of flexion, elasticity, and even sustentation, is yielded to it by its muscles. The muscular force is resolvable into the two physical forms of mechanical (or dynamic), which changes the relations of parts *en masse*, and the chemical, which changes the relations of constituent elements, and thus the constitution of the mass. The manifestation of force or energy in the above-named forms implies expenditure of material entering the organism as nutrition, and is the indispensable condition for the resupply of such material to the acting muscles. Muscular nutrition requires muscular expenditure; otherwise it becomes both faulty and insufficient.

Failure of the spinal and associated muscles leaves the column unsupported in proportion to the degree of such failure. Insufficient power of these muscles affords inadequate support, and at the same time withdraws from the column its elastic and its flexible functions, and thereby inflicts on it grievous injury, which, if continued, becomes incorporated in some morbid form in its tissue.

The immediate effect of suspension of muscular power is well illustrated in a case of falling asleep in the sitting posture. The head and shoulders are surrendered to gravitation, are pulled forward, causing the column, the posterior boundary of the body, to become *bent*, the convexity being backward. When, therefore, a posterior curvature is observed, the inference is unavoidable that the weight of the upper portion of the trunk has for some time been inadequately or improperly supported by the parts to which nature has assigned that duty. The difference in the two cases is that, in case of sleep, the supporting muscles immediately resume control when slumber has departed, while in that of deformation the loss of control of the column by its muscles is absolute. A renewal of the supporting power of the appropriate muscles is required alike in both instances. Substitutional and indirect methods of support are impracticable; if practicable, then injurious, because undermining the vital power of the muscles, on which the responsibility of support ultimately falls.

The above statements, so far as representing the supporting function of the spinal and associated muscles, are too obvious to admit of question. Indeed, the therapeutics of angular deformities is practically based on them. But mechano-dynamic facts are only partial, and alone afford erroneous therapeutic views and practice. The inseparable accompaniment of the mechano-physics of muscular function is its chemico-physics. It is essential that this department of muscular function be practically recognized. Otherwise the therapist is indifferent as to the source and the nature of support, and falls into the error that mechanism will serve the desired end, even though vito-chemical physics, of which muscles are the sole source, be omitted, even ignored. For muscular support of the column, though dynamic and mechanical as respects the column, yet involves change of the substance yielding the energy affecting every cell of the muscles engaged, and as far beyond as the motor influence extends. This last process is as essential to the maintenance of the muscle and the perpetuity of the supporting power as are the motions communicated to the column to the maintenance of *its* nutrition and functions. Both necessarily fail in the absence or even decline of these indispensable conditions. Nutritive acts are the fundamental basis of all organic power, and it is idle to devise substitutes therefor.

The attempted substitution of mechanical devices for the natural supporting power, under the idea that such substitution is somehow remedial, grows out of the restricted conception of the needs of this class of cases, and of the physiology of muscular functions above shown. The necessity to the sufferer for the vito-chemical phase of muscular functioning is lost sight of, and all provisions for supplying that need are consequently omitted. When, therefore, it is found that the spinal column has developed a posterior projection, angular or otherwise, much more is signified than defect of mechanical support. The disastrous consequence to the form of the vertebrae is ushered in and, in general, attended by defective functioning of muscles in their vito-chemical phase of function, precedent to their mechanical failure. It is easily seen that the supply of mechanical sup-

port by art, however perfect this may be, can not have the least influence toward restoring an adequate vito-chemical phase of muscular function, nor can such supply mitigate the consequences arising from defective chemical functioning of muscles.

The morbid posterior projection of the spinal column includes, therefore, the following particulars: Defective support and defective control of the motions due the column by the muscles on which this mechanical function devolves; defective evolution of energy in its dynamic form by the same muscles; defective degree attained by their vito-chemical functioning; defective elimination of products of waste due to such functioning; injurious retention of unfunctioned, and therefore unstable, ingredients. The muscles henceforth become incapable of providing for the nutrition and renewal of their own substance. This defect imposes the same disadvantage on the tissues of the column, which have been shown to depend on the energy developed in muscular substance. These failures are necessarily self-perpetuated. Remedies are required to reach, not merely one, but each and all these several defects above shown.

*Spinous Processes and their Functions.*—To show more clearly the way in which muscular failures operate upon the mechanism of the column to produce the morbid form, further details respecting its mechanical and its vital constitution are necessary. In describing the vertebrae, their *spinous processes*, projecting posteriorly from each, were mentioned. These processes are very intimately connected with the development of the morbid form under discussion—not merely because of the extraordinary prominence of one or more of them which characterizes and affords the earliest intimation of the disease, but also because these processes have a direct and important mechanical function in connection with the supporting muscles.

The spinous processes may be assumed to project from a half-inch at the lower part of the column to an inch and a half at its upper portion. They incline downward (the upper much more than the lower), thus overlapping each other, and, when the column is erect, consolidating the vertebrae into a whole of extraordinary resisting power, since the arrangement described practically increases the antero-posterior diameter of the column.

The great importance of these spines lies in their function as mechanical levers, through which the control of the column by its muscles is increased many times. Their aggregate length determines the aggregate leverage they afford for any force applied at their ends—the fulcrum being the center of the vertebrae. The physiological purpose of this mechanism is too clear to be mistaken. It affords a practical and effective counterpoise to the weight of the trunk anterior to the column so long as it is available. This counterpoise declines and ceases with the decline and suspension of the power by which it is made effective. Thenceforward the column is practically shorn of its spines. They become again operative through restoration of the spinal muscles to their due power, while under artificial mechanical support they are of no account.

The spinous processes present an extensive surface for the attachment of the muscles which control the column

through them. The peculiar and complex arrangements of these muscles, their divisions and subdivisions, their extension from the bodies of vertebrae to the spines of other vertebrae, and the contrary, well known to students of anatomy, are admirably adapted to afford all the complex motor results which the column is well known to manifest. The acts of bending, twisting, and combinations of these motions become practicable and easy. In these motions the spinous processes engage, and thereby become instrumental in largely increasing the initial energy afforded by the spinal and associated muscles.

The importance of the forces, dynamic and vito-chemical, having their seat in the spinal and associated muscles, is so great and so liable to escape recognition in practice, and the consequences of failure are so difficult to overcome, that further illustrations tending to enforce the leading facts appear justifiable.

Let us imagine a piece of wood or whalebone similar to what is sometimes used by ladies—long, thin enough to secure elasticity, and wide enough to resist efforts to bend it in its transverse or widest diameter. Let notches be so deeply cut very near each other, at uniform depth in its breadth, that the uncut portions shall be of nearly equal thickness in both directions. The parts between the notches are comb-like teeth or serrations. These may represent the spinous processes, and the whole (Fig. 1) is a similitude of the spinal column. The piece of wood or bone thus prepared yields to force applied in any direction at any part.

Should a thin slip or string of elastic rubber be deftly attached to the ends of all the projecting spines, the representation of a column would be fitted with a similitude of spinal muscles. If, now, attempts be made to bend this preparation in the direction *opposite* to the spines and rubber, such attempts would be met with stout resistance, and the resistance will be proportionate to the *length* of the teeth or spines. It is thus shown that the spines of the column are true levers, and, by assisting to counterbalance the weight of the anterior part of the body, have the effect of practically moving the center of bodily gravitation forward of the column.

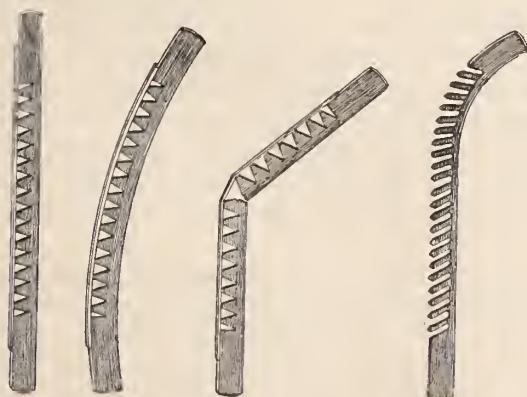

FIG. 1. FIG. 2.

FIG. 3.

FIG. 4.

Further experimenting with the same mechanical device shows that when the combined resistance of the uncut part and of the rubber is uniform, the act of bending causes it to assume the form of a segment of a circle (Fig. 2). When,

however, force is applied in excess of resistance, the device yields at *one* point only, while the remainder, being entirely released from strain, assumes the form of two straight lines meeting at the yielding point, and the angle formed is exaggerated by the nearest spine becoming thrust outward (Fig. 3).

A slight modification of the device above described enables it to become helpful for the illustration of another mechanical principle represented in the column. If the notches in the elastic object be made diagonal instead of at right angles to the uncut part, the teeth or spines will overlap each other. When it is bent, after connecting the rubber with the ends of the spines as before, these ends are projected outward and upward. The spinous levers, becoming horizontal, are extended further from the body or uncut parts; they are practically longer and afford more leverage (Fig. 4). This shows that when the body is bent, especially forward, nature provides a special mechanism to antagonize the evident mechanical disadvantage of the position. This becomes inoperative in proportion as the spinal muscles are weakened or restrained from any cause.

A very important function of the spines connects them with the form of the column. All healthy persons have *natural curves* of the column, throwing the shoulders and hips backward and the chest and abdomen forward, the center of gravity corresponding with a perpendicular line between these extremes. It is pretty certain that the action of the spinal muscles, acting through the levers provided therefor, is instrumental in causing these curves. The curves are absent in children, and appear with the use of spinal muscles. These curves, therefore, naturally disappear with the suppression or with the loss of muscular power. But the maintenance of the erect position *necessitates* the maintenance of the same perpendicular over the base. The decline and loss of musculo-spinous sustentation causes the trunk to fall forward; the hips are therefore compelled to project in the same direction, and the *intervening part of the column* is carried in the *opposite or backward* direction from mechanical necessity.

*Review of the Consequences of Insufficient Power of Spinal and Associated Muscles.*—The results toward which decline of function of the sustaining muscles of the column tend may now be clearly understood. The advantages of spinous leverage are unavailable; the weight of the anterior superior portion of the body is unantagonized; the trunk falls forward, dragging the column after it, into a curved or inclined form. The anterior longitudinal half of the column is shortened; its tissues, by virtue of their elasticity, become compressed. This compression takes effect only in the frontal portions of the vertebrae and intervertebral cartilages.

It is under these circumstances that the distinction between the natural *alternate* or interrupted compression and *continuous* compression may be realized. The one is physiological, the other pathological, leading to further advanced pathological states. Physiological compression is never constant; it is alternate and interrupted; in other words, rhythmic. This form of motion is everywhere present in living organisms. The substitution of *continuous* pressure in place of the *interrupted* form is equivalent to suspension

and ultimate destruction of vitality. Decline of the motions characteristic of the column is as fatal to that organ as would be decline of mechanical action of the lungs, the abdomen, the circulatory and other special mechanisms of the body. It means impairment of tissue nutrition; it is a morbid condition and the harbinger of the gravest consequences.

It is necessary at this point to remind the reader that the disclosures of *post-mortems* and the distorted vertebrae seen in pathological museums do not in the least indicate the *causes*, or rather the nature, of the failures of the physiological order to which such results are due. They only represent the stages arrived at in special instances of the disease, not the initial or the intermediate stages, nor the primary factor of the affection. This is simply defective function and cognizable by the understanding rather than the eye.

Continuous pressure of the anterior portion of the columnar tissues produces local consequences which next demand attention. The diminished space into which the structures of the column are crowded urges therefrom the fluid contents of the interspaces of the tissues, closes the inlets for arterial blood, and deprives them of supplies, both of nutritive materials and of oxygen. At the same time the lack of *alternations* of motion prevents that exchange of material necessary for the maintenance of local vitality.

Compression as above defined not only debars inflow of fluids bringing support of vitality, but unquestionably facilitates outflows; for structural parts, under the circumstances of diminishing and departed vitality, tend toward a liquid exit form, and are urged from the point suffering morbid compression, to join contiguous venous fluids. This process is technically known as *absorption*. The anterior parts of the vertebral bones and cartilages under this process become thinner than the posterior parts of the same, or wedge-shaped.

A change of form superinduced by local absorption under pressure is by no means confined to the columnar tissues. It is a common occurrence in other tissues subjected to the same or similar causes. Examples are abundant in physiology, pathology, and therapeutics. Local loss of substance is inevitable when vital structures are compressed, whether spontaneously or through the intervention of art. This statement is corroborated by reference to the local effects of the hernial pad of the truss, to the leg on which is worn a tightly fitting garter, to the waist of the would-be fashionable. Local compression is used as a successful surgical recourse to restrain morbid increase, as of tumors. The ligation of arteries to restrain a morbid supply of nutritive materials for a region of the body is a neat instance in point. The effect of pressure in each case accords with what is above stated to occur in the columnar tissues. Examples are not wanting of the same consequences of local compression in osseous structures, as when instruments are applied to crooked limbs, superinducing compression of one side of a shaft of bone to secure straightening. The misshape of vertebrae seen in *lateral* curvature of the column is but another example of morbid compression, partly from weight,

with the co-operation of unequal development or asymmetry of the two lateral halves of the body.

Even the hardened bones of the aged are not exempt from the operation of the same law. The rounded form of the shoulders of old men and women and of those whose occupation compels much continuity of compression of the anterior longitudinal half of the column, are familiar illustrations. Even the lower segment of the column has been molded to a curve under similar influences.

The inquiry will be made, Why is the angular form assumed by the column in some instances, while the curved form results in others apparently similar? The angular form is in accord with the mechanical principles engaged, as has been shown. When a stick is overstrained it breaks at one, not at several points. No object, physical or vital, can possess throughout absolutely uniform powers of resistance. Even this quality could avail nothing, because no assurance would be afforded that morbid forces would be presented to all parts with absolute uniformity. Local manifestations of disease in general indicate the weaker—that is, less resisting—points of the organism.

The plausibility of the theory that local injury to the column is the usual cause of localization, if not of the disease itself, has led to its adoption by many pathologists. When, however, it is considered that children and youth receive numberless blows, shocks, and hurts upon the column, with no other result than rapid recovery, the same as follows in case of injury to other parts, the probability as regards the class of causes mentioned is much diminished. Besides, the most searching inquiries usually fail to elicit any history of previous mechanical injury in angular cases that could be fairly construed as an adequate cause of the morbid outline.

*Radical Sources of Angular Deformity.*—The mechanical and the dynamic failures which ultimate in vertebral affections have now been outlined. These failures clearly have their source in defective energy due from muscles. The spinal column is composed of tissues which have no motory power, while diversified motory functions are demanded of the column, the execution of which is confided entirely to appropriate muscles, the non-performance of which is in itself morbid and leads to further expressions of disease.

But the failure of musculo-dynamics was stated above to account in part only for the pathological situation, this form of failure being as evident in lateral and other morbid curves of the column as it is in the angular form. Other considerations must be added to complete the pathological picture, and to afford the necessary therapeutic suggestions.

The muscular system has been shown to possess two co-ordinate functions—that of mechanico-physics, which has been sufficiently explained, and that of chemico-physics, whose importance demands further elucidation. While mechanical energy is being expended, whether for objects exterior to the vital organism or those interior to it, organic ingredients are being converted at corresponding rates into the well-known emergent forms. As shown in another connection, the constituent ingredients of the vital organism, together with all superfluous nutritive matters, become in

this way transformed from unstable to stable forms. So far as is known, the muscular system, including the involuntary as well as the voluntary muscles, is both directly and indirectly responsible for the execution of this work.

Now, defective functioning of muscles on the chemico-physical plans may be regarded as resulting in two principal ways, depending on the vital capacities of the subject, natural or acquired. It is unnecessary to refer here to but one of these ways. In this the subject *inherits* weak muscles, especially of the involuntary class—those belonging to internal organs. Or, being bred in unhygienic surroundings, such as defective ventilation, too high temperature of living-rooms, lack of adequate incentives, mental and physical, etc., the same sort of laxity of muscle is *acquired*, especially in youth. The essential defect consists in insufficient motor impulse derived from muscles to insure the desired degree of chemico-vital physics. The consequence of imperfect functioning is that either the gross expenditures are insufficiently transformed, or that a part only of such matters reach emergent forms, while a residue remains unaffected, and of necessity is retained.

The circumstance which determines the last-mentioned condition is the different degrees of susceptibility to the influence of oxygen of the different classes of organic ingredients. The nitrogenized class is much more refractory than the non-nitrogenized, and to secure the physiological degree of oxidation a certain degree of expenditure of motor energy is demanded. This natural difference is, therefore, greatly increased when the amount of oxygen supplied to the system is restricted by the feeble working of the respiratory mechanism, and when it is again restricted by the inadequate incentive arising from too feeble contact of changing ingredients entirely due to defective motions.

Whether or not the proposition be accepted that excess of albuminoids in some form is characteristic of the scrofulous series of diseases, this fact is undeniably recognized in practice, if not by formal statements. It is the *source of this condition* which most needs recognition. Ordinary prescriptions for the benefit of the scrofulous condition, however manifested, are quite certain to include what may properly be termed *reducing agents*, designed, both directly and indirectly, to aid in various ways the process of transforming irrelevant, superfluous, and obstructive ingredients of the vital organism to some stable and emergent form.

If further reasons are required why angular instead of circular forms of the column supervene under the physiological failures above detailed, it may be sufficient to note that the scrofulous condition is one of less vitality than exists in any other, and therefore more favorable to physical morbid changes from physical causes. The least, even temporary, increase at one point of morbid impulse determines the permanent fate of such locality.

The principal reasons for the very moderate and questionable success of the usual therapeutics of angular curvatures have now been shown in the statements above made of the nature of the physiological failures from which this affection arises and on which it depends. Therapeutic requirements have a natural basis in physiological defects. To substitute something else to maintain appearances is

unworthy of the profession. What is plainly required in these cases is restoration of the supporting power of muscles, restoration of the elastic and flexible functions of the column, through which alone *its* nutrition becomes possible, and, from first to last, restoration of the chemico-physics of the spine in connection with that of the whole organism by such means as render these permanent and not deceptive.

## SOME POINTS IN THE PATHOLOGY AND TREATMENT OF DISEASE OF THE NASAL PHARYNX.\*

BY JOHN N. MACKENZIE, M.D.,  
BALTIMORE.

THAT the nasal pharynx is exquisitely sensitive to reflex-producing impressions is a fact which has been known for some time, and the older medical literature contains isolated examples of neurotic phenomena of various kinds emanating from pathological conditions of this region. These reflex neuroses of the nasal pharynx were, however, almost unknown except to special workers in this field until the publication of a brochure by Dr. Tornwaldt, of Dantzig,† in which prominent attention was drawn to the subject, and which invested the so-called bursa pharyngea with a pathological importance hitherto unrecognized and undescribed.

According to Tornwaldt, this bursa is a constant integral part of the rhinoscopic picture, and can always be recognized, sometimes as a furrow-shaped, sometimes as a blind *cul-de-sac*, directly in the middle line in the center of a curve drawn from the upper edge of the posterior nares to the atlas. This sac is the frequent seat of various pathological processes—hyperæmia, cystic formations, hypersecretion, and simple and purulent inflammation; and these often lead to reflex disturbances—such as asthma, cough, nasal polypi, various ear troubles, neuralgia, inflammatory conditions of the naso-bronchial tract, etc. He furthermore maintains the proposition that naso-pharyngeal catarrh has its starting point, in very many cases, in a localized pharyngeal bursitis, and that its cure is only possible after destruction of the bursa itself. His treatment, accordingly, consists in the obliteration of the bursa by means of nitrate of silver, following insufflations of this agent (one to ten) with the application of the fused solid directly to the sac. Tornwaldt's hasty enthusiasm carries him to the startling statement that, of 892 cases of naso-pharyngeal disease examined by him, 202 were primary affections of the pharyngeal bursa.

There are many objections which may be urged against the theory of Tornwaldt. In the first place, the very constancy and existence of the pharyngeal bursa is a subject of dispute among distinguished anatomists, and, according to my experience, the appearances described by Tornwaldt are by no means constant in the rhinoscopic image.

\* Read before the American Laryngological Association at its eleventh annual congress.

† "Ueber die Bedeutung der Bursa Pharyngea," etc., Wiesbaden, 1885.

In the second place, when we consider the changes which take place in the pharyngeal vault during the different stages of inflammatory affections of the nasal pharynx—the frequent formation of cysts of varying shape and contents, the formation of depressions, furrows, and other conditions of the pharyngeal tonsil—it will be readily understood how easily mistakes in diagnosis may occur, or how difficult it often is to differentiate between well-recognized appearances in the pathological anatomy of post-nasal inflammation and the theoretical primary bursitis of Tornwaldt. That such errors have been indeed committed is evident from some of the literature on the subject.

It is highly improbable, nor are there any just grounds for belief, that an organ of such comparatively trifling anatomical and physiological importance should be vested with the peculiar privileges assigned to it by the followers of Tornwaldt. Since I became aware of Tornwaldt's researches I have searched in vain for what might be unequivocally termed a primary pharyngeal bursitis. When the bursa has been involved, it has been so invariably in connection with well-marked and far-advanced naso-pharyngeal disease. So that, from the standpoint of my own clinical experience, I am unable as yet to confirm the observations of Tornwaldt. Naso-pharyngeal disease is the most common affection of this climate, and the innuendo of Carroll Morgan—that the postulate of Tornwaldt regarding the great frequency of primary disease of the bursa, living, as he does, in a city of small population, has not been confirmed by the vast majority of specialists residing in large cities, and commanding an immense amount of clinical material—may possibly carry with it considerable force.\*

While, then, Tornwaldt's observations must, for the present, be taken with a considerable amount of reservation, they have, at least, directed prominent attention to a field of naso-pharyngeal pathology of exceedingly great interest and importance. From them we may learn the lesson that, in order to dissipate certain inveterate naso-pharyngeal affections, we must not rely on astringents, alteratives, *et id omne genus*, but we must destroy the source of the discharge.

My own observations concerning this class of naso-pharyngeal neuroses may be briefly summed up in the following propositions:

1. The nasal pharynx is, in quite a large proportion of individuals, exceedingly sensitive to reflex-producing stimulation.

2. The areas chiefly involved are the posterior portions of the turbinated erectile tissue and various points along the upper and posterior portions of the naso-pharynx.

3. In consequence of this extreme sensitiveness, a local pathological process, which in many persons would give rise to no reflex neuro-vascular changes, may awaken a host of neurotic phenomena referable not only to the region primarily involved, but also to other and even remote organs of the body. These may include cough, asthma, and various neuralgic affections, or the local structural lesion may be the starting point of the various sympathetic affections of the respiratory tract.

4. That this class of naso-pharyngeal neuroses are explicable on the same general principles laid down in the article read before this association, May 29, 1886 (*vide* "Transactions," page 154 *et seq.*), and the pathology of the nasal and post-nasal affections is, therefore, one and the same.

5. That the treatment should be carried out according to the general directions laid down in the article just mentioned.

6. That when the morbid process originates in the pharyngeal tonsil, attention should not be directed to the bursa alone, but an endeavor should be made to extirpate the tonsil, as far as possible, in its entirety.

7. That, while a favorable prognosis can not be safely predicted by treatment of the bursa alone, extirpation of the pharyngeal tonsil often offers the most favorable prospect in long-standing cases of post-nasal inflammation.

## PARAPLEGIA FROM A GUNSHOT WOUND OF THE SKULL OVER THE CORTICAL LEG CENTERS.

BY FREDERICK PETERSON, M. D.

THE following is the history of a unique case of simultaneous injury to both cortical leg centers, occurring in the practice of Dr. W. H. Heath, attending surgeon to the Sisters of Charity Hospital at Buffalo :

J. P., a male, aged fifty-seven, widower, born in America, served in the army during the late war, and was perfectly healthy up to that time. Since then his only illness has been of a rheumatic nature. He never had syphilis. During the early part of this year he became low-spirited and despondent from want of employment, but his was not a case of melancholia. On April 30, 1889, in a fit of desperation, he shot himself with a 32-caliber revolver. The remarkable feature of the shooting was the spot selected to receive the discharge. Directing the muzzle of the weapon against the top of his head, he shot vertically downward. The bullet entered exactly in the antero-posterior median line, something like an inch posterior to the bregma and about seven inches anterior to the occipital protuberance. It became impacted in the bone, splintering the inner table of the skull. Consciousness was apparently lost but for a few seconds. Almost immediately he felt a sensation "like an electric shock," and the lower extremities became completely helpless. He was taken at once to the Sisters' Hospital, and the disc of bone containing the impacted ball was removed. A number of loose particles of the inner table were also removed. The injury had lacerated the longitudinal sinus, so that the wound had to be plugged to check the haemorrhage. The dura was slightly injured by spicules of bone, but the cerebral substance beneath it apparently escaped exposure or visible laceration. Dr. Herman Mynter first saw the patient, and sent him to the hospital. There was some retention of urine the first day from shock, and it was drawn off with a catheter; but there was no evidence of sphincter paralysis, and has been none since the shooting. The knee-jerks were enormously exaggerated from the first, and ankle clonus was very marked. Both legs were paralyzed. There has been no muscular atrophy, no anaesthesia, and no analgesia, and no cranial nerve was affected. Up to about the middle of July he was confined to his bed by the loss of voluntary control over his lower extremities, but before that some

\* "Maryland Medical Journal," March 19, 1887.

improvement had taken place, and the amelioration of the paralysis had gradually advanced, apparently from above downward, so that on July 15th the thigh muscles had regained considerable power, and at the date of this writing (August 14th) he is walking about with a cane. Though there is a great gain of voluntary power, as shown in his ability to walk, yet the slightest touch upon the patellar tendon still produces a violent response, and the ankle clonus remains as before.

There has been no disturbance of his intelligence, nor at any time any tendency to convulsive seizure in the lower extremities.

An exact localization of the injury according to the rules of crano-cerebral topography has not been made, but the statements given afford an approximate estimate of the relation of the bullet wound in the skull to the cerebral convolutions. In the first place, the ball entered precisely in the antero-posterior median line, depressing the inner table and lacerating the longitudinal sinus; hence, if any injury to the brain substance itself occurred, it must have been along the margins of the longitudinal fissure. The area for the lower extremity, as is well known, includes the upper portions of the anterior and posterior central convolutions, and the convolution around the upper extremity of the Rolandic fissure which, upon the median surface, is known as the paracentral lobule. The leg area extends, therefore, from the convexity over upon the median surface, and the margin of the hemisphere at this spot is the most prominent part of the area. The upper extremity of the Rolandic fissure does not pass over the margin, and is situated between 40 and 60 millimetres behind the bregma, according to Dana. From Dr. Heath's measurement we learn that the bullet entered one inch behind the bregma, or 25 millimetres, leaving a distance of 15 millimetres, or possibly more, between the anterior border of the bullet wound and the fissure of Roland. The hole made by the ball itself could scarcely be less than 10 millimetres in diameter, and radiating from the wound were the depressed spicules of the inner table for probably 10 millimetres more, which would bring the farthest limit of bone injury to some 45 millimetres behind the bregma. As the leg center extends at least as far as 15 millimetres in front of the fissure, it is evident that the motor area lay to some degree below the injured portion of the skull. The pathological nature of this lesion is mysterious. Paraplegia followed immediately upon the presumed injury to the cortex of the motor centers for both lower extremities. Was it shock to the centers, or sudden compression, or sudden hæmorrhage? The longitudinal sinus was injured and bled freely from its upper wall, and a subdural hæmorrhage is also a possibility; the sinus being lacerated, blood might have flowed out and formed a large clot between the paracentral lobules. But any attempt at explanation must be purely speculative. The lesion was local from the symptoms developed, and from the fact that unconsciousness was merely momentary. If it had been irritative to the leg centers, would there not have been a tendency to spasm?

I do not know of any other case like this in medical literature, and it is to be hoped that Dr. Heath will keep it under observation for some time to come, that further data may be added to the valuable notes which he has furnished me.

## AN UNFORTUNATE RESULT OF WHITEHEAD'S OPERATION FOR HÆMORRHOIDS.

By CHARLES B. KELSEY, M. D.

THE following case is that of a patient brought to me a few days since by Dr. Peckham:

A woman, aged thirty-five, was operated upon eight months since in one of our city hospitals for haemorrhoids by Whitehead's method. "The operation had never healed."

On examination, the anus presents a circle of excoriated mucous membrane ending suddenly in healthy skin. The mucous membrane, which has been drawn outside of the rectum and united to healthy skin, is an inch broad for one half the circumference of the anus and half an inch broad for the remainder. In other words, the circular incision in the operation was entirely outside the margin of the anus, and the mucous membrane has been drawn down to it, changing a mucocutaneous opening into one covered by mucous membrane.

The plan of treatment advised was to dissect this mucous membrane loose, cut it off, bring the skin up as near the verge of the anus as possible, and allow the wound to heal by granulation. A stricture of the anus would, of course, be the natural consequence, but one which I think could be managed and would be better than the extensive ulceration which is sure to follow the excoriation now begun.

It is needless to say that the patient's present condition is a very miserable one.

**Creasote in Tuberculosis.**—Professor Sommerbrodt, of Breslau, in two communications to the "Therapeutische Monatshefte," declares that an experience of over five thousand cases has proved to his own satisfaction that creasote is not merely a useful drug for the symptomatic treatment of tuberculosis, as has been conceded by others, but that it exerts a specific influence on the disease by the resistance it offers to the cultivation of tubercle bacilli. Dr. P. Guttmann had by his experiments shown that tubercle bacilli could scarcely be cultivated in sterilized serum containing  $\frac{1}{4000}$  of its volume of creasote, and the culture entirely failed when the solution was a little more concentrated. He concludes that if it were only possible to administer sufficient creasote for the blood to contain that drug for some time in the proportion of  $\frac{1}{4000}$  of its own quantity, tubercle bacilli would probably cease to develop. This, he contends, is impossible, not only because the required quantity of creasote in the blood would be more than twenty grains, but because it would be impossible to determine what quantity of creasote would have to be administered to make twenty grains of it circulate in the blood. Sommerbrodt believes that it is possible to give the necessary quantity of creasote. He has been prescribing for some time to many hundreds of tuberculous patients capsules of creasote, each containing one grain of the drug. These capsules were taken, three the first day, and every succeeding day one more until the eighteenth day, after which the same quantity—from twenty to twenty-five grains per day—was continued for many months. The author says that it is impossible to presume that the twenty grains of creasote have already entirely passed out of the blood by the time the second or third dose of the drug is given, so that probably such an accumulation of creasote takes place in the tissues as to fulfill Dr. Guttmann's postulate. He has, at any rate, had the most gratifying success with this medication, and his experience was that the more creasote a patient could bear in a day the greater was this success. The *modus operandi* of the creasote, Dr. Sommerbrodt says, has not yet been sufficiently cleared up. . . . He suggests, therefore, that serum from a man who has for some time taken more than twenty grains of creasote be used to cultivate tubercle bacilli, so as to find out if this acts differently from the serum of another person used for the same purpose.—*Lancet*.

NEW YORK, SATURDAY, OCTOBER 5, 1889.

**THE RELATIONS OF INFLAMED TONSILS TO RHEUMATISM.**

A COMPARISON of the experience of various observers in regard to a given subject is always of value, especially when the personal equation is reduced to the minimum and the collated experience may be verified—without deductions for errors of observation—by any interested student. Of such a character was the discussion on “Tonsillitis, its Varieties and Relations to Rheumatism” that took place at the recent session of the Laryngological Section of the British Medical Association (“British Medical Journal,” September 14, 1889).

Dr. C. W. Haig Brown classified tonsillar inflammations as simple and specific, the latter being subdivided into exanthematous (scarlatinal, morbillous, etc.) and diphtheritic, also as sporadic or epidemic and as follicular or interstitial. The follicular variety, he said, was most common, and the disease appeared when the air was saturated with moisture, in December and January, and again after hot, dry days with high humidity. Drain poisoning frequently caused the disease; and he referred to an institution in which the repair of improper drainage had reduced the percentage of amygdalitis to five and rheumatism to one, against twenty-one and four before the repairs were made. Of 119 educated persons with inflamed tonsils, 28 had rheumatoid pains with the attack, 38 had previous attacks of rheumatism, and 10 had rheumatic parents, though they were free from this disease themselves. The aptitude of each disorder to recur, the sour-smelling perspiration, the pain in the back and limbs independent of arthritic pain, due to inflammation of the fibrous elements of the muscular fascia, the occurrence of cardiac murmurs in amygdalitis, as well as of endocarditis and pericarditis in rheumatism, lent a similarity to the diseases that outweighed their points of difference. He had not found that the salicylates, beyond their sedative power, influenced amygdalitis. This causative and clinical relationship led to the conclusion either that rheumatism as frequently found expression in the throat as in the fibrous or serous membranes, or that the inflamed tonsil, having received the rheumatic poison, became the medium of its transmission to the circulation, or that specific germs manifested their presence by inflammations of the tonsils and the fibrous and fibro-serous membranes. The last, by analogy with other diseases, seemed the most probable conclusion.

Dr. A. E. Garrod acknowledged the frequent association of sore throat and rheumatism, and reviewed the various observations that had referred to this association. He considered that the fact that many sufferers from rheumatism had amygdalitis was evidence that the arthritic pain accompanying the latter was rheumatic, and that the frequent association of pharyn-

gitis, amygdalitis, and rheumatism was evidence that the former was a manifestation of the rheumatic state, though it was, of course, conceded that there were many cases of sore throat that had no connection with rheumatism. When sore throat was the leading feature of the attack there was little tendency to affection of the endocardium or pericardium. No importance was attached to arguments based on the results of treatment.

Mr. Lennox Browne, who professed to have been the first to insist upon the aetiological, semeiological, and therapeutic analogy between tonsillar inflammations and the rheumatic diathesis, agreed with Sir Andrew Clarke that the sudden suppression of the generation and discharge of lymph-cells by the tonsil, the accumulation of effete matters in the crypts, and the filling up of lymph spaces with the products of bacterial life and evolutionary matter contaminated the blood and originated the rheumatic troubles. He believed that the action of sodium salicylate in inflammation of the tonsils proved the rheumatic character of the disease.

Dr. R. Hingston Fox referred to amygdalitis accompanying the exanthemata, distinguished between epidemic sore throat and simple tonsillar inflammation, and accepted Dr. Cheadle's seven phases of the rheumatic series: endocarditis, pericarditis, pleurisy, amygdalitis, exudative erythema, chorea, and subcutaneous nodules. In this series the lymphatic system, with which the tonsils, the ileo-caecal glands, the serous cavities, and perhaps the joints were connected, was especially concerned. The association between these diseases was further shown by the facts that often one individual was attacked at different times by two or more of them, and that several members of one family might be attacked by them.

Other speakers expressed themselves to much the same purpose. While there is a consensus of opinion regarding the association of the diseases in question, and the importance of inquiring about rheumatic symptoms in amygdalitis is emphasized, yet the latter symptoms seem to be the result of a pto-maine poisoning. A more extensive study of both diseases is necessary to arrive at an exact conclusion regarding their pathological identity.

**A GOVERNMENT REPORT ON THE SWINE DISEASES.**

THE Commission of the United States Department of Agriculture, appointed in December, 1888, to investigate swine plague and hog cholera, has made a report, of which the chief conclusion is that these are distinct diseases, and not the same disorder, as has been maintained by Dr. F. S. Billings and some others. The Commission, composed of Dr. E. O. Shakespeare, of Philadelphia, chairman, and Dr. Meade Bolton and Dr. T. J. Burrill, journeyed far and wide and experimented diligently in order to settle the points in dispute. Their report is provisional and introductory to further and closer laboratory work.

One important observation made by the Commission is worthy of mention, as having an application to human infective diseases, since it recognizes a principle of cumulation in infection which explains what is called the alleged deficiencies of

vaccination and other protective agencies. To quote from the report briefly: "There is no known infectious disease, either of man or beast, capable of producing by one attack a degree of protection which is surely and absolutely effective against a second attack. Experience has abundantly shown that animals which are naturally or artificially protected can be *practically overwhelmed* by enormous doses of the germs of the disease and thus be made to suffer a recurrent attack, which may even be fatal." Thus it is that we not infrequently observe a second attack of small-pox in a person who, having "no fear of the disease," as it is often expressed by some such thoughtless person, so comports himself that a needless and wanton degree of exposure is incurred. That such an exposure does not engender the second attack oftener than is the case is surprising. In other words, the antidote being limited in its supply or potency, and the poison being practically unlimited in supply and fresh and virulent as to its potency, there ought to be nothing surprising, or, indeed, contrary to a rational expectation, in the recurrent attack as a result of an excessive exposure to the germs of infecting diseases. In such instances it is not the correct view to ascribe them to the "failure" of the protective agency applicable to each respective case: they are simply cases where the doses of poison have been so great as to overwhelm the protection. These views are not unfamiliar as matters of speculation and of analogy, but it has only been within the last few years that the work of the bacteriologist has brought the matter to the point of demonstration, that there is a quantitative, as well as a qualitative, element in germ-disease production. And the primary lesson to be deduced is that already suggested—that any unnecessary exposure to infectious disease is unwise.

#### THE ENTRANCE OF AIR INTO THE CIRCULATION.

UNTIL within recent years it has been an accepted fact that the entrance of air into the venous or arterial circulation was rapidly fatal; and many cases of sudden death during operations have been attributed to this cause. Recently Dr. Hobart A. Hare, of Philadelphia, in the "Therapeutic Gazette" for September, has reported a series of experiments on more than seventy dogs, in which he injected air in quantities varying from a minute bubble to forty cubic centimetres into the jugular vein or the carotid artery. Experiments with a cannula left tied in the proximal portion of the jugular vein did not show any suction of air. Death did not follow the injection of air into the vein; but, when it was injected into the artery, death occurred almost at once, if as large a quantity as twenty cubic centimetres was injected. The author remarks that, in operations, the collapse of the walls of vessels will generally prevent such an accident. The reported cases of sudden death are probably due to clot, and the evidence seems to Dr. Hare inconclusive that any of these deaths were due to air entering the vessels.

These experiments agree with those of Senn, whose work seems to have been overlooked by Dr. Hare to some extent.

In his exhaustive consideration of the subject of air embolism ("Transactions of the American Surgical Association," 1885), Dr. Senn found that the injection of twenty cubic centimetres of air into the carotid artery did not cause death, but that larger quantities were fatal, though less so than when thrown into the veins, the contractions of the left ventricle forcing the air into the venous circulation. The fatal issue in the latter condition appeared due to the mechanical overdistension of the right ventricle of the heart, with consequent paralysis, or to asphyxia consequent on pulmonary embolism. In his experiments he found that an elevation of the wounded part—as of the head in wounds involving the longitudinal sinus or the jugular vein—favored the entrance of air into the veins. In this paper quite a number of reported fatal cases from the entrance of air into the circulation were analyzed, and the evidence seemed sufficient that there was paralysis of the heart, and that there were air bubbles in that organ and in the blood-vessels.

Undoubtedly quite a number of the reported cases of sudden death from air embolism rest on insufficient foundation; in many no necropsy was made to verify the reported cause of death. It must also be remembered that even such moderate surgical interference as the introduction of an aspirator needle has caused death; and such traumatic shock has probably been the actual cause of death in many of the obscure supposed cases of air in the blood-vessels. In the last analysis of the work of these American experimentalists—substantiated as it is by European observers—it seems demonstrated that the accidental introduction of small quantities of air into the blood-vessels during an operation is not fraught with danger to the patient. Where dangerous symptoms are presented, Senn recommends aspiration of the right ventricle or auricle.

#### MINOR PARAGRAPHS.

##### THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

THE fifteenth annual meeting, which was held in Evansville, Indiana, on the 10th, 11th, and 12th of September, under the presidency of Dr. George J. Cook, of Indianapolis, was in every way a most successful one. The programme included nearly a hundred papers, many of which, however, were read only by title, as the time allotted for the meeting would not admit of the carrying out of the full programme. The attendance, which was large, included that of many representative men from Ohio, Kentucky, Tennessee, Missouri, Indiana, Illinois, and Pennsylvania; also visitors from some of the Eastern States. The association, which is a growing one, bids fair to rival the American Medical Association in membership. By its by-laws all questions of ethics and differences between members are referred without debate to the Judicial Council, whose decision is final. Thus nothing that might tend to produce unpleasant feelings can be brought before the association, whose time during its sessions is devoted entirely to scientific work. The social features of the Evansville meeting were of a most enjoyable character, and, like the arrangements for the meeting, reflected great credit upon the Committee of Arrangements, of which Dr. A. M. Owen, of Evansville, was chairman. The association will hold its next meeting in Louisville, under the presidency of Dr. J. M. Matthews, of that city.

## THE NEW YORK ACADEMY OF MEDICINE.

THE exercises incident to the laying of the corner-stone of the Academy's new building, on Wednesday afternoon of this week, doubtless went far, as they ought to have gone, to further the general interest in matters calculated to improve the medical profession, and especially in the Academy's own prosperity, that has sprung up in New York within the last few years. On that occasion the profession itself was most creditably represented, and the participation of so popular an ex-President as Mr. Cleveland doubtless drew the thoughts of many influential laymen to the desirableness that the community should do everything in its power to raise the status, and thereby the efficiency of its medical men. In particular, Dr. Jacobi's address, which we publish in this issue, ought of itself to secure the objects in pursuit of which he spoke. It was straightforward, simple, and to the point, suggesting the good wine that needs no bush. If such a succession of presidents as Dr. Barker, Dr. Jacobi, and Dr. Loomis can be continued, the Academy will not be at a loss for suitable spokesmen whenever occasion arises for it to come before the public with appeals for the aid and encouragement that are its due.

## HOW MUCH SHOULD A CITY PAY ITS HEALTH OFFICER?

THE Michigan State Board of Health has recently published a paper by its secretary, Dr. Henry B. Baker, in which he asks how much the average city or village can afford to pay its health officer. He answers the question by saying that statistics which can not be questioned prove that in those localities in Michigan where the recommendations of the State Board of Health are carried out about eighty per cent. of the deaths from diphtheria and scarlet fever are prevented by the thorough isolation of all infected persons and the thorough disinfection of all infected persons, things, and places. Statisticians, he adds, usually value a person in the prime of life as worth to the community about a thousand dollars. Dr. Baker thinks that in a village of fifteen hundred inhabitants a health officer can easily save the lives of two children and one grown person in each year, and he concludes that such a village can well afford to pay its health officer two thousand dollars for the prevention and restriction of scarlet fever, diphtheria, and typhoid fever, and save money by the transaction.

## ST. JOHN'S GUILD.

THE report of the past season's work by the St. John's Guild shows that over 30,000 children and mothers were received on the floating hospital, and 1,500 sick children and others were treated at the Cedar Grove Seaside Hospital belonging to the Guild. The expenses exceeded the receipts by \$3,000.

## LEPROSY IN THE SANDWICH ISLANDS.

ACCORDING to the "British Medical Journal," Dr. Lutze, who until recently was an assistant in Dr. Unna's clinic at Hamburg, has been invited by the Hawaiian Government to proceed to Honolulu, to remain there for some time to study leprosy in its habitats, and to investigate the effects of certain newly proposed methods of treatment.

## ITEMS, ETC.

**The Kings County Asylum.**—Dr. Walter S. Fleming has been appointed medical superintendent of the Kings County Insane Asylum at Flatbush. He succeeds Dr. J. J. Shanks, re-

signed, being promoted from the position of assistant physician at the St. Johnland Branch Asylum.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 1, 1889:

DISEASES.	Week ending Sept. 24.		Week ending Oct. 1.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	63	16	55	11
Scarlet fever.....	24	4	34	3
Cerebro-spinal meningitis.....	0	0	1	1
Measles.....	9	0	13	2
Diphtheria. ....	55	15	55	14

**The late Dr. Joseph Beale,** of the navy, who died on September 23d, in his seventy-fifth year, was Surgeon-General of the Navy from 1873 to 1877, and had been on the retired list for twelve years. He was a native of Philadelphia, was educated there, and spent his last years there. He entered the navy as an assistant surgeon when he was twenty-three years old, and was on the active list for forty years. During the late war he participated in blockades and engagements at various points from Fort Hatteras to Mobile.

**The Toledo Medical College.**—Dr. F. B. Robinson, of Grand Rapids, Wisconsin, has been appointed to the chair of anatomy.

**The New Haven Hospital.**—By the wills of the late Philip Maret and of his daughter, Mrs. Gifford, the hospital will receive about \$200,000, and the New Haven Dispensary \$5,000.

**Changes of Address.**—Dr. Elizabeth Neely Bradley, to No. 32 East Forty-fifth Street; Dr. Louise Fiske Bryson, to No. 159 West Forty-eighth Street; Dr. E. L. H. McGinnis, to No. 35 West Thirty-eighth Street; Dr. Henry Maedonald, to No. 334 West Thirty-fifth Street.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 22 to September 28, 1889:* POPE, BENJAMIN F., Major and Surgeon. By direction of the Secretary of War, the leave of absence granted in S. O. No. 54, August 17, 1889, Department of Texas, is extended one month. Par. 6, S. O. 224, A. G. O., September 26, 1889.

LORING, LEONARD Y., Major and Surgeon. By direction of the Secretary of War, the station is changed from Fort Mojave, Arizona Territory, to Fort Wingate, New Mexico, and he will report for duty at the latter accordingly. Par. 7, S. O. 219, A. G. O., September 20, 1889.

CHAPIN, ALONZO R., Captain and Assistant Surgeon. With the approval of the Secretary of War, leave of absence for fourteen days is granted. Par. 10, S. O. 223, A. G. O., September 25, 1889.

BURTON, HENRY G., Captain and Assistant Surgeon, will, by direction of the Secretary of War, report in person, on the expiration of his present sick leave of absence, to the commanding officer, Davids Island, New York, for temporary duty at that station, and by letter to the superintendent of the recruiting service. Par. 3, S. O. 223, A. G. O., Washington, September 25, 1889.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending September 28, 1889:*

GORGAS, A. C., Medical Director. Detached from Examining Board and ordered to hospital, Philadelphia, Pa.

HORN, W. T., Medical Director. Detached from hospital, Philadelphia, Pa., and to wait orders.

BOGERT, E. S., Medical Inspector. Detached from New York Navy Yard and assigned to Examining Board.

McMURTRIE, D., Surgeon. Detached from U. S. Steamer Vermont, and ordered to Navy Yard, New York.

BABIN, H. J., Surgeon. Ordered to the Receiving Ship Vermont.

HALL, C. H. II., Passed Assistant Surgeon. Resigned from the Naval Service, to take effect November 1, 1890, and resignation so accepted.

### Society Meetings for the Coming Week:

MONDAY, October 7th: New York Academy of Sciences (Section in Biology); Medico-chirurgical Society of German Physicians; Morrisania Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica Medical Library Association; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Hartford, Conn., City Medical Association; Chicago Medical Society; Monmouth, N. J., County Medical Society (Freehold).

TUESDAY, October 8th: New York Medical Union (private); Medical Societies of the Counties of Albany (annual), Chenango (tri-annual), Greene (semi-annual—Cairo), Jefferson (quarterly—Watertown), Oneida (quarterly—Utica), Ontario (quarterly), Rensselaer, Schoharie (semi-annual), Tioga (Owego), and Wayne (semi-annual), N. Y.; Newark, N. J., and Trenton (private), N. J., Medical Associations; Bergen and Cumberland (semi-annual), N. J., County Medical Societies; Litchfield, Conn., County Medical Society (annual); Baltimore Gynaecological and Obstetrical Society.

WEDNESDAY, October 9th: American Rhinological Association (first day—Chicago); New York Surgical Society; New York Pathological Society; American Microscopical Society of the City of New York; Medico-legal Society; Tri-State Medical Association (Port Jervis, N. Y.); Pittsfield, Mass., Medical Association (private); Franklin (quarterly—Greenfield), Hampshire (quarterly—Northampton), Middlesex South (Cambridge), and Plymouth (special), Mass., District Medical Societies; Philadelphia County Medical Society.

THURSDAY, October 10th: American Rhinological Association (second day); New York Laryngological Society; Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society; Medical Society of the County of Cayuga, N. Y.; South Boston, Mass., Medical Club; Pathological Society of Philadelphia.

FRIDAY, October 11th: American Rhinological Association (third day); New York Academy of Medicine (Section in Neurology); Yorkville Medical Association (private); Medical Society of the Town of Saugerties (anniversary).

SATURDAY, October 12th: Obstetrical Society of Boston (private); Worcester, Mass., North District Medical Society.

### Letters to the Editor.

A FORMULA FOR MEMORIZING THE CAUSES OF ABNORMAL INTRACARDIAC SOUNDS.

WASHINGTON, September 10, 1889.

To the Editor of the New York Medical Journal:

SIR: I propose the following formula for memorizing the causes of abnormal intracardiac sounds as one of the simplest yet proposed:

*A, B, C,  
B, C, D.*

Murmur heard loudest at Apex: With first sound = Backward flow, or mitral regurgitation. With second sound = Constricted orifice, or mitral stenosis.

Murmur heard loudest at Base: With first sound = Constriction of orifice, or aortic stenosis. With second sound = Downward flow, or aortic regurgitation.

C. V. N. CALLAN, M. D.

### Proceedings of Societies.

#### ASSOCIATION OF AMERICAN PHYSICIANS.

*Fourth Annual Meeting, held in Washington, D. C., on Wednesday, Thursday, and Friday, September 18, 19, and 20, 1889.*

The President, Dr. FRANCIS MINOT, of Boston, in the Chair.

The President's Inaugural Address dealt with the subject of the progress of medicine during the past fifty years. If such strides were made in the future as had characterized the last half decade, we had every reason to hope the time was not far distant when medicine would approximate the exact sciences. Bacteriology had revolutionized our notions of the causes and nature of many diseases and of their proper management. Much useless and pernicious medication had been abandoned, while the number of valuable remedies had been greatly increased. The possibility of prevention was advancing with the knowledge of the causes of disease, and hygiene had become an important branch of medical education. Even in tuberculosis, that wide-spread and most fatal of maladies, the results of prophylactic treatment, founded in part on the great discovery of Koch, were found to be most encouraging. It was not unreasonable to hope that this dread disease might in time become as amenable to control as small-pox. Medicine he considered almost as much indebted for its present position to chemistry and other branches of the physical sciences, and even to the mechanical arts, as it was to clinical observation and pathology. He felt he ought to touch also upon the great influence of the medical press in elevating the standard of the profession and in diffusing scientific knowledge to all parts of the world. This it did by the publication of original articles, clinical and other lectures, reports of interesting and instructive cases, and proceedings of societies and conventions. Thousands of practitioners unable to leave their homes were thus brought into communication with the highest authorities in medicine, and could avail themselves of the most recent advances of medical science. Finally must be recognized as one of the great advantages of medical conventions the privilege of becoming personally acquainted with the men from all parts of the country of whom they had heretofore known only by reputation or through their writings. In this way the profession was more closely drawn together, prejudices were laid aside, and harmony on the subject of medical ideas was promoted. The organization of the association he had the honor of addressing was peculiarly adapted to aid the progress of medical science. It represented no one section of the country, but included practitioners from all parts of the United States and Canada, whose experience, observation, knowledge, and ability were thus concentrated for comparison and mutual instruction. The president concluded his address with a respectful tribute to the memory of H. D. Schmidt, J. Call Dalton, R. P. Howard, and E. T. Bruen, deceased during the past year.

After a short session devoted to general business, the reading of papers was formally commenced.

**The Early Stage of General Paralysis.**—Dr. C. F. FOLSOM, of Boston, contributed this paper. It was compiled to express the author's opinion that there was perhaps a tendency to ignore, deprecate, or underestimate a train of insidious yet palpable symptoms, which, if more carefully observed, would assume importance as evidencing the initial brain lesion. He then went on to cite at length a number of cases in which some transient deviation from the normal mental equilibrium, antedating by a considerable period any pronounced symptoms, had led him to make a diagnosis of approaching general paralysis, which had been subsequently confirmed by the disease fully developing. These cases also illustrated that in the early stage of the disease the motor disturbances might be very slight or might altogether escape detection. That striking loss of muscular power or control generally regarded as a part of the disease was not always apparent until a later period. The mental symptoms were difficult to detect, but this could be more readily done in some vocations than others. For instance, the requirements for an orchestral leader being of so complex an order, the least failure was detected. In professional and business men a less degree of impairment would be recognizable than in mechanics. In routine employment, without much thought, a large degree of deterioration might exist unnoticed. In day-laborers an early diagnosis was impossible. The earliest signs of paralysis would probably be the slightest possible brain failure. If, for instance, a strong, healthy man at or near the prime of life, distinctly not of the nervous, neurotic, or neurasthenic type, showed some loss of interest in his affairs or an impaired facility in attending to them; if such a man became varingly absent-minded, heedless, indifferent, negligent, apathetic, inconsiderate; if, while able to follow his routine duties, his ability to take up new work was, no matter how little, diminished; if he gave less willing mental attention and concentration, showed less power in conception, perception, reflection, or judgment; if there appeared lack of initiative, and exertion caused unwonted mental and physical fatigue; if the emotions were intensified or excited readily by trifling causes; if the sexual instinct could not be reasonably controlled and the finer feelings were even slightly blunted; if the person in question regarded with a placid apathy his own acts of indifference and irritability, and especially if at times he was able to see himself in his true light, and then suddenly failed to do so; if any symptom of cerebral vaso-motor disturbance became evident, however vague or variable—the foregoing might be regarded as suspicious indications, though there might be more or fewer in any given case. The group of symptoms given might seem very striking, but were really compatible with the performance of usual duties and required careful and prolonged observation of the patient and painstaking interrogation of his family and friends for their detection. They would be recognized perhaps as much from the peculiar quality of the mental impairment, difficult to describe, as from its degree. These often antedated, at least in time of their recognizability, any physical symptoms. The latter, when they appeared, might be so slight as to be unappreciable for a long time except as an unusual sense of fatigue and weariness. Commonly there was loss of flesh. There were always elements of uncertainty in the early diagnosis of general paralysis, for there existed few forms of mental disease in adult life that it might not simulate in obscure cases. It might be confounded with Bright's disease, epilepsy, hysteria, lead or mercurial poisoning, cerebral complications, and so forth. Its relation with syphilis was too frequent to be accidental, yet it could not be classed as properly a stage of that disease, nor was it benefited by specific treatment. He did not deem the prognosis so hopeless as it was generally considered. The present methods adopted in

treatment were really detrimental, and even when nothing but partial cure or marked amelioration could be hoped for such would be best achieved by methods which secured the patient absolute rest.

Dr. J. J. PUTNAM, of Boston, thought that it was a most essential thing to recognize the disease at the earliest possible moment. There seemed to be some mysterious connection between it and syphilis. He would like to ask whether Dr. Folsom had had any case in which chronic lead poisoning might have entered as a factor.

A case had come under his notice a few weeks ago in which a diagnosis of general paralysis had been made, and in which the symptoms, he was forced to admit, would readily allow of such conclusion. Still this patient was not so far gone as not to be able to appreciate his own condition, and had suggested the possibility that to the drinking of water which there was reason to think had been richly charged with lead his symptoms might be due. And it was also true that in this case there were local indications suggesting lead poisoning.

Dr. WILLIAM PEPPER, of Philadelphia, thought the disease due to slow degenerative changes in some group of cortical cells. Then any depressing cause might act in elaborating this morbid process. Still he believed there must be a period during the initial change when progress might be stopped and recovery be possible. He considered the ground taken in Dr. Folsom's paper as most important, and would suggest that he be asked to read again that portion of his paper which dealt with the appreciation of the earlier indications of general paralysis.

Dr. FOLSOM, in his reply, stated that he had never seen any cases of the pseudo-general paralysis of lead. As to cures, he regarded this as meaning a capability on the part of a patient to return for a time to his usual work. Speaking of the alleged syphilitic cases benefited by iodide of potassium, he could cite one in which the patient had been treated for every stage of syphilis. He had developed certain symptoms pointing to general paralysis. Under the iodide treatment, during which he had been given as much as a hundred grains a day, a perfect recovery had apparently been made, and the case might have been regarded as a cure from the speaker's test. Two months ago a circumstance had come under his notice which had indicated that the disease had made considerable progress, and the case would surely go on to terminal general paralysis.

**Tetany.**—Dr. JAMES STEWART, of Montreal, after dealing in his paper with the subject-matter from a general standpoint, illustrated his remarks by describing in detail the following case. The patient, a man, forty years of age, had suffered for eight years with regularly recurring attacks of tetany. He had served as a soldier during the American civil war, during which, and since, he had been a victim to chronic dysentery and malarial attacks. The first subjective symptom of the tetany had been diplopia, followed soon after by characteristic contractions of the flexors of the hands. Sometimes the flexors of the forearms and the adductors of the arms had become spastic. The muscles of the face had constantly suffered, while those of the lower extremities had been but rarely involved.

The galvanic irritability of the nerves had been found to be materially increased, as was the mechanical irritability of both nerve and muscle. The knee-jerk, which had been exaggerated during an attack, had been absent during the intervals. The quantity of urine excreted in the course of the attacks had been normal in amount, but had been found to contain both urea and indican in considerable excess. Herpetic eruptions with œdema of the hands and arms had not infrequently appeared as sequelæ of an unusually severe attack. The general symptoms presented by the patient, who had been under observation now for some years, were those of gradually increasing

dullness and apathy; he could not reply promptly to questions, and complained of a general numbness. There existed also some swelling of the lips and face. These symptoms closely resembled those of myxedema, and the idea had forced itself upon the author that perhaps there existed a myxedema grafted upon the tetany. His researches upon the subject of his paper had led him to the following conclusions: Tetany might be divided into three varieties:

1. Epidemic or "rheumatic" tetany, common in Europe but extremely rare in America, the course of which was acute and favorable.

2. Tetany from exhausting causes, such as lactation, diarrhoea, etc. Course also chronic and favorable.

3. Tetany from removal of the thyroid gland. The cases after such operations either were quickly fatal or became chronic and incurable.

4. A very fatal form of tetany produced by dilatation of the stomach.

From this enumeration infantile tetany was excluded, because, though it was doubtless true that tetany might occur in childhood, that which was frequently so designated was in reality not the disease at all. When the thyroid gland was removed from animals for the purposes of experimentation, a condition supervened very similar to the typical tetany in the human subject. Of the many forms of muscular contractions seen in man, in none, excepting perhaps in chorea, would be found such marked increase of the electric irritability of the nerves and muscles.

The investigations by pathologists seemed to throw no light toward a possible aetiology for the disease, and no morbid anatomical changes which could in any way be deemed characteristic have been described, but it appeared that tetany following removal of the thyroid gland was due directly to such loss, and that the gland itself influenced the nutrition of the nervous system. Possibly it might be accepted as a general proposition that impoverishment of the nerve centers acted as a prime factor in the production of tetany.

**Tetany and a New Theory of its Pathology.**—In this paper the author, Dr. JOHN T. CARPENTER, of Pottsville, Pa., said that tetany might best be defined as a nervous disorder, accompanied by spasms of an intermittent character, extending from the extremities to the muscles of the jaws. These spasms might, during the intermissions, be reproduced at will by compressing the affected parts, either in the direction of the principal nerve trunks or over their blood-vessels, thus impeding the circulation. But this definition failed to reach the underlying pathology of the disorder; indeed, later observers had taken the ground that there is no definite lesion connected with the disease. This might be true—no definite lesion, perhaps, but still a definite cause. Was tetany a special disease, or the sequel of precedent phenomena? Was it an independent morbid entity, or the consequence of some other diseased condition of the system? These questions might be answered by an analysis of the conditions and circumstances under which tetany had been observed, which had been many and varied. Diarrhoea had frequently been a condition; so also had constipation. The post-puerperal state and lactation in women had been frequently noted. But, again, children and adult males were also subjects of tetany. Typhoid fever and phthisis had furnished a number of cases. So had exudative disease of the pharynx. Could we make any generalization among all these varying conditions? Could we make clearly evident any fundamental peculiarity among all these different morbid states? He believed this could be done. Such a study had led him to the conclusion that the well-known general condition of systemic infection called sepsis might be safely asserted and surely proved to underlie or accompany every an-

tecedent disease that had been observed to be connected with tetany. From these deductions might be formulated the axiom that tetany, as a general rule, follows upon such diseased conditions of the system as are observed to produce morbid discharges from mucous surfaces whose absorption is known to cause symptoms in remote parts of the body due to the circulation of septic poison. Taking first the post-puerperal state, modern obstetric physicians believed that sepsis was usual at this period, and to its influence they justly ascribed the so-called "milk fever," the puerperal inflammations, and many other of the disorders of puerperal women. If, then, a septic condition could exist sufficient to cause these disorders, it was not difficult to see that such might readily account for the appearance of tetany in the post-puerperal. He then went on to consider seriatim, in this connection, diarrhea, constipation, and phthisis, his summing up being that, in all recorded observations of morbid processes antecedent to tetany, a probable sepsis might be inferred; and no other cause, common to them all, has so far been discovered. To this fundamental peculiarity, therefore, must be assigned the causation of the final result, as a disorder consequent thereupon.

Dr. F. P. KINNICKUT, of New York, said that he had seen two cases of intermittent tetany from dilatation of the stomach in pyloric stricture. The cases had both been cancerous and very favorable to the absorption of poisonous material.

Dr. A. JACOBI, of New York, took exception to the theory of Dr. Carpenter. There might be cases in which sepsis might have some influence; but when the attack was temporary the immediate influences which produced it were temporary too. He looked for the proximate causes still in nerve irritation. The disease was not, as had been stated, frequent in Europe. When it occurred it was usually limited to attacks of localized, circumscribed convulsions. He remembered, during thirty-six years of practice, to have seen only five cases, and of these only one was that of an adult.

**Thrombosis of the Cerebral Sinuses and Veins.**—Dr. A. B. BALL, of New York, read a paper on this subject, and in the course of an exhaustive and elaborate survey stated that the conditions which underlay thrombi of the cerebral sinuses and veins were essentially the same as those which determined thrombi elsewhere in the venous circulation. These conditions were still very imperfectly understood. As to the influence of the blood when at complete rest in inducing the thrombotic process, it was still a matter of dispute whether blood stasis was ever by itself the initial cause. There was a theory promulgated by Eberth that white thrombi were formed mainly by agglomeration of blood plates, differing in this respect from ordinary blood coagula. Whether we took this view or that advocated by Weigert, Walshe, and others, that thrombosis and coagulation were essentially the same process, there was no doubt that slowing of the circulation must be regarded as of great importance. If the initial step were acknowledged as being an adherence of the formed elements of the blood to the vessel walls, obviously such adhesion was more likely to occur with a retarded blood-current. In situations where an active circulation was maintained—as in the heart, in the aorta, and even in some aneurysms—excessively roughened surfaces might be present without being covered by a thrombotic deposit, such slight adhesion of the formed elements of the blood to the vessel wall as might occur from time to time being swept away by the blood-current, and in absence of thrombosis these were readily disposed of in the general circulation. The speaker then considered the part played by vessel lesions and morbid blood changes as factors in thrombosis. He concluded by giving an interesting history of cases of artificial occlusion of the cerebral sinuses in dogs. If dogs were the same as men, then the very extensive occlusion

which could be tolerated before a characteristic train of symptoms appeared and death supervened, as demonstrated during the series of experiments made by Ferrari, threw grave doubts on the reported cases in which fatal cerebral lesions had been assumed to depend upon a comparatively limited obstruction of cerebral sinuses.

In the course of the remarks which followed the reading of this paper Dr. JACOBI observed that among the causes of thrombosis he thought he might enumerate a disproportion between the white and red corpuscles; by this he did not mean a condition of leucocytæmia. Then the absence or relative absence of muscular tissue in the walls of the veins, and it was here that ergot came in as a remedy. Again, absence of water in the blood or too little water. Patients in certain conditions were not given water enough, and it would be found that such could be relieved by injection of water or salt water. Then, again, it was always good treatment to stimulate the heart in every disease which would last long or had a tendency toward producing heart failure. He believed we did not make proper use of heart stimulants, and usually waited too long before we began with them. Any of the four causes he had touched upon might produce thrombosis.

**Effusion of Chyle and Chyle-like Fluids into the Serous Cavities.**—Dr. SAMUEL BUSEY, of Washington, read a paper on this subject, in which he considered the morbid processes possibly concerned in effusion of chyle into the pleural cavity, of chylous and oily fluids into the peritoneal cavity, and of chyle-like and fatty fluids into the tunica vaginalis testis. He pointed out the infrequency of chylothorax and chylous ascites and the increase in cases of lymphocele and elephantoid diseases in this country. Chylothorax he described as mainly the result of injury, and chylous ascites as caused by rupture of chyle-conveying vessels, produced by pressure of abdominal and thoracic tumors, cicatrices, inflammatory adhesions, cardiac affections, diseases of the coats of the thoracic duct, receptaculum chyliferum and lacteals, and other conditions impeding the movement of chyle or its exit into the left subclavian vein. Oily ascites was generally associated with tuberculous and cancerous affections. Lymphocele was the result of gland obstruction, caused by embolism with the ova of filariae. A diagnosis of these conditions he said was only rendered positive by examination of the fluids, and the prognosis was unfavorable in cases of effusion into the pleural and peritoneal cavities, but favorable in lymphocele, in which latter the treatment would be surgical, in the former expectant.

**Substitutes for Opium in Chronic Diseases.**—Dr. J. F. A. ADAMS, of Pittsfield, Mass., contributed this paper, in which he began by stating that there were times when the dangers and disadvantages of this most brilliant of drugs seemed wholly out of proportion to its benefits. A growing dissatisfaction with opium was the motive of his paper. The disadvantages of opium consisted in the fact (1) that in an overdose it was an active poison. (2) In an ordinary dose its benefits might be largely offset by various functional derangements. (3) Its use involved the danger of the opium habit. The usual reason for giving opium was the belief that no other remedy was capable of accomplishing the result desired. Recent discoveries had, however, done much to lessen our dependence upon it. The avidity with which the new analgesics were seized upon by the medical profession and their powers tested was an indication of the deep-seated antipathy to opium, and the desire to be emancipated from its rule. He then went on to define in detail the advantages and disadvantages of the following drugs when employed as analgesics, in their order of value: antipyrene, acetanilide, and phenacetine. Other analgesics of great value were quinine in neuralgia, especially the malarial variety, cocaine,

used hypodermically, galvanism, and massage. The hypnotics which might with advantage supersede opium were paraldehyde, hydrate of amyl, and sulphonal. For chronic diarrhoea he had almost discarded the use of opium, preferring to treat all such cases antiseptically. To this end he was now in the habit of using sodium salicylate and salol, and both these had proved most satisfactory. Naphthalin had been highly recommended for the same disorder. In recapitulation, he said that we now had remedies at command which might be used instead of opium in all of the chronic affections in which this remedy was formerly our main dependence.

(To be concluded.)

#### AMERICAN GYNECOLOGICAL SOCIETY.

*Fourteenth Annual Meeting, held in Boston, September 17, 18, and 19, 1889.*

The President, Dr. H. P. C. WILSON, of Baltimore, in the Chair.

(Concluded from page 361.)

#### A Case of Abdominal Lipoma simulating Ovarian Tumor.

—Dr. A. REEVES JACKSON, of Chicago, read a paper with this title. One such case had been seen by the author of the paper, an erroneous diagnosis of ovarian tumor having been made. The abdomen had been opened and the tumor found to consist of large masses of fat springing from the mesentery and other portions of the peritonæum. It had not been considered feasible to remove them; the incision had been closed, and the patient had seemed no worse after recovering from the operation. Péan had reported two similar cases, which were embodied in the paper. The diagnosis of ovarian tumor had been made in both. Sir Spence Wells had also reported a case, the operation for which had resulted fatally. Byford, of Chicago, had operated successfully on one case, and Homans, of Boston, had had two fatal cases. Thus the diagnosis in all cases had been faulty, and all but two of the operations had resulted fatally. The conclusion was that such tumors were exceedingly rare, and that operations in which their removal was effected almost always resulted fatally.

Dr. S. C. GORDON, of Portland, Me., reported one case which had occurred in a male patient. He had been unable to remove it. The patient had recovered from the operation, but had died a short time afterward.

Dr. W. C. GOODELL, of Philadelphia, thought such tumors usually coexisted with large masses of fat in the abdominal parietes. He had seen one case. He differed with the diagnosis of ovarian tumor which an associate had made. The tumor had been a mass of fat attached to the omentum, and had not been removable. The patient had died soon afterward.

Dr. E. C. GEHRUNG, of St. Louis, had seen a case which he had considered inoperable. The patient had lived seven years after his opinion had been given, the tumor reaching enormous dimensions. An operation had been performed, which had quickly proved fatal. The tumor had been a vast mass of fat, weighing sixty-eight pounds.

Dr. FORDYCE BARKER had seen one case in which the patient had died on the third day after the operation.

Dr. G. J. ENGELMANN doubted whether all the cases reported were lipomata, to which the discussion should have been limited.

The president, Dr. H. P. C. WILSON, of Baltimore, Md., delivered the annual address, which was largely historical and reminiscential. He proposed as a question for discussion the propriety of laparotomy during or just before menstruation. Storer had recommended the first week after the conclusion of

menstruation as the most desirable time for such operations, but the speaker believed it was better to operate during the uterine *flood* than during its *ebb*, the flow from the uterus perhaps tending to prevent inflammation. He had been driven to this opinion by certain experiences in which he had been compelled to act, and had never seen occasion to regret such action.

Dr. GOODELL had performed ovariotomy six times while menstruation had been in progress, and thought that such a time was not inopportune. He would prefer, however, to decline to perform hysterectomy or myomotomy during menstruation.

Dr. A. P. DUDLEY had frequently observed that a discharge of blood from the uterus was to be expected within a few days after the performance of laparotomy, and it had occurred to him, in view of this fact, that the normal flow of menstruation should not contra-indicate an operation. He had operated several times during the past year while menstruation had been in progress, and did not think he would refuse to do hysterectomy at such a time.

Dr. R. BATTEY, of Rome, Ga., said it was a historical fact that the original Battey's operation had been performed while menstruation had been in progress. Metrostaxis might be expected, in almost all cases, two or three days after laparotomy had been performed.

Dr. KOLLOCK, of Cheraw, S. C., had operated twice during menstruation, and saw no objection to operating at such a time.

Dr. H. C. COE believed that some women would bear an operation performed during menstruation favorably, and others would not. The latter class would include those who were very susceptible to pelvic inflammation.

Dr. P. F. MUNDÉ had not observed that haemorrhage was more profuse when laparotomy was performed during menstruation than when it was performed at other times. He considered that the question of menstruation was insignificant in deciding as to the propriety of an operation, but extra care should be used to prevent sepsis in case an operation were done at such a time, an absorbent pad being applied to the vulva. He would not advise the removal of a myomatous uterus during menstruation.

Dr. A. J. C. SKENE, of Brooklyn, N. Y., thought the experiences narrated proved nothing as to the propriety or non-propriety of operating while menstruation was in progress. In general, surgical operations should be avoided during the performance of any function. In case of a patient who suffered with dysmenorrhœa, he would prefer to operate before the menstrual period to economize her vital force.

#### An Experience with Sloughing Intra-uterine Fibroids.

—Dr. ELY VAN DE WARKER, of Syracuse, read a paper with this title. The paper was based upon the following cases:

CASE I.—Sloughing intra-uterine fibroid in a subject of extreme obesity. Operation of total removal abandoned, and the sloughing layers of the tumor removed with the curette. Recovery, and death some years subsequent to operation, with symptoms of malignant uterine disease.

CASE II.—The patient had been forty-six years of age; had had one child; history of repeated abortions. Extreme blood loss and high temperature, with œdema of extremities; cervix very resistant. Rapid dilatation and removal of fibroid in sloughing condition. Recovery, and death in a year after from chronic nephritis.

CASE III.—Patient aged thirty, sterile; fibroid extruded entirely from the uterine cavity and pendulous within the cavity of the cervix, with low insertion of pedicle. Tumor in a sloughing condition; haemorrhage and pyrexia. Operation and recovery.

CASE IV.—Patient, aged forty, had had three children. Rapid

disappearance of a pelvic tumor, attended by severe flooding, and demonstrating the presence of an intra-uterine fibroid in a sloughing condition two weeks subsequently. Extreme high temperature and exhaustion. Operation and recovery, complicated with hystero-tetanus without trismus, preceding the operation. The neurotic symptoms relieved by bromide of potassium and asafoetida.

CASE V.—Patient, aged fifty-one, had had several children. Long-continued error in diagnosis, the uterine symptoms being ascribed to cancer for fourteen years. Blood loss continued with more or less activity for that period. Sloughing intra-uterine fibroid demonstrated. Pyrexia for about four weeks; exhaustion extreme; blood loss so excessive that mucous membranes were blanched. Operation and death from shock.

The following summary was based upon the facts connected with this group:

1. The use of the curette to remove the sloughing periphery of an intra-uterine fibroid when non-removable from any complication, as in Case I from excessive obesity, or in cases of extreme exhaustion that rendered extirpation extra hazardous.

2. That the process of sloughing began at the outer layers of the mass and extended layer by layer into its deeper structure.

3. Rapid dilatation of the cervical canal afforded ample space through the parts for the manipulations of removal; and that sponge tents and other slow methods of dilatation were unnecessary (Case IV).

4. That fibroids, formerly intra-uterine, when extended from the uterus and pendulous in the cavity of the cervix with its pedicle therein attached, were rarely found in a sloughing condition; and that Case III was an exception to this rule.

5. That a form of hystero-tetanus, without trismus, might follow either certain forms of blood-poisoning or uterine lesion (Case IV). Within the experience of the author this condition, only met with in the puerperal state, was attended with septicaemia.

6. That blanched mucous membranes, in excessive and long-continued blood-loss due to intra-uterine fibroids, afforded a certain indication that the limits of safety had been reached in operative treatment of sloughing fibroids, and that a doubtful prognosis must be given (Case V).

7. That septicaemia with long-continued pyrexia was necessarily a fatal condition when due to a sloughing fibroid, unless relieved by the removal of the offending mass; that removal, wholly or in part, was a life-saving operation and was imperative; that the operation was comparatively easy and attended with but little danger, except in cases of blanched mucous membranes.

Dr. M. D. MANN narrated one successful and three fatal cases of sloughing fibroid which he had treated. They showed the danger of the condition and the danger and difficulty of operative measures for its relief.

Dr. BATTEY had seen one case in which sloughing of a fibroid tumor had followed removal of the ovaries. Such a result might also follow the use of ergot.

Dr. WYLIE recommended the free application of antiseptics to a tumor several hours before an operation was undertaken. He objected to the use of a vaginal or uterine tampon after operation, as it might interfere with drainage, which was of fundamental importance. Atrophied fibroid tumors in old women would sometimes present symptoms resembling those which accompanied sloughing fibroids.

Dr. GOODELL thought that operations for the removal of sloughing fibroids should not be unduly prolonged. It was better to do two or several operations, if necessary. A tumor could sometimes be removed with facility by using a guarded obstetric crotchet.

Dr. GORDON attributed the sloughing in the class of tumors under discussion to an imperfect vascular and nerve supply.

Dr. VAN DE WARKER, in concluding, believed that the sloughing was caused by a special mechanism in which pressure was the principal element. The nerves and vessels were affected secondarily. The antiseptic applications advised by Dr. Wylie seemed to him useless, as they could hardly penetrate in a few hours beyond the sloughing zone.

**Death from Visceral Lesions following Ovariectomy.**—Dr. H. C. COE, of New York, read a paper thus entitled. It was a gratifying fact that as ovariectomy became more thoroughly understood and facility in operations increased, the death-rate was greatly lowered. A great extension of the limits of abdominal surgery had resulted, and conditions which were once considered incurable were now within the pale of legitimate surgery. Unfortunately, reliable records of laparotomy cases which had proved fatal and were followed by autopsy were very scanty. He had been able to collect fifty cases in which the records were satisfactorily complete. These formed the basis of his investigations.

Cardiac lesions were first to be considered, the most frequent being fatty degeneration, dilatation, and mitral disease. Heart failure might not occur until several days after the performance of laparotomy. Serious cardiac complications might arise from the pressure of a distended stomach or intestines, and this was most frequently seen in those cases in which opium was used for the relief of pain. Cardiac irritation reflex in character might also arise, owing to disturbance of the abdominal sympathetic plexus. Lung complications had sometimes been found at autopsies when their existence had not been suspected during life. Dyspnoea existing before an operation might be caused by an overlooked pleurisy rather than by the pressure of a tumor. After operations there might be reflex irritation of the lungs, bronchitis, pneumonia, or oedema, the latter frequently resulting just before death. Renal complications were also frequently overlooked during life. There might be albuminuria due to the pressure of a tumor, and pus in the urine with vesical or renal trouble or both. After an operation there might develop hydronephrosis, acute pyelitis, and interstitial nephritis.

Acute or chronic gastro-intestinal disease might precede or follow laparotomy. The stomach might be irritable from venous stasis. It often suffered acute dilatation after an operation. Gastro-intestinal inflammation might cause diarrhoea which would speedily tend to a fatal issue. Intestinal stricture with its serious resulting conditions might follow peritoneal inflammation with adhesive bands, and the latter were much more common than was usually supposed. The spleen, the lymphatics, the liver, etc., might be diseased and complicate ovariectomy in cases in which a favorable prognosis had been ventured. All of this taught that sepsis was not the only ill to be anticipated in abdominal surgery, and that a more careful and thorough interrogation of the abdominal and thoracic viscera than was usually accorded was necessary if one would eliminate an important factor in causing a fatal termination to ovariectomy.

**Renal Diseases caused by Disease of the Pelvic Visca.**—Dr. G. J. ENGELMANN, of St. Louis, Mo., read a paper with this title. Disease of the kidneys might result from urethral disorder, pressure upon the ureters or kidneys, perverted nervous influence, etc., the influence of the nervous system in causing the disease being especially important. Disease of the bladder which was due to the pressure of a tumor was usually discovered, but the diseased conditions of the ureter resulting from pressure were more obscure and might not be discovered

until fatal mischief had been wrought, the sequence of evils beginning with ureteritis and ending with contracted kidney. Disease of this character usually made slow and insidious progress, backache being one of its prominent symptoms. That such conditions might occur was readily suggested by the exposed course of the ureter from the kidney through the pelvis. It was exposed to pressure everywhere—from tumors, from inflammatory exudate, from the hard surface of the brim of the pelvis. In malignant disease of the pelvic organs the ureters and kidneys were very frequently involved. This might not be apparent until an autopsy was made. Cardiac complications were rare even though the kidneys might be in a state of degeneration. Pressure from ovarian tumors was less likely to cause renal and ureteral complications than that from hard and unyielding fibroids. Active interference should begin as soon as there was the least suspicion of pressure upon the ureters. Pain in disease of the kidneys might be obscured by that which was due to coexisting pelvic disease. The pain sometimes seemed to dart along the course of the ureter from the kidney to the bladder. There might be associated with it vesical tenesmus, frequent and scanty micturition, burning and lancinating pains in the back, with lassitude, etc. The pain might extend toward the liver or across the small of the back, and it might continue for hours or days with scarcely an intermission. All these phenomena might appear suddenly, as after a fall, an attack of cystitis or cellulitis. Edema of the extremities with uræmia might quickly follow. Examination of the urine at such a time would reveal the presence of pus, phosphates, hyaline, granular, and epithelial casts. It was fortunate if the disease were limited to one ureter and kidney. The prognosis was serious unless the case were seen before the disease had made much headway. If it were possible, the cause of pressure—be it tumor, or whatever else—should be removed. Ergot internally might be of service, also the use of heat, iodine externally, and the galvanic current. Catheterization of the ureter by opening its lumen and possibly draining off the pus from the kidney might be of service.

Dr. W. M. POLK coincided with the statements which had been made that in pelvic disease there were other organs which should also be interrogated before deciding upon laparotomy. Women in fashionable life who indulged in the pleasures of society and the pleasures of the table seemed quite prone to complications of kidney disease with pelvic disease. Such women bore ether and the shock of operations badly. After operations upon such cases there were also intestinal complications frequently, and excretion in general was interfered with or suspended.

Dr. HOWARD KELLY wished to emphasize the propositions laid down by Dr. Engelmann. Reports of cases in which pelvic and renal disease coexisted were common enough. It was easy to understand that such complications might exist, bearing in mind the anatomical relations of the ureter and kidney. Tuberculosis of the bladder, cancer of the uterus, bladder, and vagina, retro-peritoneal sarcoma, peritoneal adhesions, and vesico-vaginal fistula might all complicate or be associated with disease of the ureter and kidney. The ureter was often encroached upon by the gravid uterus in the latter months of pregnancy, and inflammation of its vesical extremity was a very common condition. Palpation of the ureter was readily performed, and would clear up many uncertainties. Catheterization could also be performed if indicated.

Dr. B. B. BROWN, of Baltimore, had seen a case of hydatid of the ureter in which a diagnosis had been made after dilating the urethra and exploring the bladder and ureter, which had been dilated by the tumor, with the finger.

Dr. COE, in concluding, recalled several cases in which hy-

drenephrosis had been found after death which had been unsuspected when laparotomy had been performed. The operation of kolpo-uretero-cystotomy which had been recommended for certain cases seemed to him an uncalled-for operation, as it was impossible to say that it would be efficient in any given case. He had seen a case in which it had been performed, the pelvis of the kidney being washed out while there were several abscesses in the cortex which could not be reached by the irrigation.

Dr. ENGELMANN, in concluding, reiterated the necessity of careful investigation to ascertain the presence or absence of renal disease in connection with disease of the pelvic organs. The subject was one which would broaden the field of gynaecological work.

**Pelvic Congestion versus Pelvic Inflammation.**—Dr. S. C. GORDON read a paper on this subject. Of all conditions which had given rise to dispute and misunderstanding among surgeons, none was more prominent than pelvic inflammation. The term chronic pelvic inflammation which was used by many writers was a misnomer, for while the condition indicated by the term presented some of the phenomena of inflammation, it was not an inflammation in the proper sense of the term, and this had long since been shown by Peaslee and others. Acute pelvic inflammation might recur an indefinite number of times, the result being resolution, suppuration, or an indurated mass, and it was the latter which was so often termed chronic inflammation. With the induration coexisted venous congestion. This implied hypernutrition and eventually hyperplasia. The pelvic tissues and organs in general might be involved, and patients so affected seemed especially susceptible to renewed attacks of acute inflammation. It had appeared to him that such a condition existing in cases where operations upon the cervix uteri were required was not benefited by the preparatory treatment advised by Emmet as a preliminary to such operations. It seemed more logical to him, besides more economical of time and money to the patient, to operate upon such patients at once, relieve the passive congestion by free bleeding during the operation, and expect resolution to follow. This plan had been adopted by him, operations upon the cervix being preceded by thorough curetting of the uterine mucous membrane, and the method had been entirely satisfactory. It was unnecessary to say that such operations should always be performed under anaesthesia. Indeed, so fearful was he of exciting pelvic inflammation that he preferred to use an anaesthetic if only an intra-uterine application were to be made.

Dr. T. A. EMMET stated that he did not advocate preparatory treatment, except while an acute inflammation existed. As to pelvic tenderness, that could be excited by pressure of the finger at any time after pelvic peritonitis had existed and the peritoneum had become scarred and folded. It was a fundamental fact that inflammation of the pelvic connective tissue meant destruction of that tissue; its vessels were deprived of support, venous congestion or phlebitis and lymphangitis resulting, and the proximity of the peritoneum must in most cases also necessitate peritonitis. This process might result in resolution or abscess, and it was frequently followed by peritoneal scars and bands. The venous congestion was frequently relieved by steady pressure from a vaginal tampon of cotton-wool.

Dr. A. P. JOHNSTONE, of Danville, Ky., believed that the peritoneal bands and adhesions which were of such frequent occurrence were in many instances the primary cause of the susceptibility to pelvic inflammation which was common to so many women. The tension and pressure of these adventitious products prevented the growth of epithelium in the tubes and uterus. The lymphoid tissue of the endometrium normally developed into epithelium, but faulty conditions, including the one

which had been mentioned, caused the development of connective tissue instead of epithelium.

**The Surgical Treatment of Posterior Displacement of the Uterus.**—Dr. W. M. POLK read a paper with this title. Backward displacements of the uterus could not always be relieved by pessaries; hence arose the necessity for other means of treatment. Brandt's method of treating such conditions by massage would not be considered, as the reader had not sufficient knowledge or experience of it to discuss it intelligently. There remained treatment by measures purely surgical. Such measures consisted in the operation from the outside, or Alexander's operation, and, on the other hand, the various operations which necessitated laparotomy. Matured experience had led the reader to prefer Alexander's operation in all cases in which it could properly be done, supplementing it by the use of an intra-uterine stem pessary in certain cases. Should prolapse of the ovaries coexist with the uterine displacement, this condition would likewise be relieved simultaneously with the other. Procidentia uteri could also be relieved by this operation, though there might be a field for hysterectomy in severe cases. Repair of the pelvic floor should be accomplished in addition to Alexander's operation in all cases in which it was indicated. If the round ligaments had undergone fatty degeneration, it was obvious that laparotomy must be done and an intra-abdominal operation performed. The same treatment would be required if the retroflexed uteri were firmly adherent to the pelvis, or if the tubes and ovaries were diseased. Many operations had been proposed for shortening the round ligaments within the abdomen. All of them implied either the use of existing supports or the making of new ones. Of those in which the latter procedure was adopted, ventro-fixation seemed the most useful, though it had certain objections which were obvious. Of those in which existing supports were utilized, Tait's and Imlach's consisted mainly in reefing the broad ligaments, the tubes and ovaries having first been removed. Wyllie's consisted in doubling the round ligament upon itself, stitching the folded portions together, and the reader's consisted in drawing the ligaments together in front of the uterus and stitching them together in that position.

Dr. W. H. BAKER, of Boston, agreed with the reader of the paper that Alexander's operation must always be a safer procedure than any in which the abdomen was to be opened, and hence was always to be preferred whenever it was feasible. If the abdomen were to be opened, he preferred ventro-fixation as an operative procedure. An objection to it was that the attachment of the uterus to the abdominal wall had given way in some instances and necessitated a secondary operation.

Dr. HOWARD KELLY preferred ventro-fixation to the attachment of the uterus to the anterior segment of the pelvis, as advocated by Zweifel, as the latter procedure brought the uterus into a faulty position, and would be likely to produce vascular derangement. His own results with ventro-fixation had not always been as desirable as could be wished, but they had improved since he had adopted the plan of casting his sutures around the utero-ovarian ligaments from behind forward. He had tried Schücking's method of ventro-fixation with good results in two cases.

**The Relation of Uterine Retro-deviation to Pregnancy.**—The secretary read a paper by Dr. A. MARTIN, of Berlin. It was an admitted fact that pregnancy was impossible at least in some cases in which retroflexion of the uterus existed. The paper which was presented was based upon the experience of the author, which included seventy-nine cases seen in hospital practice and forty-two in private practice. In all of these cases there were typical symptoms which resulted from the displacement. Two questions must be considered in the discussion of

the given subject: 1. Was retro-deviation a bar to pregnancy? 2. Was retro-deviation during pregnancy as serious a condition as had been commonly supposed?

The symptoms which had presented themselves in many of the author's cases had been haemorrhage, uterine catarrh, tubal disorder, and peritonitis. In other cases no such disturbing symptoms had arisen, and pregnancy had gone to term without mishap. If retroflexion were congenital, sterility would probably ensue, and it might be that the majority of cases in which sterility coexisted with retroflexion were of this character, though it was necessary, of course, to interrogate the procreative ability of the husband in all cases before giving an opinion. It was not believed that retroflexion of the gravid uterus in multiparae was due to improper care or treatment during childbed, at least not in all cases. Conception frequently occurred in cases in which retroflexion existed, and this proved that retroflexion was not necessarily a bar to pregnancy. If there were abrasions or catarrh of the uterus, the same careful treatment was indicated as in the non-gravid state. In all of the cases in the author's table there had been abortion in only four, and in ninety-seven there had been delivery at term. Diagnosis of the retroflexion had been made at periods ranging from the second to the sixth month. Replacement of the uterus was indicated in all cases in which it could be done without the use of undue force. Of course this excluded cases in which adhesions were dense and firm. The bladder of the patient should first be emptied; she should then be placed in the knee-elbow position, and replacement effected by pressure with one or two fingers. A pessary should then be introduced, and this might remain until the sixth month of gestation. If replacement or a pessary were inadmissible, a vaginal tampon of cotton-wool might be serviceable in giving support to the uterus. Many cases of retroflexion were relieved by spontaneous replacement, and in many others there was no consciousness on the part of the patient of any morbid condition. In extreme cases one must consider the propriety of emptying the uterus, or even of extirpating it.

Dr. BACHE MOE. EMMET had seen few cases in which pregnancy had been complicated with retroflexion—in fact, he had usually considered such a displacement as a bar to pregnancy. In cases in which retroflexion could not readily be cured he thought that conception might be favored if the womb were raised by a vaginal support, and if pregnancy were present such a procedure would favor its continuance.

Dr. HOWARD KELLY had experienced the importance of curing uterine retroflexion in the cure of sterility which resulted. He believed that retroflexion of the gravid uterus was cured spontaneously in most cases, and that abortion or other severe accidents rarely resulted. The uterus might develop in an abnormal and very faulty position, even though its position were normal at the time of conception. He could conceive of the necessity and propriety in extreme cases of opening the abdomen and relieving a displaced uterus.

Dr. T. A. EMMET considered that backward displacement was always an indication of local inflammation. Such a displacement had little to do with the question of conception, in his opinion, especially if the Fallopian tubes were permeable. He believed he had succeeded in preventing abortion in retroflexed gravid uteri by the use of vaginal packing. If replacement of the uterus were possible, he preferred to place the patient in the knee-elbow position for that purpose, but the replacement would be likely to result in abortion unless it were done without violence. He would not use a pessary after such displacement, as it was attended with danger.

Dr. A. J. C. SKENE did not believe that any condition could arise which would justify the extirpation of the retroflexed gravid uterus.

Dr. H. F. HANKS, of New York, emphasized the necessity of treating retroflexion during pregnancy to prevent abortion, and preferred vaginal tampons to pessaries.

Dr. J. R. CHADWICK believed that pessaries were allowable in the cases under discussion. He thought that abortion in such cases was an infrequent accident. Pregnancy rarely occurred if the retroflexed uterus were firmly fixed by adhesions.

Dr. BOLDT had read reports of cases in which death had resulted from inability to reduce retroflexion of the gravid uterus. It was in such cases that abdominal section was justifiable.

**Results of Repression of Menstruation.**—Dr. E. C. GEHRUNG read a paper with this title. It had been sufficiently demonstrated to him by an experience of several years that menstruation might safely be repressed by the vaginal or uterine tampon in cases in which the patient could ill afford the loss of blood which accompanied that process. Such a treatment was useful both for prophylactic and for curative purposes. A sanguineous discharge was not a necessary accompaniment of menstruation. In many cases there were only molimina, or a discharge of mucus, or a serous discharge. A bloody discharge was only an accidental accompaniment of ovulation, oestivation, etc., and failed to produce harm in many cases, just as was true of other transmitted habits. In many other cases it was the recognized cause of anaemia. He had never heard that this loss of blood could serve any useful purpose, and its occurrence was not more reasonable than the doctrine of Broussais that men should be bled monthly. If plethora were present, it should be treated rather by redistribution than by abstraction of blood; and if bleeding were ever a safety-valve, it was only in rare instances. What advantage was it to women that they made blood rapidly if they were to lose it as rapidly? It was dangerous to teach that by bleeding, superfluous elements were disposed of. The vaginal tampon was the best means for stopping menstruation, as it gave no shock to the nervous system and communicated no poison to the organism, as did ergot and other drugs. It was indicated with excessive menstrual or intermenstrual flow in all cases. With the scanty menstruation which was often a condition in anaemic women it would prove a source of relief to the anaemia and to the accompanying nervous symptoms. If amenorrhoea were present, the depraved general condition which usually coexisted must first be corrected by diet, tonics, etc., which would tend to restore menstruation. Then the tampon should be used periodically until health returned. The paradox was only apparent; the cause of the morbid condition must first be relieved, and then the morbid condition itself. Other conditions for the treatment consisted in certain neuroses and neuralgias, and in suitable cases it had been found efficient. It was not known that the method had ever been attended by bad results. It would relieve many cases in which mutilating operations would be necessitated if it were not used.

Dr. H. J. BOLDT could not consider menstruation a pathological condition, nor its haemorrhage accidental. Common as free menstruation was in women, anaemia from such a cause was relatively rare. Again, anaemia might persist after the uterine appendages were removed and menstruation had ceased, thus being entirely independent of menstruation. Cases of purpura haemorrhagica in which the effusion occurred periodically after the ovaries and tubes had been removed also showed the power of the habit of menstruation as a physiological function. If menstruation were excessive, the vaginal tampon would be indicated, but it would not be well to retain it as long as seventy-two hours, the limit which had been made by the reader of the paper. If it was indicated in women who flowed too freely, it would be well to begin its use two or three days before menstruation was due.

Dr. A. W. JOHNSTONE thought it an error to consider menstruation pathological. It was as necessary a function as respiration. Its object was probably to wash away over-ripe lymphoid corpuscles. The lower animals with whom the womb was in a horizontal position did not menstruate, though there was with them a discharge resembling menstruation, while in apes and monkeys which stood erect menstruation was a regularly performed function, and the flow might be profuse. If the vaginal tampon were used, plugs should also be placed at the mouths of the Fallopian tubes, and, this being done, danger would follow the unrelieved congestion in the broad ligament, which would tend to produce an indication for removal of the tubes and ovaries instead of the contrary, as the reader had stated. The speaker could not help the conviction that menstruation was a portion of the mechanism which prepared woman for pregnancy, for which condition she seemed physiologically intended.

Dr. A. REEVES JACKSON was not satisfied with a theoretical explanation when it was opposed to observed facts. The method of repression for excessive menstrual flow had been used by him for years, and always with beneficial results, and in so far as the reader's method applied to excessive flowing it was indorsed by him.

Dr. GEHRUNG, in closing, stated that he had proposed to use repression only in cases in which the loss of blood during menstruation could not be well sustained. He still thought that excessive menstruation depended more upon vascular than upon nervous influence, the womb and its vascular system being in a weakened condition.

**Intermediate Trachelorrhaphy.**—Dr. H. J. BOLDT read a paper on this subject. It was admitted by most gynaecologists that a great variety of ills might follow extensive lacerations of the cervix uteri, Nöggerath and a few others of prominence not conceding this proposition. Symptoms resulting from such lacerations had been observed by the reader as soon as three months after parturition, but they were usually delayed for a much longer period. An analysis of the histories of three thousand parous women had been made by the reader with the result that one hundred and nine were found in which positive symptoms existed which seemed to be traceable to injuries of the cervix. It being a fact, therefore, that lacerations of the cervix and resulting bad symptoms were possible, and that too in a considerable number of cases, there was a fair foundation for consideration of the expediency of anticipating such bad symptoms by an early operation in cases in which severe lacerations were found. In twenty-six cases the reader had adopted such a plan, in only four of which had there been an unsatisfactory result. Such an operation might be done within a month after parturition; it could be done in one's office without anaesthesia, the patient could go home and attend to her customary duties, and there would be no loss of time, which to many housewives meant a great deal. In doing the operation the surfaces of the torn portions were scraped and the angles freshened, after which catgut sutures were carefully and not too tightly placed. A straight trocar needle was used, a very sharp scraping instrument, and a tenaculum devised for the purpose. The object of the operation was to prevent the conditions which necessitated Emmet's operation.

Dr. BACIE McE. EMMET thought that the object which was sought by the proposed operation was a good one, but he questioned whether there were cases in which such an operation was indicated. It would be impossible to say in advance that Nature would not repair the mischief which had been made, and if she did, no operation of any kind would be indicated. At the early period suggested after labor it was improbable that the uterine tissues would be in condition to favor a successful operation in

most cases. He also strenuously objected to the recommendation to do such operations in one's office, and felt, in addition, that the skill of a gynaecologist was required for such cases—that is, that they should not be performed by the general practitioner before he dismissed his obstetrical patients, should the propriety of such operations be admitted.

Dr. SKENE disapproved of the proposed operation as unnecessary. Bad symptoms should be the only indication for the performance of Emmet's operation. It should not be done without an anaesthetic, in his opinion, nor in one's office.

Dr. B. C. BAER, of Philadelphia, understood the proposition in question to be, Was laceration of the cervix *per se* a lesion or not? If it were a lesion, the reader of the paper was right in proposing that an obstetric patient with such a lesion should not be discharged until that lesion was repaired.

Dr. T. A. EMMET believed that the proposed operation should not be performed, nor should trachelorrhaphy in any form be done in the absence of symptoms. If a puerperal patient received proper care, the injury which resulted from a severe labor would be repaired by nature, such care including proper diet, sunshine, vaginal douches, etc. One could not say within a month after labor whether an operation would ever be required. Women who had many pregnancies, which followed each other in quick succession, were the ones who most frequently required trachelorrhaphy.

Dr. ENGELMANN did not think the paper had been quite fairly discussed, in view of the fact that the extent of the injury to the cervix after labor was frequently so great that an operation would almost certainly be required at a future time on account of the characteristic symptoms. He did not approve of doing such operations in one's office.

Dr. BOLDT, in concluding, still believed that intermediate trachelorrhaphy would be beneficial for those who would be almost certain to require such an operation at a subsequent period if it were not done. In view of general disapproval, he would waive the propriety of doing it in one's office.

**The Value of Laparotomy in the Diagnosis and Treatment of Minor Forms of Intra-abdominal and Intra-pelvic Disease.**—Dr. T. A. ASHBY, of Baltimore, Md., read a paper thus entitled. The limits of laparotomy would apply in general to obscure conditions within the abdomen or pelvis in which all other available means of diagnosis and treatment had been unsatisfactory. There was still an unreasonable prejudice against laparotomy for diagnostic purposes in certain quarters, for it must be remembered that there was no danger in an abdominal section *per se*, but in the way in which it was done. There should be no mortality from simple abdominal section, and it was proper to perform it for any condition which could not be diagnosticated by other means. For tubal and ovarian disease he would not advise it, with the rash, who advised it for every such case, nor with the ultra-conservative, who seldom if ever advised it, but with those who followed a middle course in such matters. Laparotomy was indicated for morbid growths within the abdomen, which might be small, but in which relations could not be determined by other means. It was always indicated, he thought, in ectopic gestation, and was much to be preferred, as an expedient, to the use of electricity. It was also indicated for persistent pelvic pain, whether from neuralgic conditions or displaced organs, provided other measures had failed to accomplish the desired end. It was also indicated for many forms of intra-abdominal and intra-pelvic haemorrhage.

**Partial Rotation of the Ovum in Early Pregnancy as a Cause of Placenta Prævia.**—Dr. E. W. SAWYER, of Chicago, read a paper suggested by two cases in practice. It was admitted that the ovum was not very firmly attached to the decidua during the early days of pregnancy, hence it was not im-

possible that transmitted violence to the womb might succeed in detaching it, causing it to rotate downward on its axis and lodge in the lower segment of the uterine cavity. This was on the supposition, which was usually accepted, that the ovum was normally attached at first in the upper zone of the uterus. As the ovum became implanted in its new situation, new villosities would develop from the chorion, and the placental site would thus be transferred from the upper to the lower zone in greater or less proximity to the os internum; that is, there would be more or less pronounced placenta praevia. Two battledoor placentæ illustrative of this condition were exhibited, also diagrams hypothetical of the process described.

**The Protective Influence of Vaccination during the Intra-uterine Life of the Fœtus.**—Dr. C. KOLLOCK, of Cheraw, S. C., read a paper on this subject. Congenital malarial fever had many times been observed by the reader in new-born infants in the malarial country in which he lived. The germs of this disease being transmissible during fœtal life, it was certainly a fair presumption that vaccinia was equally transmissible. French investigators indeed had proved this, and his own investigations had been merely confirmatory of theirs. He had inoculated thirty-six pregnant women, fourteen being primiparae. The children were also all vaccinated after birth, failure resulting in five of the children of primiparae, and in sixteen of the multiparae. That is, this number of children had been protected by vaccination of their mothers. It was probably better to vaccinate during the later months of pregnancy, when the foetal circulation was active.

Dr. SAWYER, of Chicago, corroborated the statements which had been made, his experience being based upon thirty thousand vaccinations made during the past few years.

**A Case of Nephrotomy for the Removal of Calculus of the Kidney.**—Dr. J. R. CHADWICK, of Boston, read a paper thus entitled. In the case narrated calculus of the left kidney had been diagnosticated by eminent authorities, and an operation had been performed for its relief. The kidney had been opened, carefully explored with the finger, and thoroughly irrigated, but no calculus could be found. Since the operation the bad symptoms had returned, and were always exaggerated when the patient worried. It was believed by the reader that the symptoms were purely of nervous origin.

Dr. A. F. CURRIER, of New York, suggested that the stone might have been in the cortex of the kidney, but so small that it was overlooked, not being appreciated by the examining finger, and so impacted that it could not be washed out. A case presenting somewhat similar phenomena was narrated.

Dr. G. J. ENGELMANN suggested that the possibility of obscure pelvic disease should receive consideration in such cases as the one which had been narrated, and that important information might thus be gained.

#### AMERICAN LARYNGOLOGICAL ASSOCIATION.

(Continued from page 271.)

**Some Points in the Pathology and Treatment of Disease of the Nasal Pharynx.**—Dr. J. N. MACKENZIE, of Baltimore, read a paper on this subject. (See page 371.)

**Some Personal Observations upon the Acute and Chronic Enlargements of the Adenoid Tissue at the Vault of the Pharynx, and the Means used for their Relief.**—Dr. D. BRYSON DELAVAN, of New York, read a paper with this title. (To be published.)

Dr. F. H. HOOPER, of Boston: I have been much interested in both of these papers and agree, in the main, with what has been said. I think Dr. Delavan's explanation of the case seen

by Sir William Dalby and others correct. The extreme vascularity and erectile nature of this adenoid tissue were impressed upon me by one of my own cases. A young lady, twenty years of age, came to me with an attack of acute coryza, and I found what I considered a good-sized adenoid growth at the vault. After the acute attack subsided the growth had almost entirely disappeared.

I think the post-nasal probe an indispensable instrument for a proper examination of the naso-pharyngeal cavity in adults. The parts often look smooth when examined with the mirror, and I have been surprised in these cases, when examined with the probe with the aid of the mirror, to find what a large amount of hypertrophied tissue might be present. In many cases we might be deceived regarding the condition of this cavity if we relied upon the eye, while an examination with the probe or the finger would set us right. When adenoid tissue is present it ought to be removed as thoroughly as possible. The two chief indications for its removal are obstructed respiration and defective hearing. When a child's nasal breathing is obstructed by these growths they should be removed immediately, no matter what the season of the year might be. With regard to the question of haemorrhage, I have never seen alarming bleeding except in one case. This was in a very sickly boy, ten years of age, with typical hemophilia, on whom I declined to operate in the usual manner. In this case fatal haemorrhage followed gentle scraping of the adenoid mass with the fingernail. The amount of secretion during the operation depends, I think, upon some idiosyncrasy of the patient rather than upon the nature of the anaesthetic, whether chloroform or ether.

Dr. S. W. LANGMAID, of Boston: There is one thing that has not been mentioned in regard to anaesthetics. As Dr. Hooper has said, we do not give chloroform. We give ether, with the greatest confidence as a stimulant, to patients with a failing pulse. If the pulse is feeble, it increases in volume and strength during the administration of ether. Yet, confident as we are in the use of ether, I had an experience a few weeks ago which is not uninteresting. I was asked to operate at the Children's Hospital. I had not seen the child until it was brought to the table. It was a scrofulous, rather weak child, and I was told that it had hip disease. I proceeded in the ordinary way and removed the adenoma. All at once there was heart failure, requiring the rectal injection of ammonia and brandy, and also the subcutaneous injection of the same drugs.

Dr. HARRISON ALLEN, of Philadelphia: I wish to confirm the statements of Dr. Delavan. I had intended to prepare a paper upon the subject which he has so admirably treated. This is now unnecessary. It may interest the fellows to know that the cases that I have had confirm in every particular the conclusions which he has presented. There is a state of pharyngeal distress and ear distress in adults due to something at the vault of the pharynx. Whether it is a recession, or a juvenile condition, or pharyngeal palsy, or some other factor, the truth remains that there is something which the eye will not detect, but which the probe will detect, and, above all things, the finger will detect. The finger can not be used without the employment of an anaesthetic. I think that this is an important thing to be considered. I always insist that an anaesthetic should be given if the condition of the heart admits. This condition is not one that can be treated by niggard processes. Under anesthesia you can clear out the pharynx and you have the aid of the sense of touch. I have noticed that this material may remain at the anterior part of the vault over the sphenoid bone. I have not been able to dissociate it from some trouble connected with the union of that suture. There is often a recession which is not detected by the mirror.

In respect to ear complications, we read in books devoted to

the ear of obstruction of the Eustachian tubes. I have never found mucus in the tubes where aural trouble was complained of, and you may often see a quantity of mucus, pus, or something else occupying the tube and no ear distress. Is it not possible that the ear distress is due to a state of vascularity and congestion determined by pressure outside of the tube by the adenoid? At any rate, a very small amount of this tissue will cause these symptoms, and often nothing but the finger-tip will reveal its presence. Doubtless this may exist without symptoms, but where reflex symptoms are complained of and the patient comes for diagnosis and treatment, we should make a thorough exploration under an anaesthetic, and if anything is found, take it away. I have often etherized patients and found nothing, but I have never regretted it. There is often no way of determining the presence or absence of this condition without anaesthesia. I always use ether. I was educated never to use chloroform, and I am timid about it. Whether or not this is simply the result of early impressions I am unable to say; I am not able to analyze it. I have used ether without accident.

**Dr. J. C. MULHALL**, of St. Louis: I have for several years laid it down as an axiom for practical guidance that the pathology of the pharyngeal tonsil was exactly the same as that of the faecal tonsil. Some two years ago a physician of St. Louis came to me with an acute attack, with a temperature of 103° and a great deal of distress and pain about the ears. On examination, I told him he had a follicular inflammation of the pharyngeal tonsil, and he was very much surprised. There was a great deal of swelling of the parts with some exudation from the follicles. That we may have acute exacerbations of the hypertrophy of this part there is no doubt.

I wish to call attention to an instrument which has been very satisfactory in my hands and which was invented by Dr. Gradle, of Chicago. The only objection that I have to it is that the blades open laterally. In one case, in attempting to use this instrument, I caught a portion of the soft palate and tore it. Another objection to the instrument is that it is difficult to grasp that portion of the adenoid that lies close to the septum, and that you are liable to grasp the septum. I have had a forceps constructed with the blades opening antero-posteriorly, and with this instrument I have always been able to remove all the tissue in that region. I have operated a great many times, and only in two or three instances did I require an anaesthetic. Since the introduction of cocaine I have found that the disagreeable part of the operation, which is the scraping of the instrument against the healthy pharyngeal wall and palate, can be avoided. I have applied cocaine thoroughly to these parts, and have succeeded without general anaesthesia. I have never seen any shock in these children. Only on one occasion, where, by the way, this adenoma had escaped detection for ten years, was there any difficulty in inducing the child to return. I have never seen any haemorrhage. I should like to repeat the fact, not generally known to the profession, that the pharyngeal tonsil is liable to the acute diseases that affect the faecal tonsil.

**Dr. F. I. KNIGHT**, of Boston: I should like to give, as I have no doubt that it will be of interest, the experience of one of our surgeons in pre-rhinoscopic days. This surgeon had had a great deal of experience in the removal of naso-pharyngeal tumors. One day he told me that he had a case of naso-pharyngeal tumor, and that he would like me to look at it with my mirror. He had done a preliminary tracheotomy, and intended to slit the palate and remove the tumor. I examined the patient and told him that I did not see anything except a little hypertrophied gland tissue. He replied that he had felt a tumor with his finger. He again introduced his finger, and the look of astonishment that came over his face was wonderful. It was one of those cases of acute exacerbation of the adenoid

hypertrophy—one of those cases which occur but once in a lifetime.

In regard to chloroform, we have always been instructed that, while chloroform may be given with perfect safety in the recumbent posture—as, for instance, in midwifery—we have always been told not to give it in the sitting posture. I would ask Dr. Delavan if he operates with the patient in the sitting or recumbent posture.

**Dr. DELAVAN**: I always place the patient on his back. I should not consider it safe to use chloroform in the sitting posture.

**Dr. W. E. CASSELBERRY**, of Chicago: There is one point concerning the technique of the operation for naso-pharyngeal adenoma which I have not seen mentioned. I am impressed with the importance of thoroughly eradicating these growths. This was especially shown in two cases recently in which the operation was performed for the relief of reflex symptoms. In one case spasm of the glottis, and in the other spasmodic asthma, was associated with adenoid enlargement. In both cases material relief followed the operation. The patient with spasmodic asthma, from having the attacks every week or every few days, remained free on one occasion as long as six months. The spasm of the glottis, attacks of which had recurred several times daily, now came only two or three times a month. In neither case was the operation sufficiently thorough to eradicate all the growths, as prominences here and there could subsequently be seen with the rhinoscope, and sufficed, doubtless, to occasion the remnant of symptoms.

With a view to greater thoroughness, I thought it might be possible to see what was being done during the progress of the operation. In order to do this I tied the velum forward with an elastic band passed through both nostrils and out through the mouth. I used the Vienna chloroform mixture, for two reasons—first, because I thought that it might occasion less secretion, and, second, because I desired to have my gas-lamp in immediate proximity. I operated with the patient in the sitting posture, and ether no doubt would be safer, and, with the substitution of the electric light for the gas flame, would be unobjectionable. The operation, so far as seeing was concerned, was not an entire success. In one case I could sponge out the blood and occasionally get a view; in the other case I was unable to do even this. I, however, found that tying the velum forward facilitated the operation. It was no longer necessary to hook the velum forward with the finger, which delays the operation. It might be urged in this connection that tying the velum forward would prevent the ready swallowing of the blood, and thus favor its entrance into the air-passages. To obviate this, as soon as a piece was taken out I had the patient's head and body inclined forward. It is important to do this at all times when there is anything like free haemorrhage, and when operating with the patient in the sitting posture. The tying of the velum forward and the inclining of the patient forward are two points in the technique of the operation which have given me great satisfaction.

**Dr. J. N. MACKENZIE**, of Baltimore: In operating I do not adopt the plan referred to by Dr. Delavan and Dr. Hooper. Unless the patient is young, or unruly, or comes from a distance, I generally operate at different sittings, removing a portion every day, or every other day, for about a week or ten days. In this way I get rid of the growth with no haemorrhage to speak of, with very little pain, and without the use of anaesthetics. If the patient seems to feel pain, I use cocaine or some other local anaesthetic.

In regard to the point made by Dr. Hooper with reference to passing a probe over a smooth and apparently healthy surface, I have had this experience. Some time ago I treated a

case of obstinate post-nasal catarrh in which there was apparently no hypertrophy of the pharyngeal tonsil as seen by the mirror. An immense quantity of muco-purulent discharge poured out of the pharynx every day, and I became completely dissatisfied with my work. It suddenly occurred to me to make a deep incision in the pharynx, and, with the acquiescence of the patient, I made an incision with a curved knife into the smooth and apparently healthy tissue. This was followed by the discharge of a large amount of a colloid sort of matter, and with great relief to the patient after a few days. He is still under observation. I am trying to remove as much as possible of the pharyngeal tonsil. Since the incision the amount of discharge has lessened very notably.

I have seen only one case in which haemorrhage was very severe. It was the case of a young colored girl sent to me from one of the lower counties of Virginia. The growth was apparently of an adenomatous character. The soft palate was pushed forward almost to the teeth, the whole mouth was filled with this enormously stretched palate, and nothing could be seen beyond the mass of flesh and tumefaction. There was a little slit on the side through which she could take liquid nourishment. The child was badly nourished, and also had a large adenoid tumor of the neck. When I put my finger into the naso-pharynx, it caused a most alarming haemorrhage. When I examined the nose, a tremendous flow of blood took place from both nostrils. She had also strabismus, and both eyes were exophthalmic. I hesitated about performing any operation. I took her to the Baltimore Academy of Medicine, and several surgeons examined her. One of them put his finger into her mouth, and the bleeding was so great that we thought she was going to die. None of them would undertake the case, and neither would I. Afterward she left the hospital by climbing a tree and jumping the fence and escaping.

As a rule, the haemorrhage in operating is very slight. It may pour out of the nostril, but it always stops of itself. I think that haemorrhage on digital examination may be considered almost a diagnostic sign.

I have never met with any accident. The only thing that I recall was in the case of a little girl who was thoroughly anaesthetized and the operation done at a single sitting. A bichloride solution was left with which to syringe out the naso-pharynx. The next day there was a rise of temperature to 103° or 104°, with some pyæmic symptoms. These all passed away after washing out the retro-nasal space.

I consider these cases of adenoid growths as among the most brilliant that we meet with in nasal surgery. There is only one other point to refer to, and that is the nature of these growths. They have been spoken of as adenoid. The growths that I have seen in Baltimore have been of a papillomatous character. I have examined a number of them under the microscope, and their structure does not differ from that of papillomatous growths in other localities. There is, however, a variety which is adenoid; and I believe that is the form which Dr. Hooper sees in Boston, and which Meyer saw most frequently in Copenhagen. We should distinguish between these different varieties. The adenoid growths are more difficult to remove, and occasion more pain than the soft papillomatous growths.

Dr. DELAVAN: I have nothing to say in addition, except to reiterate the fact, which I appreciate the more the oftener I operate, that the operation is painful and that in many cases cocaine does not meet the requirements. Indeed, it seems impossible that it should in a growth of considerable size, for the cocaine can only be applied to a small portion of the surface, and that the most remote from the pedicle. The operation is painful, and in the majority of cases an anaesthetic will give great help not only to the operator but to the patient.

**Note on the Galvano-cautery in the Treatment of Hypertrophied Tonsils.**—Dr. C. H. KNIGHT, of New York, read a paper with this title. (To be published.)

Dr. T. A. DEBLOIS, of Boston: I think that the principal objection to the removal of the tonsil, or rather snipping it off, is the production of a scar in the mouth. I have not cut a tonsil for a great while. I used to cut every one that I could. I have used the cautery point in two cases of enlarged tonsil, with excellent results. I have not heard Dr. Knight refer to the use of the electrolytic needle, which I have employed with satisfactory results. The pain under cocaine is very slight. A very small amount of electricity will produce chemical changes in the fluids of the part. Half a dozen punctures each day will in a short time, in the majority of cases, produce a great diminution in size. I use this only in adults. I do not employ it in children, for in them the tonsils are very apt to lessen in size.

I agree with Dr. Knight in regard to the pain and distaste of the cautery point. The smell is very objectionable, particularly in the clinic room, where the smell will last half the morning. These patients do not come back if they can help it. I think even then it is preferable to the use of the guillotine.

Dr. CHARLES E. SAJOUS, of Philadelphia: I have frequently used the galvano-point. I think that in his first paper Dr. Knight stated that eight or ten applications were sufficient to bring down certain tonsils. Such has not been my experience. It has generally taken eighteen or twenty sittings to reduce tonsils of any size. So far as the odor and pain are concerned, I think that after the first or second visit we have very little trouble with the patient on that score. I can lend my voice to that of Dr. Knight in support of the galvano-cautery point in the treatment of enlarged tonsil, especially where the density is not great. In these cases cicatricial contraction assists in reducing their size. I burn as deep as the knife will go—about a third of an inch.

Dr. W. H. DALY, of Pittsburgh: If we wish to retain the respect of one another and of the profession generally, it seems to me that we should do our surgical work in a surgeon-like manner. I must say that I have very little patience with methods of treatment of enlarged tonsils which would subject the patient to half a dozen sittings with a plaything like the instrument that my friend Dr. BeBlois speaks of. I am astonished that a man of his proportions, mentally and physically, would indulge in the use of such a child's toy as that. I speak of this derisively because I have used it repeatedly until I satisfied myself that I was wasting my time and stultifying not only myself but my patients.

I believe that in the normal throat there is no tonsil that you can discover beyond the line of the half arches, and that should be the rule to guide us in abscission—and I mean abscission and not burning with the galvano-cautery knife. We should have one object in view, and that is to restore the abnormal throat to a condition as near anatomically perfect as possible. First use the amygdalotome if you wish to, but this will not do the work completely. Then with a probe-pointed curved bistoury and toothed forceps trim off the remaining portion of the tonsil until the half arches fall where nature intended them to fall—to their proper places. You will then have improved phonation and improved general health, and, if the patient has a predisposition to pulmonary disease, he will not be handicapped by a condition of affairs which God Almighty did not intend should exist in health at least.

I reiterate, then, that if we wish to retain the respect of each other and of the profession—for our special branch is the youngest of all—we must throw away our toys and playthings and do our work like sensible men and surgeons.

**Dr. DEBLOIS:** If Dr. Daly wishes to cut off tonsils with an axe, he may be allowed to do so. If he wishes to cut them off behind the horns, he ought to be permitted to do so. But there are other ways of reducing the size of tonsils. I do not think that he should speak of the electrolytic needle as a toy, for it does its work. I do not think that he should be permitted to sit down upon the whole system because it did not happen to work in his hands. I have seen tonsils atrophy under its use. There is no reason because we do surgery that everything should be cut off, and nothing treated so as to atrophy, if that is possible.

**Dr. F. H. BOSWORTH,** of New York: I have listened with no little amazement to this discussion. I believed that the simplest operation in surgery in the hands of a competent laryngologist was cutting out of the tonsils. I can conceive no possible justification in submitting a patient to eighteen or twenty operations when the whole thing can be done in a moment. I indorse every word that Dr. Daly has said. The enlarged tonsil requires to be taken out just as much as a fibroid tumor of the uterus, and it should be taken out entire, not in pieces. I do not suppose that any man would say that a fibroid tumor of the uterus should be partially removed. In the same way there is no justification for removing a part of the tonsil. No one would think of removing a fibroid tumor in eighteen or twenty sittings. There is no case on record of death from haemorrhage after the operation of cutting out the tonsils, and this is the only danger attendant upon the operation. I do not think that Dr. Daly's remarks are in the least overdrawn.

**Dr. C. C. RICE,** of New York: There are a few cases of enlarged tonsils in which the use of the galvano-cautery is the best operation that can be employed. I have in mind a case operated on within the last few weeks—that of a gentleman about forty-five years of age, who has had attacks of suppurative amygdalitis repeatedly; the tonsil was very large, very firm, and filled with blood. One tonsil had been excised by a physician in New York and the man nearly bled to death. He bled, in fact, until syncope took place. I saw him some weeks later, when he was suffering with a fresh attack of amygdalitis. The tonsil which had been removed was excised with the guillotine and the pillars were not injured. I preferred, with such a history, to use the galvano-cautery for the remaining tonsil. I would say to those who think that little can be accomplished with the galvano-cautery, that the whole of a large tonsil in an intelligent adult can be removed at a single sitting. The tonsil was treated with cocaine, and the edge of the galvano-cautery point was inserted into the tonsil at the level of the pillars and the tonsil cut through. The whole of the tonsil down to the pillars was removed at one sitting. There are a few such cases in adults, where there has been a history of haemorrhage and where frequent attacks of inflammation have left the tonsil immensely congested, where the galvano-cautery used in this manner is efficient. In excising large congested tonsils in adults I have several times proceeded in the following manner: I have employed a dull amygdalotome, and have pushed the blade down very slowly. Cocaine is used so that the patient can easily tolerate the instrument in the mouth for some time. There is little pain. In this way the blood-vessels are compressed before they are cut.

**Dr. C. H. KNIGHT,** of New York: My object is to call attention particularly to the loop operation, which in my opinion is superior to ignipuncture. It can be done at one sitting. The portion of tonsil removed does not indicate the extent of the operation. A good deal of the tissue that remains will slough, and contraction takes place. The thoroughness of the cautery-loop operation has been equal to that with cutting instruments. I would not for a moment be suspected of opposing amygdaloto-

my. Yet we sometimes meet with cases which can not be cut. It is to these exceptional cases that the galvano-cautery is adapted.

**Dr. DALY:** I merely want to add a word in justification of my remarks, that may have seemed bold and harsh. I do not get up to apologize. I apprehend that this is a society for scientific advancement. It is not a mutual admiration society. It is well enough to indulge in our love feast with our legs under the mahogany at our annual banquet. I believe that here is the place where candid opinions should be expressed, even if they are not expressed in as polished language as they ought to be. This is better than to pat a man on the back and say, "You are doing the very thing—just go on in that way," when in truth we believe he is doing the wrong thing, while he is quite capable of doing what is creditable and efficient, both for himself and for his patients.

**The Treatment of Diseased Tonsils when unattended with Hypertrophy.**—**Dr. JOHN O. ROE,** of Rochester, read a paper on this subject. (To be published.)

**Dr. H. L. SWAIN,** of New Haven: I have had an interesting case in which the recurrence of swelling of the lingual tonsil was due to the presence of these hard or caseous masses in the faecal tonsil. I only succeeded in subduing these attacks by treating first these crypts in the faecal tonsil. The treatment which proved successful, and easily so, was the laying open of the crypt with the galvano-cautery knife and thoroughly cauterizing the interior, more by ignipuncture than by any attempt to burn out the whole cavity. The case has been watched for several months and the result remains good.

**Dr. J. SOLIS-COHEN,** of Philadelphia: These conditions of the tonsil have given me a great deal of trouble for years. I find that many cases of spasmodic cough are due to nothing else than the presence of these masses in the crypts and lacunæ of the tonsil, sometimes even without any evidence of their presence on the surface. I find these not only in the enlarged tonsil, but also in the apparently contracted tonsil. It is sometimes necessary to produce some gagging so that the posterior surface of the tonsil will present itself before you detect the mass. In obscure cases of spasmodic cough I have for a long time carefully examined the tonsil as a possible source of reflex irritation.

Where the tonsils are enlarged I believe the best treatment to be excision. In those cases where the tonsil is atrophied or apparently atrophied—for even here the tonsil may be as large as a large almond—I press the matter out with a blunt scoop, and then use a simple astringent consisting of one grain of creasote, one grain of iodine, and five grains of iodide of potassium to the ounce of glycerin. By getting this well down into the lacunæ, you can sometimes cure these cases. Where this does not answer, I have taken a pair of curved serrated scissors, such as were long ago recommended for other purposes by Dr. Benjamin Ward Richardson, to cut the crypts open. One blade is put into the orifice and the part is cut through, and then with a dull scoop the crypts are scraped as thoroughly as possible. Sometimes this leaves ragged edges, but these can readily be snipped off.

I believe that this disease is not so well appreciated by the profession as it should be. I have seen many cases of prolonged cough, extending over a period of five or ten years and longer, completely and permanently relieved by treatment of this condition.

**Dr. DELAVAN:** My experience is entirely in harmony with the statements of Dr. Lennox Browne upon this subject, and I agree with the reader of the paper. The pathological tonsil is, I think, by no means limited to the one in which hypertrophy alone is present. There are many other conditions of the tonsil

which give rise to difficulties both direct and reflex, and which can only be relieved by attention to the tonsil.

**Dr. DALY:** There is another condition which was not brought out in the paper, and which I have more than once observed in cases where the lacunæ had become filled with cheesy matter, and that is that the patient would become really ill, suffering with headache, loss of appetite, lassitude, and other evidences of disordered secretion; and, before I adopted the method of absceising the tonsil and obliterating the lacunæ, I made sufficient observations to satisfy myself that these accumulations were the cause of the general symptoms by an auto-infection.

There is another point: these accumulations render the breath exceedingly offensive, and to some persons this is especially disagreeable. I am much obliged to Dr. Roe for giving us this excellent paper and dealing with this subject in such a common-sense way. I believe that the treatment should be radical and curative, not tentative.

**Dr. F. I. KNIGHT:** It seems to be a question whether or not in such cases the underlying condition is not some constitutional fault, or possibly some digestive disturbance. In some typical cases I have seen the follicular exudation not only upon the tonsil, but also upon the tongue, the lingual tonsil, the soft palate, and the back of the pharynx. It seems as though they frequently came in connection with some constitutional disturbances, and we shall not succeed in relieving the patient entirely from this exudation until we modify the constitutional or digestive condition.

I had one notable case, such as Dr. Cohen describes, where the patient for years had an irritative cough, and discomfort always referred to one side of the throat. The cause of the trouble had escaped detection by several observers, and I did not discover it for several visits. On making her gag and throw out the tonsil, I found the point of one of these exudations. I then passed a probe in as far as possible and scooped out a cretaceous mass as large as a pea or larger. The symptoms were at once relieved.

As far as local treatment is concerned, I would say that I have had satisfaction with the cautery point, or with any destructive agent which I have had the patience to introduce into each one of these follicles after it was emptied.

**Dr. S. JOHNSTON,** of Baltimore: As bearing upon this condition of the tonsil, I would state that in three cases which have come under my observation the exudation from the follicles, instead of being a soft, cheesy material, resembled little spicules of bone or small crystals of alum. These adhered with great tenacity to the tonsils, to which, however, they were not confined, but were also found on the fauces and the post-pharyngeal wall. They can sometimes be drawn out with great difficulty, and are exceedingly painful to the patient, who often complains of a foreign body in the throat. Two of my cases were in children and the third was a physician from a neighboring county. I tried a great variety of remedies, but the best results were obtained from chromic acid in ten-per-cent. solution. After one application, the parts being previously sprayed with an antiseptic solution of phosphate of sodium and carbolic acid, these crystals could be drawn out with the forceps. The specimens were not examined microscopically. If any of the gentlemen have had similar cases I should be glad to hear of them.

**Dr. RICE:** I have recently seen a most remarkable case of retained tonsillar secretion—remarkable on account of the large amount of cheesy material present; not only does it fill the lacunæ of the faucial tonsils, but the lymphatic tissue at the back of the tongue is whitened with the deposit. In this case the tonsils are normal; there are no adhesions to the pillars. I

have listened with interest to the remarks of Dr. Daly, and I had hoped that some information would have been gained as to the constitutional conditions causing or associated with this retention of tonsillar secretion. I have tried to discover any constitutional peculiarities in my case. The patient has had diphtheria two or three times, and everything in the way of an explanation seems to point toward local causation.

I can bear witness to Dr. Daly's belief that this retention affects the general health. It also causes an offensive breath. While the general condition of my patient is quite good, she suffers with headaches, symptoms of indigestion, and is frequently tired and miserable. The tongue is very much coated. This tonsillar cheesy material has been found by a German investigator to contain putrefactive bacilli.

I am treating my case with the galvano-cautery puncture.

**Dr. ROE:** I fear that I did not make myself clearly understood. I desire to emphasize the point that the retention of this fetid filthy material in the tonsillar lacunæ is the cause of the general illness of the patient.

**Dr. ROE:** I am glad to know that the observations of so many of the fellows present have been in accord with those which I have made on these particular diseased conditions of the tonsils. There is one point regarding the aetiology of the first condition of the tonsils described in my paper that has been, I believe, entirely overlooked. It is that this lacunar catarrh and disease of the crypts are the result of hypertrophy of the tonsil, and that the closing up of the lacunæ often results from the attempts that are made to reduce the size of the tonsil during childhood by repeated applications of astringents, which have no other effect than to close the external orifice of the lacunæ and to cause a retention of the secretion which distends the crypts of the tonsils, and the secretion, becoming decomposed, adds to the abundance of the discharge. The tonsils, accordingly, become diseased throughout, and are in appearance, when cut through, much like a honeycomb. I have found the application of remedies thrust into the openings of such tonsils to be of no value, because so few of the crypts can be reached. The only radical treatment is the removal of the diseased portion. This is also the case with the fibrous form, which results from atrophy of the stroma and the deposit of fibrous tissue. In both of these cases the function of the tonsil is practically abolished, and the only way to remove the difficulty is to remove the diseased mass.

## Miscellany.

**The New York State Examination of Persons intending to Study Medicine.**—The Board of Regents of the University of the State of New York has issued the following circular:

1. The Legislature during its recent session enacted the following law to elevate the standard for admission to practice medicine:

"AN ACT to provide for the preliminary education of medical students.

"APPROVED by the Governor, June 13, 1889. PASSED, three fifths being present.

"*The People of the State of New York, represented in Senate and Assembly, do enact as follows:*

"SECTION 1. Before the Regents of the University of the State of New York or the trustees of any medical school or college within this State shall confer the degree of doctor of medicine on any person, who has not received a bachelaureate degree in course from a college or university duly authorized to confer the same, they shall require him to file with the secretary or recording officer of their university or college

a certificate showing that, prior to entering upon the prescribed three years' study of medicine, he passed an examination conducted under the authority and in accordance with the rules of the Regents of the University of the State of New York, in arithmetic, grammar, geography, orthography, American history, English composition, and the elements of natural philosophy, and such certificate shall be signed by the secretary of the regents and countersigned by the principal or commissioner conducting said examination.

"SEC. 2. This act shall not apply to persons who have already entered upon the prescribed three years' study of medicine, nor shall it alter the time of study or the courses of medical instruction required to be pursued in the medical colleges of this State by existing statutes.

"SEC. 3. This act shall take effect immediately."

2. For the accommodation of candidates under this law, special examinations will be held at the times and places noted in the annexed schedule. All correspondence on this subject should be addressed to Edward I. Devlin, A. M., the commissioner in charge of such examinations, at the Regents' Office, Albany, N. Y.

3. All candidates must notify the commissioner, by letter, at least one week in advance, stating at what place and in what studies they wish to be examined. No fee will be charged, and candidates will be informed of the result within twenty days from the close of the examination.

4. To insure success, the candidate should have a thorough knowledge of the whole of a standard school text-book on each of the required subjects, but cube root will not be included in the arithmetic examination.

5. Printed question-papers will be issued from the office of the Regents for each examination. The answers must be written in ink on legal cap paper, and arranged and numbered in the same order as the questions. Candidates should bring paper, pen, ink, and blotter.

6. Seventy-five per cent. of correct answers is required in all subjects except orthography. In the latter study, the candidate must spell correctly eighty-five out of one hundred words, such as are commonly used in current literature.

7. In the examination in arithmetic the entire operation required for obtaining the result must be given, and the answer or result must be reduced to the simplest form.

8. The candidate must write at the top of the first page of his answer-paper (1) the place of examination, (2) the subject, (3) the date, (4) his own full name, (5) his post-office address.

9. At the conclusion of his answers on any subject, or at the expiration of the time allotted for such subject, the candidate must make and subscribe to the declaration given below, by writing on the lines immediately succeeding the last answer the words: *I do so declare*, and then his name. Every paper lacking this declaration and signature will be rejected. The declaration to which he thus subscribes is as follows:

[*Form of Declaration.*]

"Do you now, at the close of the examination in arithmetic (etc., as the case may be), conscientiously declare that you had no knowledge of the questions to be proposed, that you have neither given to any other candidate nor received from any source explanations or other aid in answering any of them, and that you have not spent more than the allowed time? If so, write in the next line after the end of your set of answers, near the right side of the paper, the words *I do so declare*, and underneath subscribe your name."

10. All papers which fall below the required standard will be returned to the candidate. For those accepted, pass cards, certifying such proficiency, will be issued, and when all the subjects are completed, the certificate provided for in Article 14 will be sent.

11. Candidates may offer at any trial one or more of the subjects required, and the subjects passed at such trial will be placed to their credit on the records of the Regents. In like manner, subjects passed in the regular Regents' examinations in the academies will be allowed and credited to candidates. Should a candidate allow an interval of five years to elapse without passing an additional subject, he will be deemed to have relinquished his candidacy, and will be dropped from the records.

12. Examinations in the subjects required by this law also form a

part of the system established by the Regents and conducted in the 308 academical institutions under their visitation throughout the State. The dates for the current academic year are November 18-22, 1889; January 20-24, 1890; March 3-7, 1890; June 9-13, 1890.

13. While candidates will find the special examinations better adapted to their purpose, they may enter the examinations held in the academies; *provided*, in all cases, that they make application to the principal at least two weeks in advance, and pass the examinations in the several subjects at the same time and under the same regulations, as the candidates in attendance at such academies; and *provided* that they pay to such academies a fee of one dollar for each subject entered for examination. The answer-papers of persons so examined will be reviewed at the Regents' office in the same order as those of pupils in regular attendance, but they will lose no time by necessary delay at this office, if their papers are satisfactory.

14. Whenever all the subjects required have been passed by a candidate, and he has mailed to the commissioner, at Albany, a claim specifying when and where each subject was passed, the Regents will grant him a special certificate, known as the *Medical Student's Certificate*. This certificate is to be signed by the commissioner or principal conducting the examination. It will not be issued to pupils in regular attendance at an academy, but only to those who have finished their academic course and are actually entering upon the study of medicine.

15. These instructions are subject to such changes as may from time to time be deemed necessary.

**SCHEDULE OF EXAMINATIONS, 1889-'90.—1. Special Examinations for Medical Students:** Albany, October 8-10, 1889, October 29-31, 1889, February 18-20, 1890, at the Albany High School. Binghamton, December 17-19, 1889, at the Binghamton Central High School. Buffalo, September 30-October 2, 1889, February 4-6, 1890, at the Buffalo High School. Elmira, May 13-15, 1890, at the Elmira Free Academy. Ithaca, October 15-17, 1889, at the Ithaca High School. New York city, October 23-25, 1889, April 1-3, 1890, in the amphitheatre of Bellevue Hospital, Twenty-sixth Street and First Avenue. Poughkeepsie, January 7-9, 1890, at the Poughkeepsie High School. Rochester, December 10-12, 1889, April 8-10, 1890, at the Rochester Free Academy. Saratoga Springs, May 27-29, 1890, at the Saratoga Springs High School. Syracuse, October 3-5, 1889, at Syracuse University, Medical Department; January 21-23, 1890, at St. John's Catholic Academy, Lock Street. Utica, March 25-27, 1890, at the Utica Public Library.

The order of studies at all examinations will be: First day—Arithmetic, 10 a. m. to 12.30 p. m.; geography, 2 to 3.30 p. m.; orthography, 3.30 to 4.30 p. m. Second day—English grammar, 10 a. m. to 12.30 p. m.; American history, 2 to 4.30 p. m. Third day—Rhetoric and English composition, 10 a. m. to 12.30 p. m.; elements of natural philosophy, 2 to 4.30 p. m.

All candidates for these special examinations must notify Commissioner Devlin at Albany, by letter, at least one week in advance, stating at what place and in what studies they wish to be examined.

2. *At academies, examinations will be held as follows:* November 18-22, 1889; January 20-24, 1890; March 3-7, 1890; June 9-13, 1890.

All candidates for examination at the academies must notify the principal at least two weeks in advance, stating in what studies they wish to be examined. The principal will then order question-papers for them and inform them of the days and hours of examination.

**The American Rhinological Association** will hold its seventh annual meeting at the Palmer House, Chicago, on the 9th, 10th, and 11th inst., under the presidency of Dr. John North, of Toledo, Ohio. The programme includes the following items: "Report of a Case of Brain Abscess emptying into the Naso-pharynx," by Dr. L. B. Gillette, of Omaha, Neb.; "The Reason why so many Physicians fail in Treating Chronic Rhinitis," by Dr. Thomas F. Rumbold, of St. Louis; "Conjunctival Troubles the Result of Nasal Disease," by Dr. J. G. Sinclair, of Nashville, Tenn.; "Ocular Reflex Symptoms in Nasal Diseases," by Dr. C. H. Moore, of Indianapolis; "Therapeutic Measures in Rhinology," by Dr. N. R. Gordon, of Springfield, Ill.; "Report of the Insane Asylum Committee appointed at the last meeting to make rhinal examinations and report 'On the Relation of Rhinal Inflammation to the Mind Affec-

tions," by Dr. Thomas F. Rumbold, of St. Louis, chairman; "Reflex Symptoms of Rhinal Diseases, with Reports of Cases," by Dr. C. L. Dreese, of Goshen, Ind.; "The Administration of Quinine where there is Defective Hearing," by Dr. E. L. Sessions, of Hillsboro, Tex.; "Rapid Operations in removing Foreign Bodies of the Nasal Chambers," by Dr. Carl Von Klein, of Dayton, Ohio; "Surgical Treatment in Diseases of the Nose," by Dr. A. De Vilbiss, of Toledo, Ohio; "Catarrhal Neuralgia," by Dr. A. G. Hobbs, of Atlanta, Ga.; "Constitutional and Hygienic Treatment of Rhino-pharyngeal Inflammations," by Dr. R. S. Knodel, of Omaha, Neb.; "The Prescribing of Sprays to be used by Patients," by Dr. Frank D. Green, of Louisville; "Asthma is a Neurosis, or the Aetiology, Pathology, and Treatment of Asthma," by Dr. J. G. Carpenter, of Stanford, Ky.; "Reflex Inflammation of the Nose and Throat," by Dr. E. L. Siver, of Fort Wayne, Ind.; "Climatology," by Dr. T. F. Rumbold, of St. Louis, Mo. In addition, papers by Dr. A. B. Thrasher, of Cincinnati, and Dr. E. McClellan, of Chicago (titles not specified), are announced.

**The New Tri-State (Alabama, Georgia, and Tennessee) Medical Association** will meet at the Chamber of Commerce, Chattanooga, Tenn., on the 15th and 16th inst. The secretary announces the following items: Demonstrations with the microscope, by Dr. James A. Reeves, of Chattanooga; "Stricture," by Dr. Daniel H. Howell, of Atlanta, Ga.; "A Case of Typhoid Fever with Subnormal Temperature and Subnormal Pulse," by Dr. A. S. Wiltse, of Kismet, Tenn.; "A Plea for the Medical Education of Females," by Dr. Charles P. Gordon, of Dalton, Ga.; "Cholecystotomy, with a Case," by Dr. E. E. Kerr, of Chattanooga; "Report of a Case," by Dr. W. T. Blackford, of Graysville, Ga.; "The Physiology of the Heart and its Valves," by Dr. W. L. Gahagan, of Chattanooga; "The Relation of the Specialist to the General Practitioner," by Dr. F. W. Skillern, of Pikeville, Tenn.; "Some Points in the Diagnosis of Skin Diseases," by Dr. E. A. Cobleigh, of Chattanooga; "Imaginary Foreign Bodies in the Throat," by Dr. Max Thorner, of Cincinnati; and "Antiseptic Midwifery," by Dr. F. W. McRae, of Atlanta, Ga. Besides these, papers by Dr. F. B. Sloan, of Cowan, Tenn., and Dr. W. C. Maples, of Bellefonte, Ala. (titles not mentioned), are expected to be presented.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the abstract of sanitary reports received by him during the week ending September 27th:

CITIES.	Week ending—	Estimated population.	Total deaths from all causes.	DEATHS FROM—

**The New York Academy of Medicine.**—At the next meeting of the Section in Surgery, on Monday evening, the 14th inst., Dr. B. Farquhar Curtis will read a paper on "Knots, Ligatures, and Sutures," and cases will be presented illustrating the surgery of the hand.

**Effects of Prolonged Chloroform Anæsthesia.**—"Some observations, made about two years ago by Dr. Ungar, pointed to fatty degeneration of the heart and liver as the cause of death after repeated prolonged administration of chloroform. Further experiments on dogs have recently been made by Dr. Strassman, which appear to confirm this view. Dr. Strassman found that the first organ to be affected was the liver, then the heart, and after that other viscera. The nature of the morbid change was not a fatty degeneration, but fatty infiltration. The actual cause of death in fatal cases appeared to be the cardiac affection, as in all such a very marked degree of change was found in the heart. In non-fatal cases the morbid change was found to have disappeared in a few weeks' time. When morphine was given previous to the chloroform, less of the latter was required, and, consequently, the changes produced were not so considerable as when the ordinary amount was given. Animals suffering from hunger, loss of blood, etc., were especially predisposed to the morbid changes due to chloroform."—*Lancet.*

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

**Authors of articles intended for publication under the head of "original contributions"** are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

## Original Communications.

### SOME PERSONAL OBSERVATIONS UPON THE ACUTE AND CHRONIC ENLARGEMENTS OF

#### THE ADENOID TISSUE

AT THE VAULT OF THE PHARYNX,  
AND THE MEANS USED FOR THEIR RELIEF.\*

By D. BRYSON DELAVAN, M.D.,  
PROFESSOR OF LARYNGOLOGY IN THE NEW YORK POLYCLINIC.

The subject of adenoid hypertrophy at the vault of the pharynx, although not a new topic, is one which has by no means been exhausted. Many points connected with it have yet to be recognized and explained. No apology, therefore, would seem necessary for its study, if to it could be brought new facts, clearer light, or fruitful discussion.

It is not the object of this paper to deal with matters long ago investigated and already fully understood. It is hoped, however, that a few practical suggestions, gained through clinical study and tested in the light of experience, may be added to the present stock of information bearing upon the matter. With the history of the subject and with the already recorded experience of others it will be unnecessary, for the most part, for us to deal; nor can the usual categorical arrangement of matter be made, since the points to be presented are more or less disconnected, independent, and fragmentary. Still, it has seemed desirable that they should be collected and thus presented at once.

The material presented herewith may be classed under three general headings—namely, as relating (1) to etiology, (2) to pathology, and (3) to treatment. As to the origin and development of adenoids, the theory has generally been accepted that they usually commence to grow during childhood, that they remain stationary during youth, and, finally, that, if left to themselves, they will shrink away and disappear with maturity. Hence it has been taught, so far as they themselves are concerned, that they might be allowed to remain without interference on the part of the surgeon, the disastrous symptoms which are caused by them in the child being the immediate reason for their removal.

While, in a majority of instances, the above assertions are beyond question true, there are, on the other hand, many cases which seem to prove them incomplete, and which in themselves would offer abundant material for special consideration. Indeed, when carefully studied, the exceptions will be found, we believe, to embrace several large and important groups of cases—cases which occur by no means uncommonly, and which are capable of giving rise to annoying and even to serious symptoms.

Again, with regard to the pathology of the condition, much has yet to be learned as to the varieties of deformity which it may show, the relative importance of these varieties and of the symptoms growing out of them, and of the influence which it may exert upon surrounding organs.

In the treatment of adenoids many improvements upon

the methods usually adopted are possible, several dangers are to be avoided, and greater certainty and accuracy of result are to be attained.

And, first, with regard to the origin of adenoids, one of the most important statements quoted above is to the effect that hypertrophy begins in early life.

While, without doubt, many cases originate during early childhood in some one or more of the causes already familiar to us, it now and then happens that a patient will refer the first symptoms of the difficulty to a period later than puberty. Of such cases it is my belief that many are the immediate and direct sequelæ of an attack of diphtheria or scarlatina, most commonly of the former. The structure and pathology of Luschka's tonsil are largely analogous to those of the faucial tonsil. A general condition of enfeeblement, repeated catarrhal attacks, and other well-known causes may result in hypertrophy of the faucial tonsil at almost any age short of middle life, and, to a certain extent at least, the same may be true of the adenoid tissue at the vault of the pharynx. Not alone may it happen, therefore, that the enlarged Luschka's tonsil may not atrophy as the child grows older, but, as has been stated above, hypertrophy may even take place after the period of childhood has been passed. Cases are not uncommon in which enlargement sufficient to cause injurious results has persisted through middle life. The writer lately operated, with marked relief, upon a gentleman aged forty-four. In another patient, a well-known surgeon of over fifty, he has observed a distinct enlargement, dating back to childhood and even now giving rise to troublesome catarrhal symptoms, cough, and reflex irritation.

Among adults, however, he has seen a condition of moderate hypertrophy, most frequently in women of thirty or under. This class of patients are usually somewhat stout in figure, and resemble each other in general type. They may or may not have concurrent disease of the faucial tonsil. They are subject to attacks of catarrh of the upper air-passages. They are apt to suffer from various impairments of digestion. Many of my own cases have been in singers, whose voices have been directly injured in consequence of the above irritation, vocalization being difficult, the notes husky or at least impaired as to their brilliancy, and moderate efforts being followed by fatigue. All of these symptoms are aggravated by the slightest cold. Often the patient is able to locate with considerable accuracy the seat of maximum irritation. Examination of the upper pharynx shows a pharyngeal tonsil which very rarely extends below the upper margin of the Eustachian prominence, but which is distinctly enlarged and congested, and bathed in mucus. The Eustachian prominence, meanwhile, is pressed upon by it, in some cases with injurious force, and while the thickening may be but apparently slight, its effects may be serious. Among other results, impairment of hearing may be quite out of proportion to the amount of hypertrophy present; but it is often, however, wanting. Local topical treatment in these cases seems of little or no avail, while operation is followed by distinct relief.

One of the most interesting phases of adenoid disease is

\* Read before the American Laryngological Association at its eleventh annual congress.

that condition in which a temporary enlargement of the tissue at the vault of the pharynx takes place under special excitation, the enlargement subsiding with the disappearance of the cause. As this condition has not been heretofore described, so far as the writer is aware, special attention is called to it. It is well illustrated by the following case, which is exceedingly instructive as explaining a very possible source of error and disagreement.

A young lady of eighteen, blonde, somewhat delicate, but on the whole well developed and in the enjoyment of fair health, was treated by an eminent American otologist during one winter for deafness, with tolerably good results. In the following summer she went abroad. While in London she consulted Sir Richard Dalby, who, making a digital exploration of the upper pharynx, stated that he found there a considerable mass of adenoid growths which, in his opinion, should have been long ago recognized and removed. Sojourning in Paris, the patient was placed under the care of one of the best specialists in Europe, who made a rhinoscopic examination and failed entirely to confirm the diagnosis of the London physician. In the fall she returned to New York and again visited her American physician. He, having heard the testimony from abroad, re-examined the vault of the pharynx and found an abundant hypertrophy. He admitted his failure to find it at former examinations, said that the criticisms of the gentleman in London were merited, and sent the patient to me for operation. In the course of time she appeared. Careful rhinoscopic examination of a pharynx remarkably easy of demonstration revealed absolutely nothing except a decided redness and a very slight degree of thickening at the pharyngeal vault. With this series of successive contradictions the parties concerned were much discomfited.

It was not possible that any of the observers could have made an error in a condition so plain and so easy of demonstration, and it occurred to the writer that some cause based upon an acute attack must have been present at the time when the enlargement was noticed.

Further investigation developed the fact that the patient had contracted a severe coryza both on the outward and the homeward voyage, and that she was suffering from these colds when examined in London, and afterward in New York. Examined before her departure, again in Paris, and finally in New York after the subsidence of the acute symptoms, no appreciable enlargement was present. The hypertrophy, therefore, was due to these acute attacks; it existed during their course, and finally, when they subsided, it disappeared. This phase of adenoid disease does not seem to have been described. Certainly it is so little understood as, in the present instance, to have misled three of the most eminent specialists living. It appears to be analogous to the acute enlargement of the tonsils commonly seen in patients in whom these glands are irritable and liable to swell during attacks of cold. It is a condition capable of causing much annoyance. Perhaps the best descriptive title which could be applied to it is acute recurrent enlargement of the adenoid tissue at the vault of the pharynx.

While cases such as this, in which the subsidence of the hypertrophy is nearly complete, are unusual, the acute enlargement of pharyngeal adenoids already to some extent hypertrophied is a matter of the commonest occurrence, and opportunities for studying it are constantly afforded. The

condition is important, on account both of the temporary inconvenience which it causes and also of the tendency which it manifests to leave behind a permanent enlargement of greater or less degree.

Chronic hypertrophy, as generally met with, is of two tolerably distinct varieties. In the first the adenoid element seems to predominate, while externally the surface of the enlargement is irregular, often simulating a true papilloma. The consistency of this variety is one of its chief characteristics, for it is soft to the touch, friable, easily broken up, and showing a tendency, when torn away, to separate in large, spongy masses. In the second variety the conditions are essentially different. The hypertrophied mass partakes more of the nature of a well-defined tumor, its base being tolerably small, its surface smooth, its consistence firm, and its substance composed more largely of fibrous tissue elements. Operation upon the latter variety is far more difficult than it is upon the former, as its dense structure offers greater resistance to the efforts of the surgeon, which, when successful, result in the detachment of but small fragments of firm tissue, in marked contrast to the large masses which are easily torn away in the variety first mentioned.

The actual amount of hypertrophy present may be no criterion of the amount of occlusion or of irritation which it may cause, for, in some cases, a comparatively small growth will give rise to symptoms of considerable severity. Again, thickening of the tissue at the vault of a degree hardly sufficient to attract attention may indicate the existence of a condition such as described in Case IV, and thus become of great value as a diagnostic sign. Palpation in such cases is not a sufficiently exact means for determining the truth, and recourse must be had to the rhinoscope, aided, perhaps, by the probe, to establish the diagnosis.

Although the general effects of obstructed nasal respiration are sufficiently well understood, there is one series of results which merits more careful attention than it has yet received—namely, the permanent deformities of the bony framework of the nose and hard palate, due primarily, as it appears, to atmospheric pressure and associated with obstruction to nasal respiration. While with the angular upper jaw and high-arched hard palate it is sometimes possible to find a normal nasal septum, the contrary is the rule. Some of the most aggravated conditions of septal deformity are met with in these cases. The well-known experiment of occluding one nostril in a growing rabbit has proved conclusively that marked asymmetry of the nose may result, and there is every reason to believe that similar causes acting in the young child may be followed by like deformities, and that, too, at a very early period in the child's history. That marked deformity of the septum and of the other bony structures of the nose may arise early in life from obstruction to nasal respiration due to adenoid hypertrophy in the naso-pharynx is certain, so that impeded nasal respiration from the presence of adenoids during the period of constructive activity is a constant menace to the healthy development of the osseous structures of the nose. The following case (III), observed by the writer, is instructive as illustrating the truth of the above:

T. M. O., aged three years and a half, a mouth-breather, was found on examination to have a large adenoid which was confined to the left side of the pharynx, the right side being comparatively free. The right nasal cavity was abnormally wide and unobstructed; the left was absolutely occluded, the septum being pressed tightly against the turbinated bodies. The adenoid was removed under chloroform, and it was proposed subsequently to restore the position of the septum by gradual pressure. Meanwhile, however, the child was encouraged to breathe as much as possible through the left nostril. The effect of this, within a few months, was to cause such decided improvement in the position of the septum that special efforts at dilatation seemed unnecessary.

The location of the growth is a matter of considerable importance, not alone with regard to the means used for its removal, but also because of the influence exerted upon the auditory apparatus. While it is not uncommon to find that a very considerable amount of hypertrophy may be attended with little or no impairment of hearing, the converse is generally true. Congestion, deafness, and tinnitus are often present in cases where the amount of attendant hypertrophy is remarkably slight.

In proof of this, the following typical case will serve as an illustration:

Miss S., aged twenty-four, at twenty-one had an attack of scarlet fever, following which she suffered a progressive loss of hearing until the deafness became almost complete. Examination of the tympanum showed a moderate degree of opacity. Examination of the upper pharynx revealed a small amount of hypertrophy of all of the adenoid element of the locality; the tissue at the vault was not so markedly involved as that at the lateral walls of the pharynx, posterior to and a little above the posterior pillar. The enlarged tissue at the vault was removed by slow degrees at repeated sittings by means of the curette, the galvano-cautery, and chromic acid, and was only accomplished after the exercise of much trouble. A fair degree of improvement in the hearing distance followed this, but the best results were not attained until the whole of the offending tissue had been removed from the lateral walls of the pharynx. Subsequent to this the tinnitus vanished and a rapid and gratifying return to little less than the normal hearing distance was accomplished.

To this case might be added the records of many more, all more or less striking. Thoroughness, therefore, is of considerable importance in the removal of these growths, and we are forced to believe that testimony to the contrary is unsafe; although even so careful and accurate an observer as Dr. Hooper states that, in his belief, it is not necessary to be too energetic, or to imagine that every particle of the growths must necessarily be brought away. The principal object of the operation, he says, is to establish free nasal respiration. If this be effected, a small amount of adenoid tissue left behind may not do harm. The vitality of the remaining tissue is probably destroyed, and it will atrophy. The growths do not recur after removal.

With these opinions, as applied to certain cases at least, experience has forced us to disagree, for, as we have just seen, the establishment of free nasal respiration is by no means the only end to be attained, although we may freely admit that it is the principal and most important one.

As is now well known, the idea that a partial removal

of the faecal tonsil will be followed by atrophy of the part left behind is, generally speaking, incorrect. As a rule, only so much will ultimately disappear as has been taken away by the surgeon. The same appears to be the case with Luschka's tonsil. In several cases which the writer has had an opportunity to examine at intervals for several years after operation, the tissue left by him at the time of the operation has remained, going through the same processes of congestion under the influence of attacks of cold and of improvement under favorable conditions which were observed in the original growth. From the history of such cases as the one exemplified in Case II, in which the injurious effects of even small hypertrophies are shown, it seems worth while to insist that operations for the removal of adenoid tissue of the upper pharynx should be thorough and complete. If, as often happens, the thorough removal of the tissue is not easily accomplished in one operation, there can be no impropriety in so informing the parents and in operating again. At least, the patient should be occasionally examined, and the case not abandoned until the removal of all offending tissue has been radically effected. Failure in the above precaution may seriously invalidate the result of a really good operation and reflect unmerited discredit upon the operator. It is impossible to overestimate the importance of this precaution, to which fact your attention is particularly called.

Not uncommonly the subjects of this disease are the children of tuberculous parents. Indeed, the frequency with which it is found associated with a tuberculous history is somewhat remarkable. Hereditary syphilis, too, is responsible for many cases, some of the worst which have come under the observation of the writer having been in the children of syphilitic parents. This, of course, is no more than would be expected, as the hypertrophy of the pharyngeal adenoid tissue is but another expression of the general strumous condition under which such patients labor. In operating upon pharyngeal adenoids, the greatest difficulty seems to be in the thorough removal of the tissue anterior to the vault and just above the roof of the nasal cavities, and of that upon the lateral walls in the region of the fossa of Roscnmuller. Particular attention should be paid, therefore, to these localities, and, if necessary, any remaining tissue subsequently removed.

Jelenffy and others have referred to the danger of fragments of detached tissue falling into the larynx and thus causing asphyxia. While this might happen in the course of an operation done with the ring-knife or curette, with the forceps carefully used it would not be likely to occur. It is far more probable that dangerous obstruction of the larynx should arise from the impaction of blood-clots in the glottis, an accident which has happened in the experience of the writer, with startling although not with serious results.

In operating, great care should be taken not to wound the healthy parts, as laceration of the mucous membrane is liable to be followed by persistent bleeding, if not by more serious results. In the use of the forceps, particularly with the patient in the recumbent position, it is absolutely necessary that the uvula be held carefully away from the grasp

of the instrument. Failure to observe this precaution may result in the seizure and injury of this important organ, if not in its destruction.

An English writer advises that the patient be examined the day after the operation and all ragged ends and fragments of mucous membrane found hanging from the posterior wall of the pharynx carefully trimmed away with a pair of scissors! Such a procedure should never be necessary, since it does not seem that the condition mentioned could arise excepting from great carelessness in operating. Nevertheless, the writer has seen one case—that of a young woman of twenty-two, a slender blonde, in whom the pharynx was remarkably narrow antero-posteriorly and the mucous membrane delicate—where the removal of a fragment of adenoid tissue from the vault by means of a modified Loewenberg forceps was attended with the loss of a strip of mucous membrane from the median part of the posterior pharyngeal wall of about an eighth of an inch in width and extending downward to a point below the uvula. At a subsequent sitting the same accident threatened, and was only prevented by the employment of unusual care. It is possible, therefore, that, while with the exercise of ordinary skill stripping of the mucous membrane from the posterior wall of the pharynx should not occur, in exceptional cases it may be necessary to observe unusual precaution in order to avoid it. The accident may be best prevented by following up the detached mass with the finger inserted into the upper pharynx, and, while pulling forward with the forceps, tearing away from below with the finger-nail any adherent fragments of tissue. The question of haemorrhage after these operations is important. Occurring violently during the operation, it will be an effectual impediment to the progress of the work, but can always, of course, be recognized.

The appearance or continuance of bleeding after the operation has been completed, and, possibly, after the departure of the physician, is a far more serious matter, and one which might easily lead to disastrous results. Fortunately, cases in which either of these things has happened are unusual, and, if recognized, the bleeding should be tolerably easy to control.

Thus far only five instances have come to the notice of the writer. In one child, a victim of haemophilia, fatal haemorrhage was caused by the simple exploration of the pharynx with the finger—certainly a most unusual accident. In another case a small forceps was introduced into the pharynx for purposes of diagnosis, and one small mass of tissue removed. Bleeding continued for two days. Dr. R. J. Hall informs me that he was called upon to control a severe hemorrhage in a mulatto of nineteen from the vault of the pharynx, following an operation upon that part, and succeeded in doing so by means of an astringent tampon.

My friend Dr. George A. Richards operated upon a young boy in whom profuse bleeding occurred during the operation and continued after it until syncope supervened. The child was exsanguinated, and remained in an anaemic condition for some time. In one of my own cases, in a delicate boy of four, bleeding was profuse, and the effects of the operation were felt for two months.

There can be no question that the forcible removal of adenoids is a painful operation. From all patients, old as well as young, comes the same testimony. Time and again the writer has operated upon adolescents and upon adults at repeated sittings. Time and again he has had the testimony of intelligent subjects to the effect that the act of operating was exceedingly painful. Time and again he has seen the same patient suffer for a number of hours after each sitting with neuralgia, headache, and sometimes with pain in the ears. He has found it not uncommon for a patient to run down under the shock of repeated operations to such an extent that the nervous system was severely impressed.

By reason of these considerations he has been forced to believe that in a large number of the more severe cases operated upon anaesthesia is a most valuable adjunct. Not that the risks of anaesthesia should be incurred needlessly in a patient of good nervous force and in whom the amount to be removed is small, but that, on the other hand, the great majority of patients suffering from the complaint under discussion are abnormally weak, timid, and nervous. They are difficult to operate upon, the work is apt to be imperfectly accomplished, and the results are by no means so satisfactory as when full opportunity is given to explore the pharynx at leisure, and to remove at once every vestige of adventitious growth that can be reached.

What particular anaesthetic should be used must be determined by each individual operator. Of late the writer has had chloroform administered, and, with an experience of about sixty cases, he is able to speak favorably of it. Its special advantages over ether in this operation, aside from its quickness, lack of irritating qualities, and less nauseating effects, are its ease of administration during the operation, and the fact that it does not cause the same abundant secretion from the faucial region of viscid mucus which is excited by ether, and which in many cases becomes a cause of much embarrassment during operation.

The writer has seen one case in which the removal of an adenoid from a strumous boy of fifteen was followed by a mild double otitis, which subsided after a few days. He has known the same accident to follow the work of other operators. Its possibility, therefore, should not be lost sight of.

It is highly important, when once the necessity for operating is recognized, that the operation be performed without unnecessary delay. The choice of time for operating, however, is a matter of some importance, as the operation may be followed by more or less general depression and the patient be exposed, therefore, to greater risk from the diseases most dangerous to children. The late spring and early summer offer the greatest immunity from danger, while the late autumn and winter are the most unfavorable periods. Any possibility of infection from diphtheria should be most rigorously avoided.

In a case operated upon by the writer in a large apartment house, in which a marked rise of temperature persisted for several days after the operation, with other ill-defined but threatening symptoms, it was finally discovered that an epidemic of diphtheria was present in the house.

The immediate effect upon the voice of an operation may be disappointing, the faulty pronunciation being retained. This is sometimes due, not to imperfect removal of the pharyngeal obstruction, but to a condition of paresis of the velum which has been caused by the presence of the adenoid, and which may persist for some time after its removal.

Finally, as to the general conduct of these cases it must be insisted that they are surgical, and therefore that they should be treated upon correct surgical principles by men well versed in these principles, both in theory and in practice.

I consider it most important that, after a radical operation for the removal of adenoids, the patient should remain in bed until the shock of the operation is evidently past; that he be placed upon a course of tonics, particularly iron and quinine, until any loss of blood shall have been made good and any depressing result of the operation done away with; and, finally, that it be not taken for granted that every possible benefit has been gained with the completion of the operation. Patients should be examined after recovery from the operation, and not only should the imperfect removal of tissue be remedied, either by surgical or topical means, but the attendant catarrhal symptoms which may remain should be treated, and the general condition of the patient investigated and, if necessary, improved. In this way the best ends may be secured, and what has been a good operation be made to yield finally the most brilliant results.

The all-important question, What degree of hypertrophy constitutes a pathological condition? is one which must arise in the experience of every careful observer, and which has never yet been satisfactorily answered, particularly when it is remembered that simply the removal of obstruction is by no means the only end to be attained. Certainly, an enlargement sufficient to give rise to troublesome symptoms should be regarded as important, and, if not remediable by topical means, should call for the employment of those of a more radical nature.

#### NOTE ON THE GALVANO-CAUTERY IN THE TREATMENT OF HYPERSTROPHIED TONSILS.\*

BY CHARLES H. KNIGHT, M. D.

In a paper on this subject, read at a meeting of this association two years ago, the following opinion was expressed: "Galvano-cautery should be reserved for a comparatively small proportion of cases, including those in which the haemorrhagic diathesis is present or suspected, those in which vascular anomalies may be recognized, those in which anatomical conditions prevent a sufficiently complete excision of the organ, and those in which the use of a knife is positively declined." With regard to adults it was recommended that "a patient above the age of twenty years be allowed his option after a fair presentation of the risks and advantages of the two methods"—namely, cauterizing

and cutting. During the last two years my experience in eighteen selected cases in hospital and private practice has, on the whole, confirmed my original conclusions. As to cauterizing tonsils in young children, it may be said that it is next to impossible to persuade children under ten years of age to submit to galvano-puncture often enough and to a degree sufficient to accomplish much, and the use of the cautery-loop is in them out of the question, except under general anaesthesia.

The experience of Saint-Germain,\* who is a rather extravagant advocate of ignipuncture, has been decidedly different from my own. The ages of his patients, as recorded in twenty observations, range from two to fifteen years, but it is noticeable that in his younger cases a single cauterization sufficed. The inference is natural that he is satisfied with less complete results, especially since he remarks that tonsillotomy should be practised only *when the tonsils meet in the median line*. It seems to be accepted in this country that tonsils which do not reach this degree of enlargement may be sources of irritation and should be removed. Paul Balme,† who follows the teaching of Ruault, advises the amygdalotome for children of from two to five or six years. After the latter age he finds electro-puncture practicable. He is in the habit of transfixing the tonsil at four or five places with an electrode brought to a white heat, the cauterizations being repeated three to six times, at intervals of ten or twelve days. To one who has witnessed the terror of a child who has once felt the heat of the cautery point when it is proposed to repeat the experiment, this statement seems almost incredible. In my opinion the guillotine is far preferable in children, and in those of highly nervous temperament it should be used under nitrous-oxide gas or ether, the anaesthesia with the latter not being profound. For these cases nitrous oxide is the ideal anaesthetic. Its effect is rapid, recovery is prompt, and the period of unconsciousness is ample. Thus, much of the shock attending an excision of the tonsils may be avoided, the bleeding is not appreciably more, and the operation may be done with equal thoroughness. In older children and in adults the galvano-cautie point and knife, and more particularly the cautery-loop, are of service in the treatment of hypertrophied tonsils. My attention has been especially directed to the effect of cocaine, and to a comparison of the degree of pain experienced by the same individual under different methods of operating on either tonsil. It is very difficult to estimate pain. One patient will declare that excision of a tonsil does not hurt at all, while another will make the most vehement demonstrations. But at least an approximate idea of the pain may be formed by adopting a different operation for the second tonsil.

This procedure was resorted to in five of my cases. In every case cocaine in ten-per-cent. solution was applied on a pledget of cotton or sprayed into the fauces. In one the cold-wire snare was used on one side and the galvano-cautery loop on the other. In this case the pain of the cold-wire operation was so intense that, when nine days later the

† "De l'hypertrophie des amygdales," Paris, 1888.

removal of the second tonsil with the cautery loop was undertaken, the patient, a young woman of seventeen, was so nervous and restless that great difficulty was found in applying the loop. Consequently, the cold-wire operation proved to be the more radical. There is no question, however, that in this case the hot wire was less painful, more rapid, and was followed by less inflammatory reaction than the cold snare. After the latter the pain persisted, and for several days the formation of a phlegmon was threatened.

The histories of the four remaining cases, in which the cautery loop and the amygdalotome were used, are very similar. That of my most recent case will answer for all.

The patient was a colored girl, twenty-four years old. The right tonsil was removed completely two weeks ago with the cautery loop. Five days later, reaction having subsided, the left tonsil was excised with the tonsillotome. The contrast in the behavior of the patient on these two occasions and in the subsequent appearance and action of the wounds was not remarkable. The base of the first tonsil was cut through by the hot wire in less than a minute, the patient offering but very little objection, and not a drop of blood being lost. The soreness and pain in swallowing began to subside at the end of thirty-six hours, the patient meanwhile using a carbolized gargle at short intervals. On the third day there remained a little oedema of the uvula, and there was considerable inflammatory swelling of the pillars of the fauces. Except for the slough, which was beginning to separate and which involved to a slight extent the posterior pillar, the parts presented precisely the appearance expected after an excision of the tonsil. The left tonsil, considerably smaller than the right, was removed with MacKenzie's amygdalotome on the fifth day. Haemorrhage at the time was much less than usual. The patient asserted that the pain was much more than with the preceding operation. In this case there was no subsequent bleeding, the soreness was of rather shorter duration, and the wound healed more quickly, which may be attributed to the relatively smaller dimensions of the second tonsil.

As a general rule, it is impossible to distinguish any marked difference in the sensitiveness of the stump or in the rapidity of the healing process.

These tests have satisfied me that the pain caused by the cautery-loop operation is not so much greater as to constitute a valid objection. Electro-puncture is in the aggregate more painful because of the frequent repetitions required, and is adapted only to cases in which for any reason the snare can not be used. By the use of cocaine it seems to me that but little, if anything, is gained beyond securing more complete rest for the parts and so facilitating the adjustment of the wire loop. In some cases even this effect of cocaine is defeated by the nausea which the drug is apt to produce.

In the technique of the galvano-cautery operation there is but little new. For the purpose of tucking the loop around and behind the tonsil, and holding it in position until the wire can be tightened, a little two-pronged instrument made of copper, so that it may be bent at any desired angle, and held firmly in a handle, will be found very convenient. It is a good plan, the moment the loop is seen to encircle and be in contact with the tonsil, to turn on the current for an instant. The wire adheres and may be tight-

ened at leisure without danger of slipping or being thrown off by the act of gagging. In spite of the utmost care, the pillars of the fauces are in some cases more or less damaged, but the injury is generally superficial. In many cases, owing to the shape of the tonsil, the adhesion of a pillar, or the intolerance of the patient, it is very difficult to include more than half of the tonsil. These difficulties may be in part overcome by preliminary training of the patient and by thoroughly releasing an adherent pillar.

Additions to the literature of this subject have been rather numerous. The galvano-caustic method has been approved by Dr. F. H. Potter,\* of Buffalo, in a paper read before the New York State Medical Association, and in a short communication from Dr. Jonathan Wright,† of Brooklyn. Dr. E. G. Kegley ‡ reports a case of extreme tonsillar hypertrophy in a man forty-three years old, in whom spasmodic attacks resembling hay fever, with the additional symptom of profuse salivation, were entirely relieved upon removal of the tonsils with the galvano-cautery loop. Noquet § reports a case of chronic abscess in the stump of an excised tonsil cured by use of the galvano-caustic point. This author, as well as Heryng and Charazac, expresses a preference for the galvano-cautery in removing enlarged tonsils. On the other hand, Moure prefers the amygdalotome, and he professes to have seen in children the development of retropharyngeal and circumtonsillar abscess after the use of the galvano-cautery. Three cases similar to that of Noquet have been observed by Garel,|| who strongly recommends the cautery in hypertrophied tonsils, especially in cases showing a tendency to suppurative inflammation. Kafemann △ recommends the galvano-cautery, while G. Dodart ♀ maintains that amygdalotomy should be employed but rarely, on account of the numerous accidents possible, and that ignipuncture is the operation of choice. Barette † describes the methods of operating, and expresses a decided preference for the thermo-cautery or the galvano-cautery as compared with the bistoury and the amygdalotome. In a paper by Ouspenski,‡ on "The Treatment of Enlarged Tonsils in Children," based on fifty-two observations, the method by galvano-puncture is highly praised; and Valat,§ after noticing the fact that haemorrhage following excision of the tonsils, rare in children, is by no means infrequent in adults, advises the use of the thermo-cautery.

Wilhelm Roth, \*\* of Fluntern, advises the employment, under cocaine in ten- to twenty-per-cent. solution, of the finest point of the thermo-cautery inserted at three or four

places in the tonsil, the operation being repeated four or five times at intervals of two or three days. He finds this sufficient to reduce the tonsils to their normal size, with scarcely any pain and without the risk of troublesome haemorrhage, which, contrary to my own experience, he says is not uncommon, especially in young children.

In commenting on the views of Saint-Germain, Delavan\* expresses his disagreement for three reasons: 1. The process is far more difficult and painful than amygdalotomy. 2. There is not an authentic fatal case of haemorrhage after tonsillotomy on record. 3. While he has seen and performed hundreds of amygdalotomies without having known diphtheria to occur in the wound in a single instance, he has known four cases in which the disease immediately followed the use of the galvano-cautery. The first objection should be modified to read "somewhat more difficult and painful." It is true that the galvano-cautery operations, at least those with the loop, require more time and trouble, possibly more manipulative skill, and somewhat elaborate apparatus. The second point may be admitted, and yet it is not much comfort to a patient who has lost a pint or so of blood, who is just on the verge of syncope, and who is already frightened almost to death, to be told that no one has ever yet bled to death after amygdalotomy, and he probably will not. All the statistics in the world will not reassure him. With regard to diphtheritic infection, it seems to me unreasonable to suppose that the germs of disease are any more likely to invade the system through a wound covered by an eschar than through an open wound left by amygdalotomy. The period of incubation in diphtheria varies from two days to a fortnight,† fresh wounds being earliest affected, and constitutional symptoms often preceding the appearance of the local lesion. It seems perfectly fair to assume that in these cases of immediate diphtheritic development, such as Delavan refers to and as cited by Saint-Germain,‡ the patient was already under the influence of the disease at the time of the operation. Such an accident has not occurred with either operation in my experience, and, indeed, it seems to me quite as apt to occur in the condition of the tonsils for which their removal is demanded as it is after any operation whatever. An enlarged tonsil, its crypts deepened and distended by inspissated and decomposing secretion, would seem to offer most excellent soil for the lodgment of disease germs.

One of the strongest arguments in favor of the galvano-caustic method is the fact that it insures against haemorrhage, but a case recently reported by Werner\* would seem to show that our contention in this particular must not be too positive. His patient began to bleed five days after treatment with the galvano-cautery, and is said to have been saved by compression of the carotid for ten days. Not having access to the original, I can not give further details. In the case of Capart, mentioned in my former paper, haemorrhage was undoubtedly provoked by immo-

erate use of the voice. I suspect that to this cause, and perhaps indiscretion in diet, may be added as possible factors deficiency of heat and excessive traction on the loop during the operation. It is easy to conceive that in such case the resulting eschar might fail to give sufficient protection to the stump of the tonsil. Violent exercise, loud talking or singing, or an irritating particle of food might easily be the exciting cause of haemorrhage. We can not too closely observe precautions in these particulars, especially when we have reason to mistrust the caustic effect of the wire.

My zeal in advocating this method of treating hypertrophied tonsils is tempered by two facts, which I at least feel obliged to admit. First, burning, if not more painful, is at any rate more disagreeable to most people than cutting; second, the prevalent dread of haemorrhage after excision of the tonsils is not warranted by clinical experience. I am more firmly convinced that the danger of haemorrhage after the use of Mackenzie's amygdalotome, which is by far the most convenient, most efficient, and safest cutting instrument, has been unduly magnified. This is especially true of children, and in adults it seems to be the rule that bleeding ceases on the occurrence of syncope, if not before, and seldom recurs to an alarming extent. This statement has been verified by three cases which have come to my notice within the last eighteen months, by the case reported by Fuller,\* in which the common earotid was tied without effect, and by numerous other instances. Excluding haemophilia, which is under any circumstances an alarming condition, we are not likely to meet with bleeding after amygdalotomy which need cause any anxiety. Perhaps Mackenzie's statement for tannic-gallie acid as a haemostatic is exaggerated. Should it fail, however, without wasting time with other styptics, so justly condemned by Levis, we may confidently resort to the use of the tenaculum as suggested by that writer,† or the loop of the cold-wire snare may be applied, possibly with the aid of a transfixion needle. Cases in which ligation of the external carotid artery will need to be considered should become exceptional. The researches of Zuekerkandl‡ have proved that the course and relations of the internal carotid artery must protect it from injury at least in guillotine operations. No one should be deterred from securing the relief afforded by amygdalotomy by fear of bleeding to death. Delavan asserts that there is not on record a single case of fatal haemorrhage after the use of the guillotine for simple hypertrophy. The detrimental effects of enlarged tonsils are too obvious to be ignored. The benefit following their removal is with many of us a matter of almost daily observation. The risk of the operation itself need excite no apprehension.

At the same time the limited class of cases included in my enumeration must in some way be provided for, and for these the galvano-caustic method seems to combine the most desirable with the fewest objectionable features. The removal of a tonsil in this way requires a little more time,

but in the majority of my cases the pain has not been excessive, the extirpation has been thorough, and the final result in every respect satisfactory.

## ANGULAR CURVATURE.

### THE MECHANICAL REMEDY.

By GEORGE H. TAYLOR, M. D.

THE simple and abiding faith commonly accorded to instruments professedly adapted to correct misshape of the spinal column is a legitimate matter for examination and criticism. Such instruments, it is believed, are recommended with more fervor than accuracy of knowledge, both as to the actual needs of this unfortunate class of invalids and to the force and mechanical consequences of the devices employed. Instruments to be worn on the person—*supporters*, as they are named from what is wanted of them—are adopted with too much haste, and their use continued for reasons quite opposed to those that ought to prevail. The nature and the gravity of this class of cases render it due that inquiries like the following be satisfactorily answered before the utility or necessity of “supports” is conceded. Are the mechanical contrivances commonly supplied for the purpose adapted to produce the effects asserted and desired of them? Do the principles they involve accord with or do they oppose and subvert the uncompromising facts and principles of physiology embodied in the vital organism? Such inquiries demand intelligible and satisfactory answers. The present purpose is, accordingly, to place before the reader the mechanical, physiological, and pathological principles involved, the consequences accruing to the vital organism in general and to the column in particular from the use of this class of remedies.

An intelligible presentation of the subject requires a statement of the leading causes concerned in the development of the columnar angle, so that the adaptation or want of adaptation of the means usually employed to the ends in view may be clearly seen. The column acquires its morbid form in consequence of defective function of the general and especially of the spinal muscles. No one supposes that columnar deformities occur otherwise. The too feebly sustained column is dragged forward and downward by the uncounterpoised weight of the upper part of the trunk and head. Gravitation curves the column sharply forward, and thus unsettles equilibrium of the body. The necessity of keeping the center of gravitation within the base compels other changes of the shape of the column. A corresponding forward projection of the *lower* end of the column is made necessary; this throws backward the intermediate or central part of the column. Were these last-mentioned changes not to occur, the person would be unable to stand erect. The nature and necessity of the case seem to imply that some effort on the part of the subject may be required to maintain an erect posture, and that such effort must be expended in urging the central part of the column backward, thus increasing the deforming tendency.

The purpose of instruments to be worn upon the per-

son is simply to force back the deviating portions to a position approximating the natural axial line of the column, and to keep them there by mechanical force. This remedy does not regard the pathological, but only the mechanical problem. The pre-existing and the present sources of the affection are neglected, and the pathological conception is reduced simply to exterior appearances. Even the superficial effects are equivocal and untrustworthy. The instrument is adapted to *conceal* rather than to *remove* the external manifestation. The instrument is believed to have a remedial purpose quite beyond the scope of its power and adaptation to fulfill; the confidence which is placed in it diverts attention from true remedies directed to the sources of the affection, and thus it is a means of affording a false security quite inimical to the true interests of the patient.

It becomes apparent, therefore, even upon a superficial survey of the subject, that in seeking remedies for the angular column two distinct considerations are encountered—the *mechanical* and the *physiological*. The mechanical is regarded as paramount, at least as relates to practice. There are many facts indicating that this is the *reverse* of the natural and true order, and that ill consequences of a serious and permanent character flow from this misapprehension. Attention will now be directed to some of these consequences.

*Mechanical Features of “Supports.”*—The functions or work desired of apparatus to be worn on the person are those of such partial lifting or urging upward of that portion of the body *above* the affected points as shall relieve the affected vertebrae from the pressure to which they have been exposed. To this purpose is added that of applying force and counter-force to the points of the column which deviate from the correct axial line, so as to press them back to that line. The additional purpose of preventing motion, both of the column and of its museles, is sometimes avowed.

The mechanical problem is that of overcoming the aggregate resistance of weight and rigidity of structural parts by mechanism carried on the person. The means resorted to is not dissimilar to what would be required to straighten wood or metal. The evident inadequacy of the means to the ends is expected to be compensated for by persistency in wearing the instrument. The benefit expected is relegated to the distant future, while the idea that a removable cause exists, or has existed, is seldom practically entertained.

The varieties of instruments provided by orthopædists are legion. In scarcely any direction has there been shown greater prodigality of invention. This fact indicates difficulties of uncertain nature not yet overcome—some important factor of the affection to be provided for. It is to be noted that this wealth of invention is expended in details, and therefore fails to extend a knowledge of principles involved in these cases. The organism is treated by all alike as an inert substance, susceptible of being molded at pleasure. The general purpose of instruments being mechanical, it will be necessary to subject the more usual adaptations found in the different varieties to a somewhat critical examination, to learn to what extent these adaptations are capable of complying with their purposes, and what are the ultimate consequences to the form of the column.

The first inquiry relates to the value of mechanism to prevent the weight of the upper part of the body—the part above the affected vertebrae—from resting upon them, and to resist the tendency of the stature to become shorter. The plainest and most typical of the adjustments for this purpose is the *crutch* designed to lift the body, or at least some part of its weight, by upward pressure under the arms. Whatever form be given the instrument, the top of the crutch must be continued downward through its staff; this must have a firm connection with a band about the pelvis. Thus the weight falling on the crutch is transmitted to the legs through another than the columnar or normal channel. It is evident that, if the band moves or shifts its position, the supporting purpose is worse than defeated; the patient leans upon an insecure and uncertain support and goes down with it. This consequence is obviated only by engaging the band with the top of the pelvic bones, a difficult thing seldom successfully accomplished.

The proper mechanical details being present, it is assumed that the elongation of the staves of the crutches produces the effect of urging the shoulders upward, and that the head, neck, chest, and the upper part of the column necessarily follow, and are practically *raised* by such extension of the staves of the crutches. It is assumed that a part, at least, of the weight is sustained, and that compression is diminished at the point where loss of vertebral substance is indicated by the morbid form of the column. The weight of the above-named parts is, it is taken for granted, transmitted to the pelvis through the two staves at either side of the body, instead of through its normal channel, the column. The effect of this mode of sustentation is assumed to inure to the advantage of the column.

The above-named assumptions are, in the main, mechanically erroneous. The immediate and direct consequence of mechanism having the action and relations stated is quite the reverse of that assumed. Crutches bearing upward under the arms cause the stature to *diminish*, cause *more* compression of the affected vertebrae than is due to normal weight, and cause an *increase* of the columnar angle. These statements will be clearly understood by the reader who duly follows up the necessary explanations and demonstrations. The purpose of the mechanism for lifting the shoulders relates solely to the column; not at all to the limbs, upper and lower, and to the trunk only as it is inseparable from the column. To attain an impartial and full comprehension of the action and effect of *all* instruments which include the above-described purposes, it is advisable to conceive the trunk as divested of limbs, including the bony and muscular appendages of the limbs; the shoulder blades, shoulder muscles, thighs, and glutei muscles—all may be considered as absent. The remaining trunk has an ovoid form, and contains the column in which mechanical changes are desired. The two ends of the trunk thus bereft have a tapering form; they are roughly conical. A straight edge applied to the exterior of the pelvis and to the exterior side walls of the chest marks the sides of triangles; the base of the inferior or pelvic triangle corresponds with the top of the pelvis; the base of the superior or chest triangle corresponds with the central part of the diaphragm.

The weak and uncertain hold of the pelvic band on the pelvis as a base for the support of the crutches (if that were of any consequence, which it is not) is made obvious by the tapering shape of the pelvic bones.

The decidedly conical form of the chest renders the difficulty of securing a reliable connection of the crutches with any part of its exterior still more obvious, even were there no weight of head, neck, chest, and the muscular action, which tends to destroy such connection. With the arms and their appendages replaced, there is an appearance of capability of resistance to the upward thrust of crutches. But the appearance is deceptive. The pressure of the crutches can not reach the shoulders to any effective degree; nor is such pressure or thrust communicated to parts connected with the shoulder joint; it is received and distributed otherwise.

Every one may know the significance of the deep hollows under the shoulder joints. These unfilled spaces are the intervals between large and strong masses of muscles whose junction with the arm-bone below the joint, before and behind, forms and bounds these spaces. The other ends of these muscles (which are chiefly the two pectorals in front and the latissimus dorsi behind) radiate, fan-like, over the chest and are attached mainly to the ribs. Their action is continued by the intercostals to the lower borders of the ribs. It is with the heaviest part of these muscles where their united fibers leave the walls of the chest and pass to the arms that the crutches engage. Under pressure from crutches these masses become consolidated, tense, and resisting, so that the spaces under the shoulders referred to are not obliterated. The whole upward thrust of the mechanism is received by the muscles, and is transmitted by them to the exterior walls of the chest; it is, in fact, converted into an upward pull or traction, urging outward the walls of the chest. This action is as decided and unequivocal as that of a rope over a pulley in lifting a weight. The oblique position of the ribs in the walls of the chest determines and greatly facilitates the mechanical effect of the force transmitted to them through the mechanism. The force is directed to increase the *diameter* of the chest, and, in fact, fulfills that purpose. But the air-space is *not* increased; nothing is effectual for producing that effect but to cause a *need* for more air, which the action described does not. The increase of breadth of the chest is therefore at the expense of its perpendicular measurement. The chest is *widened*, but proportionally *shortened*.

Note now the consequence as respects the spinal column. This column is a component of the posterior boundary of the chest, and inseparable from it. To diminish the height of the chest is to shorten the column. But the column is shortened only by becoming bent. The chest bulges out in front, causing the breast-bone to be displaced and deformed; also behind, causing a similar displacement and deformity of the column, and in the latter superinducing absorption of tissue which is always a consequence of uninterrupted compression of vital parts. The anterior perpendicular measurement of the column is thus permanently diminished. The head and neck necessarily follow—that is, descend in proportion to the bending of the column, and

the stature of the individual is diminished, as the effect of and in proportion to the power of the instrument.

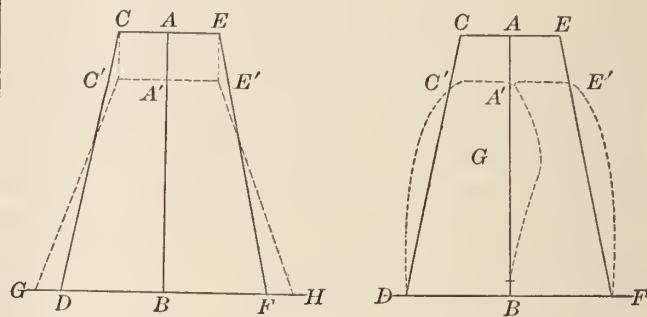

As the foregoing statements are of considerable importance, and will be found applicable in forms of instruments in which the crutch is omitted, it may gratify the reader to be able to demonstrate its mechanical correctness, and in a simple way to silence all cavil on the subject. For this purpose he may cut a narrow slip from a piece of pasteboard, say six inches long, find its center, and break it at that point, but not to separate the two equal parts; these are bent round so as to approach each other, and may be called legs. The two ends, placed upright on a table, represent a triangular figure, of which the table is its base, and the pasteboard slip the two equal sides. The apex of the triangle we may conceive as indicating the head; its two legs, the side walls of the chest; the space between the ends, the base of the chest; while a thin slip of paper attached to the apex, dropping loosely and perpendicularly midway between the legs, indicates the location of the column. Now *separate* the ends of the legs resting on the table. It is at once seen that the apex, standing for the head, is *lowered*; its distance from the line between the lower ends of the legs is diminished in exact proportion to such separation, or increase of transverse diameter. Another important fact is conspicuously shown. The perpendicular slip, bisecting the triangular space, is seen to *bend* in proportion as the distance from the apex to the base is diminished. The superfluous length of the perpendicular becomes diminished by assuming a curved form. If this slip representing the column be *notched*, and so weakened at any selected point, at just that point an *angle* appears on diminishing its height, while the parts both above and below remain uncurved. This shows that the yielding of any point protects all the remaining points.

This physical experiment corroborates mechanical principles, the demonstration of which is daily witnessed. Persons are met with whose heads appear as if beaten down, while the shoulders are thrust upward at each side of it; the chest bulges forward, while the spinal column approaches an angular form. This inference is legitimate, and to those who have attended to the subject, unavoidable, that such persons have, at some previous, perhaps distant, period been subjected to mechanical influences which have become permanently recorded in the form of the chest.

The mechanical effects of instruments designed to correct angular deformity of the spinal column may be illustrated by the following diagrams.

Let A B indicate the spinal column, and C D E F will represent the exterior of the chest. Move the point D outward to G, and the point F outward to H. It follows that the line C A E is *depressed* to the line C' A' E', and therefore that the perpendicular bisecting the figure and representing the position of the column is shortened, as seen at A' B. The same effect on the column is produced if the distance between the side-walls be increased at the middle, or any other part, as will be seen below. The sides C D, E F, instead of remaining as straight lines, are converted into arcs of circles, whereby the points C and E are brought nearer to the points D and F. The points A and

B are therefore brought nearer each other—that is, the distance between them is diminished and the line A B is caused to deviate from the perpendicular at whatever yielding point it may have, as at G. The same changes of form may be considered in their connection with *force*. Thus, the power required to move D to G and F to H was also employed in changing the horizontal line C A E to C' A' E'.

In the second diagram, the power expended in increasing the space by converting the straight into curved lines was also employed to depress the line C A E, and in causing the straight line A B to become bent at G.

The conclusions to which mechanical principles point, and which are also confirmed by practical observation, are these: The weight of the upper part of the body can not be even partly sustained, nor the spinal column raised and straightened, by apparatus whose mechanical principles and action, worn upon the person, are of the order above shown. It is further made clear that the practical mechanical consequences of such instruments or supporters is to depress or pull down the head, neck, and top of the spinal column, to diminish the stature, and to deform the chest by unnaturally increasing its transverse diameter, especially in the antero-posterior direction, projecting forward the frontal bone (mediastinum) and backward the spinal column. In consequence of these changes, the perpendicular measurement is diminished. All these mechanical consequences are exactly the reverse of those sought and promised. Such grave alterations of the form of the bones are necessarily permanent and irretrievable. These effects arise from radical misconceptions of the mechanical properties and powers of a single feature incorporated in apparatus. We may next turn attention to other features.

The mechanical effects of the *crutch* appendage of "supporters" have been here described, not because this is the form most in use, but because most typical and easily understood by unprofessional readers. Instruments which omit the crutch are pressed upon the attention of physicians by orthopaedists. These often produce the same effects in a covert manner. Instead of obviating, some of these produce additional ill effects. The potential crutch is, in fact, concealed in the construction. These are the more dangerous, because the adverse effects are unsuspected. The probability of the above statement appears when it is remembered that the conical form of the chest and its smooth, bare exterior afford no point by which it may be held while extending force is being transmitted to the de-

formed column, except in such way as forces apart the side-walls of the chest.

In the more common form of construction of the "support," the effect of crutches, or, more correctly, their modified form, is secured as follows: From the base about the hips arise two flat steel uprights—one each side of the column. These are connected at the top, and the connection extends *under both arms* entirely around the top of the chest and fastened by a buckle.

It is easily seen that the posterior upright bars, with the band encircling the top of the cone of the chest, are crutches in disguise. The bars are the staves moved to the rear, and the band is equivalent to the two tops of the crutches joined, and thus continued around the chest. The conical form of the chest causes the band to rest upon the muscular masses under the arms, to push them up, and thus transmit tensile force to the lower borders of the ribs, in the same way as in case of crutches. The instrument is operative in this way to the extent of the pressure of the band (or crutches) upon the combined muscles at the arm-pits, whether produced by tightness of the band, or by the inevitable leaning forward of the wearer, or motions of the body which produce a tendency to an upward displacement of the apparatus.

This form of instrument has, however, an additional function. The upright bars thus located are not only the means of the upward push under the arms, but are also *levers*. Their fulcrum is the posterior prominence or angle of the column. When the top or frontal band is tightened, compression of this prominence is caused, urging it *inward*, while the pressure of the band urges the top of the chest, and therefore the column, in the opposite direction—both, in fact, toward the medial line from opposite directions. Another, usually broader, band encircling the abdomen below the angle, connecting with the uprights, completes the mechanism for the application of force and counter-force applied for straightening the column.

Apparatus embodying these purposes inflict the following mechanical consequences, in proportion to their mechanical power: The upright bars in close proximity with and at each side of the column virtually destroy its mechanical peculiarities and adaptations. It is no longer flexible or elastic, but rigid. And if the purpose is fully achieved, it ceases to bear the weight of the superimposed parts of the body. The natural mechanical bodily movements are prevented. The inevitable consequence is suspension of the nutrition of the column, by withdrawing the conditions requisite therefor. These relations are morbid, and necessarily superinduce morbid consequences, even in case the column were previously healthy.

The mechanical effect of the leverage of the uprights at the back is likewise to diminish the stature. The wedge-shaped vertebrae are already diminished in perpendicular measurement of the anterior portion. The act of straightening transfers the weight resting on the whole mass to their *posterior* portions—from a whole to a half or less of resisting substance, practically doubling the pressure of the diminished area. This causes the same effects in the posterior that has previously been produced in the anterior por-

tions of the vertebrae, so that absorption occurs in the two parts successively—in one through loss of support and of motion, and again by enforced compression and restriction by the instrument. The affected vertebrae therefore become still further reduced in height, and the stature shortened by the mechanism designed to produce the opposite effect. This effect is, however, transient—in most cases probably too transient to be productive of serious injury. The shortening of the posterior longitudinal measurement is soon followed by still greater shortening of the anterior, due to physiological as distinguished from mechanical influences, and is to be pointed out.

Another cause of vertebral absorption, and consequent shortening of the column, is contributed in a high degree by the compression of the pad, always necessary in this form of instrument, over and near the columnar angle. This point, it will be remembered, serves as a fulcrum. It consequently receives the pressure arising from tightening both the anterior bands, and the weight of the body, or such portions of it as falls upon the instrument. This compression, joined with that before described, can not fail to be productive of very serious local injury at the point least capable of bearing it, since the functions necessary for the maintenance of local health, motion, flexion, and elasticity are restrained.

These mechanical considerations indicate that neither of the leading purposes of supports worn upon the person are adapted to produce the mechanical results expected of them. The transverse measurement of the chest is increased and the perpendicular diminished, the stature shortened, and the acuteness of the angle of the column, instead of becoming diminished, is positively exaggerated. It now remains to point out the physiological consequences of the same remedial method.

*Physiological Effects of "Supports."*—The ill consequences of apparatus whose mechanical power is exerted in a direction quite opposite to that expected and desired are insignificant in comparison with the physiological deterioration inseparable from its use. Even the superficial and disinterested observer can not but recognize in the levers, bands, buckles, screws, fulcrums, leather, and steel, of which these instruments are constructed, engines of repressive power, antagonistic to the motor purposes and uses of the vital organism. However well adapted a mechanical apparatus may be to mold and reshape inert substances, such adaptation and such power are no proof of efficacy in case of an entirely different class of bodies—those whose welfare is governed by interior causes, whose purposes relate to the interior development of energy, and whose laws refer to the orderly succession of the ingredients of their own composition.

To support the column or any part by mechanism is to supersede functional support, and to that extent to repress those activities from which the *power* of support, by parts to which that duty is assigned, is derived. The capacity for supporting is thus diminished, and is liable to be finally extinguished. Let us see how this principle applies to the spinal column. In health the spinal column exercises the functions of *resistance*, *elasticity*, and *flexibility*. These

functions are either suspended or very much diminished by apparatus. Indeed, the restriction or abolition of these physiological actions is the *purpose* of the instrument. It is even contended that the exigencies of these cases demand the *prevention* of all motion of the column, as though health might be restored in the absence of function in this or in any part of the organism. The idea that flexible motions of the column are incompatible with restoration is theoretical, and lacks any basis of physiological facts for its support. Statements of such an import are made by persons whose experience is too limited and meager to justify them. The physiological fact is that the spinal column *requires* flexible and elastic motions in both health and disease; and that in the latter condition this organ particularly requires the motions natural to it to dissipate the hyperæmia present or imminent, and which necessarily occurs in the absence of the local causes for changing the fluids the tissues contain.

Use or function involves *alternations* of compression. This is necessary for the health not only of the column, but of the shafts of the bones of the limbs. Pathological museums often present examples of bones whose use has for some reason—as paralysis or lameness—been for a prolonged period suspended. Examination of such examples demonstrates that the specific gravity of such bones has thereby been diminished, that the spongy portions have increased, and that the laminar divisions of cells have to a considerable extent disappeared. These facts show one of the consequences of suspended function. The peculiar location and constitution of the vertebral bones, by adding compression to defective activity, superadds *local absorption* at points where such compression is greatest, and distorted form is the result.

Scarcely second in pathological importance is repression of spinal and other muscles superinduced by all instruments worn upon the person. The degree of injury to muscular power is proportionate to the supposed efficacy of the instrument. Any mitigation of ill effects secured by diminishing the mechanical power of the instrument effects no change in its principles of action. These effects are not necessarily rendered less dangerous by becoming more stealthy. The studied effects of this class of apparatus in all its varieties, from the simple corset with springs of whalebone or steel to the posterior levers and bands for raising the column, are those of repression and not of development. Repression occurs wherever parts of the instrument press upon muscles—under the pad at the fulcrum of leverage; beneath the flat bars overlying the spinal muscles; under the bands passing around the trunk; and under the pelvic base band. The continued pressure at these points restrains muscular action and nutrition, and hinders the manifestation of both their mechanical or supporting and their chemical or regenerating functions. It also facilitates the degenerative and absorptive process, and therefore the decline and disappearance of muscular tissues.

Now, it is the failure of the vito-dynamic and the vito-chemical functioning of muscles that superinduces the disease for which a remedy is sought. The removal of the columnar symptom of this disease is clearly impossible,

while the morbid condition on which it depends remains. The inconsistency of supplying remedies which are well calculated to superinduce the affection for whose cure they are prescribed is too apparent to justify comment. Repression of muscular function is equally injurious for the ill and the well. So is excessive functioning. Both the continuance of good health and the recovery, or rather the bettering, of ill health, require proper *adjustment* of conditions to circumstances, not the abolition of conditions.

Respiration suffers from wearing repressive instruments in many ways. One way is through the deformation of the chest, caused both by the crutch and by the lever attachments common with these instruments before shown to increase the transverse, and to the same extent diminish the perpendicular, measurements of the chest. A not less conspicuous and certain effect is that of restricting the extent of the respiratory movements. The action which distends the chest and keeps its walls asunder also prevents the expiratory act from being free and complete. It follows that the amount of air changed at each respiratory act is lessened. This fact is shown and more fully understood under test conditions. The wearer of an apparatus is prevented from making much physical exertion, because exercise increases respiration, and therefore increases the extent of the motions of the walls of the chest—a condition he is unable to fulfill. Attempts to ascend stairs or even moderate acclivities put the entrapped individual “out of breath,” and he is compelled to desist. This experience proves that the oxygen attainable under the diminished extent of respiratory movements is insufficient for the emergency, or, indeed, any emergency requiring it to be increased. No advantage the instrument is reputed to confer can in the least compensate for this disadvantage.

Another way in which respiration suffers is through the diminished demand of the organism for oxygen. Restricted muscular activity diminishes the force of contact of chemical ingredients of the organism, and therefore the extent and degree of the chemico-vital activities of the organism and the amount of oxygen required. The amount of that element taken by the blood from the air of respiration is correspondingly diminished. There can be in the nature of things no remedial substitute for this loss, and the organism consequently suffers permanently in its chemical phase of function. The attentive observer may also notice that the mechanical form of the respiratory act is changed for the worse by supporting instruments. The limitation of the *lateral* respiratory movements compels the substitution therefor of a *perpendicular* form of respiration, in order to secure enough air. The subject is seen not only to breathe laboriously, but at the very top of the lungs, the movement often ascending even to the throat. Now, this mode of breathing involves far more physical labor than the natural mode, because the resistance to be overcome is greater. There is not only the bony frame which bounds the top of the chest, but the weight of all the viscera, which have to be overcome at each respiratory rhythm, when it is forced into the perpendicular form, instead of being allowed the easiest and spontaneous form. Many a poor victim of apparatus has languished under the physical labor of an un-

natural and exhausting respiratory process, which in its natural form is strength-giving. Under this expenditure there remains little or no strength to serve the volitions. The *reserve* capacity of the chest becomes so limited as to prohibit a quickening of pace or in any way creating demand for increased respiration.

It may be further observed that the perpendicular form of respiratory rhythm is liable to be prejudicial to the column, weakened by the withdrawal of muscular support, by the hyperæmia arising from diminished circulation, and by the mechanical disadvantage of the abnormal form. Every inspiratory act now becomes a sort of blow, forcing the chest, and particularly the spine, downward. The natural tendency of this physical cause is to co-operate with the other causes enumerated to increase the angle of the column.

*Apparatus modified to diminish their Injurious Tendency.*—Numerous examples of instruments are made whose harsher features above pointed out have been in various ways and in all degrees softened, till, in the mildest forms, little or nothing is left but the corset, similar to that with which not a few women delight to repress their powers. The objections above presented, of course, proportionally diminish, but can not be removed while any degree of functional repression remains.

Of late years a form of "supporter" has obtained extensive vogue which curiously blends physiological requirements with the above-described ill effects. This is the so-called *plaster jacket*. Its ostensible purpose is to secure the improved form, forcibly and quickly produced by a retentive incasement. Plaster of Paris, which is easily mixed and used and quickly and firmly sets, and can be renewed as often as desirable, is the typical substance used for the purpose, but many substitutes have been employed for the same purpose. Gutta-percha, raw hide, and felted wool stiffened with shellac, have been applied to the same use, according to the notions of different specialists. The essential peculiarity about this "support" is the mode of applying it, or rather of fitting it to the form of the wearer. The whole body of the invalid is subjected to all the tension or strain of muscle that can be well borne. The processes of being hung or suspended by the arms or head, or both combined, are the usual means. We have already seen that other and even more effectual processes are both more agreeable and more successful.

The reader will perceive the very important physiological effects superinduced by the process, which is the essential part of the so-called plaster-jacket treatment. The patient exchanges continuous compression of vertebrae for alternations of pressure—the muscular inertia for the most vigorous action of every fiber and cell. The hyperæmia of the column is consequently removed, the collateral channels of the circulation are broadly opened, arterial contractility is vigorously resumed, the chest expanded to the utmost, synchronously with the incitation of its muscles. These effects are extended, corroborated, and confirmed by the increase thus superinduced in the vito-chemical physics of the whole organism, through which the quality of the blood and fluids of the organism is approximately restored to the normal

standard; and this is done in the only way in which the special morbid quality of the blood can be permanently and satisfactorily antagonized. No wonder at the disparity in results of procedures which do and those which do not include the above-named physiological effects. The ideal purposes of remedies have in a fashion been complied with, though in many instances the intrinsic nature of the process may have been but imperfectly understood. A prolonged wearing of the instrument may and often does turn the beneficial to injurious effects. From its great weight and impermeability to air and the emanations of the body, the plaster jacket may become the most oppressive as well as repressive of instruments. The improvement temporarily assumed is then found to be deceptive, and can not be maintained unless the motor is made paramount to the restrictive in the combination of the two methods which this device practically presents.

A mode of treatment of the columnar angle is pursued in Berlin with commendable success which purports to be a modification of that above described. The "supporter" is reduced to a nominal place, being retained apparently out of deference to the prejudices of physicians and patrons who expect that appendage, and who have little accurate knowledge concerning it. The physiological factor of the treatment is pursued with great ardor and perseverance. The plaster jacket is replaced by felt, parts of which may be stiffened with shellac, or even straightened to conform to the shape by strips of thin, narrow, light steel, affording not the slightest pressure and counter-pressure. The restriction afforded to the bodily movements is less than that of an ordinary corset. The instrument is removed for the daily physiological or motor treatment. This consists of the application of *massage*, and of applied or specialized semi-exercises, prescribed and adjusted with great accuracy to the special defects of the patient. Stretchings of spinal muscles in connection with alternations of compression of the vertebrae are important features of the treatment. There is suspension and partial suspension by the arms, neck, etc., repeated at proper intervals by means of differently devised apparatus. A modification of hanging, producing the same effects, easily controlled and whose use may be prolonged, is the pivoted tipping couch or table. The patient is attached to it by the head or arms, or both, and, when tipped, the weight of the body causes the column to be compressed or distended, according to the direction in which the weight is made to act by the variations of position.

The degree of these effects, and the rate of alternation with which these variations may be passively supplied, are under instant and perfect control. The good effects on the spine of this and similar mechanical processes are direct and unequivocal.

*The Health of Michigan.*—According to the State Board of Health's Report for the four weeks ending September 28, 1889, diphtheria was reported from thirty-four places, scarlet fever from twenty places, typhoid fever from seven places, and measles from seven places. Reports from all sources show diphtheria reported at thirteen places more, scarlet fever at two places more, and typhoid fever at seven places more than in the month of August.

## MODERN MEDICAL SCIENCE.

By A. S. COE, M. D.,  
OSWEGO, N. Y.

It is a question whether the practice of medicine, until within the memory of people now living, has been a material benefit to mankind, aside from surgery and hygiene. Even now, judging from the vast amount of misapplied and useless drugs consumed by the people, it is a question whether the benefits from their use are not counterbalanced by their abuse. There are many reasons why medical science is behind all other sciences in its development and practical application to the wants of the people. Since Hippocrates, the founder of rational medicine, no real advancement was made until within the last century. The chief reason is that it has been subordinated to the vague speculations of philosophers and metaphysicians and the mysticisms of the priesthood, although long before the last century a solid foundation was being laid by the study of anatomy, physiology, histology, chemistry, and therapeutics, but no application of the knowledge thus obtained to the cure of diseases could be made until the teachings of medical science had become emancipated from the traditions of the past, and freed from their dogmatic spirit by rejecting all hypothesis and returning to the unbiased study of natural processes as shown in health and disease. Before that period the history of medicine is a dreary and barren record of endless disputes postulated upon abstract theories of the founders of rival schools, which had no foundation in nature or nature's processes. Such is the theory of Galen: of four elements—hot, cold, wet, and dry—which, mixed in proper proportions, constitute the norm of the body, and disease results from a disturbance of these proportions; of the methodists, that diseases are due to relaxations and contractions of the minute passages of the body; of Paracelsus's microcosm, the counterpart of the macrocosm, with the indwelling spirit of Archæus and his arcana of panaceas and specifics for all human ills; of the humorists and solidists and other schools of medicine which followed and disappeared, leaving nothing of value save a few chemical discoveries made by the alchemists in searching for the essence of matter, elixir of life, and philosopher's stone, and the knowledge of the therapeutical value of a few medicinal herbs. This meager outline presents a picture of childish conception of the internal structure of the body and theory of health and disease. Yet they were the net results of concrete facts resulting from the efforts of the brightest intellects of centuries. If it is impossible to postulate a true theory of health and disease, which, subjectively and objectively, are under daily observation, how absurd it is to attempt to postulate a true theory of the invisible world, which is so absolutely hidden from our senses! Metaphysics and theology, until within a comparatively recent period, absorbed and misguided all efforts to advance rational medicine and place it on a scientific basis. Metaphysics has no foundation in the real or natural world and leads nowhere, and ends in vain strivings to realize the unattainable. It consists of vague and shadowy definitions and juggle of phrases, without definite or com-

prehensible meaning, and, when divested of its flowers of rhetorics and dialectical subtleties, leaves nothing tangible behind. Its only useful purpose is to train the faculties in dialectics and rhetoric, but it creates an ideal world out of airy nothings, which is so far removed from this mundane sphere that it is impossible for it to bear fruit in relieving suffering humanity, but leads the ignorant and imperfectly educated into gross vagaries—illustrated at the present time by many absurd methods of curing diseases which have seized upon the popular mind. "Christian science" is ideal philosophy run to seed—abstract idealism reduced to the concrete and applied to the wants of humanity. All beyond the objective world is vague and incomprehensible, and all speculation pertaining thereto always has resulted in gross anthropomorphism or vague and shadowy idealism, leading on the one hand to gross superstition, inciting the passions to inhuman and barbarous cruelty; on the other hand, the speculative dreamer to fantastic conceptions of the origin of the material world and the laws governing it. To the anthropomorphic conceptions of the Deity are due the cruel and bloody religious sacrifices and frightful persecutions by Christian zealots. Theories and conceptions of the invisible world are always changing and varying as much as light varies from darkness—never stable, resting on the secure foundations of eternal truths and verities—notwithstanding the vast expenditure of the efforts of genius that has revolutionized the currents of thought and marked the epochs of time.

Natural laws or nature's processes are immutable, and the advancement of civilization, morally and physically, has kept pace with the knowledge obtained from their investigation and application to the wants of mankind. The human organism is of exceeding complexity; animated by vital force, the most complex of the forces of nature; hence medical science is the most difficult and complex of all sciences, and is yet in its infancy. It has made rapid advances in the last two decades. The pathology and natural history of a large number of diseases have been rescued by more exact methods of clinical observation and the more minute investigation of the pathologist from the obscurity in which they were shrouded. Pathological and structural changes, with their concomitant symptoms, have been traced from their beginnings. But there is a vast field yet under investigation and awaiting solution, more especially as to diseases whose causes are supposed to be due to bacteria or pathogenic germs. Unfortunately, the general practitioner, whose province is to apply this improved knowledge to the wants of the people, has not improved in equal ratio, and the public, whose enlightenment depends upon the general practitioner, is nearly as ignorant of the possibilities and limitation of medicine in curing diseases as it was when rational medicine was unknown to the profession, or before it became emancipated from the traditions of the past; when disease was supposed to be a separate entity of a supernatural origin that had taken possession of the organism; or some malign influence of the stellar and planetary system that had to be driven out by exorcisms, or conjured away by incantations, or await a more favorable conjunction of planets or stars as deter-

mined by the horoscope of the astrologer. Great faith was placed in the varying phases of the moon for good or for evil, and the potency of medicinal herbs depended upon gathering them during its favoring changes.

Many farmers, otherwise intelligent, still wait upon the changes or phases of the moon to plant their crops, and I have met an officer of the navy high in rank who had an abiding faith in the malign influence of particular phases of the moon and conjunction of the planets. The fault lies in imperfect and insufficient teaching and false conception of the duty of the practitioner in not instructing his patrons relative to the natural history of their complaints and the possibilities and limits of medicine in giving relief, and in not withholding medicine when it is not needed. The practitioner often justifies himself for his want of candor to his patrons by the Jesuitical casuistry that the patient is resolved to have medicine anyway, and, if he does not prescribe some harmless placebo, will go somewhere else and get it, and perhaps fall into the hands and become the prey of some ignorant quack, to his great harm. The patron is kept in ignorance of what is of great importance for him to know, and the profession is discredited and reduced to the level of the most arrant quackery, and by its example encourages the growth of and causes to flourish the most rank and shameless charlatany. Consciously or unconsciously, the arts of the conjurer and spiritual medium are practiced upon the credulous and confiding people, fostering the element of mysticism which seems inherent in all ignorant and imperfectly educated minds.

It is the province of scientific medicine to raise the profession above the plane of the common pretender and charlatan, and divest it of all appearance of mysticism to the people, making the separation so plain and palpable that the common mind can discriminate between the well-trained and skillful physician and the wily and pretentious quack as readily as it can between the well-trained jurist and the shyster, or the common laborer and the skilled mechanic. Before this result can be accomplished the people must be taught the causes and natural history of their complaints, the possibilities and limitations of remedies, and that nearly all diseases have a tendency toward recovery under favorable conditions by the conservative powers of nature and time; and that medication, at best, has only a temporary influence in favoring the cure. As long as the average practitioner, through ignorance or design, avails himself of the ignorance of his patrons and assumes the credit due to the conservative powers of nature, he keeps himself on the level of the charlatan. In nine cases in ten for which the practitioner is called upon for advice, little or no medication is needed. All that is required is to calm the fears of the patient and give advice as to regimen, and nature will soon correct whatever is amiss. Perhaps the tenth case is one of those diseases, obscure in its origin and insidious in its development, running through considerable cycles of time in its exacerbations and remissions before a fatal termination, and the structural changes have become too far advanced to effect a cure before the patient has become conscious that anything serious is the matter with him. Nothing can be done save to palliate the more distressing symp-

toms and defer the fatal termination as long as possible. Such are the gradual degeneration of the spinal cord resulting in locomotor ataxy, progressive muscular atrophy, spastic muscular paralysis, and other spinal diseases depending upon the locality of the lesions; also degeneration and sclerosis of the larger arteries, causing hypertrophy of the heart and dilatation of the left ventricle, and impairing the nutrition of the heart; and also chronic disease of the kidneys. Often these diseases are not recognized in their incipiency, or give so little trouble that the patient is not sufficiently alarmed to consult his medical adviser until it is too late to obtain permanent relief. As scientific medicine progresses by tracing diseases to their beginnings with their concurrent symptoms, diagnosis is simplified and made easy, and the importance of hygiene and prophylactic medicine becomes more apparent, and also the almost criminal fallacy of the indiscriminate prescribing of drugs upon general principles. In this matter it is the duty of the general practitioner to await the results of the more careful and scientific experiments of trained experts. "To make haste slowly" will save much valuable time, avoid many errors, and prevent much harm, disappointment, and humiliation, resulting from imperfect observation, hasty generalizations, and crude theories. One very essential factor is too much ignored by modern investigators in determining the *aetiology* of diseases and its bearing on treatment. A recent writer upon the "Progress of Medical Sciences" says: "The fallacy of the old medical systems, of which Boerhaave, Van Helmont, and Brown were founders, is now acknowledged, and the attempt to explain the causation and treatment of diseases on the 'pneuma' or 'vital forces,' humors, and the 'archaeus' has been frustrated by the more accurate and better-equipped labors of the nineteenth century, while the theories advanced by these brilliant intellects have fallen into disrepute." There is a tendency in modern research to ignore or not give its due importance to this factor which, in a vague way, entered into the theories of nearly all of the exploded systems of causation and treatment of diseases, designated as the "pneuma" or *archaeus*, the indwelling spirit, now called "vital force," and trace the causes of diseases to "disordered functions, impaired nutrition, and consequent structural changes," and to infections from pathogenic germs. If there were no other factors than these to be considered, the problem of the causation and treatment of diseases would be much simplified. Under the same conditions and surrounding influences the effects of causes and results of treatment would be more uniform. All exposed to pathogenic germs would be affected alike; no one would be exempt. There are inherent in some families and individuals great powers of resistance to diseases. They are exposed to and pass through frightful epidemics unscathed, or, if attacked, throw off the malady with ease, or survive surgical operations which are apparently hopeless, or frightful injuries which would be inevitably fatal to the average individual. This factor of resistance, whose value it is impossible to estimate, enters into the problem of causation and treatment of all diseases and vitiates the deductions and generalizations based upon data gleaned from clinical observation and experiment.

It is evident there is a potential principle or latent force, whether the "pneuma," "archæus," or some other indwelling spirit vaguely recognized by the founders of the old schools of medicine, inherent in the germ of all organisms, which controls and presides over their growth, regulating their form, features, and physical and mental development, including the powers of resistance to diseases. In some organisms the vital force is vitiated and feeble, and the organism becomes the prey to surrounding destructive or disintegrating agencies and internal abnormal processes. In others it is strong and vigorous, and gives the organism a perfect physical development, symmetrical and harmonious in all its parts, capable of resisting ordinary assaults from without from destructive agencies which destroy the weak. This vital principle animates all organic life, animal and vegetable, and is governed by the laws of its being and presides over the destinies of its species, preserving the strong and eliminating the weak by depriving them of the power of reproduction or causing them to be pushed to the wall by the strong in the struggle for existence. In the economy of nature the welfare of the individual is subordinated to the welfare of the species. Tendencies to disease are often due to inherited vitiated and weakened vital force, which defects often remain latent until the organism is called upon to resist an unusual strain; then it succumbs to the first rude shock; or the defects may manifest themselves by abnormal processes within, in malignant neoplasms, degeneration and decay of tissues of the spinal cord or the inner coats of blood-vessels, tubercular deposits in glands or other organs, without any apparent cause. The production of the specific pathogenic germ in each respective disease does not prove absolutely that these germs are the causes of their respective diseases as long as a perfectly well constituted organism resists all of these diseases under the same conditions and influences. There is a defect in the *a priori* reasoning; the bacilli may be the result, not the cause, and as "innocent of mischief as maggots in a neglected wound." There may be and probably is another factor which prepares the soil for the reception and propagation of these germs. All healthy and perfectly constituted organisms resist fungous and other parasites which prey upon decaying or imperfectly vitalized organic matter. Fungous growths are not found on healthy and vigorous plants, or vermin on healthy and well-nourished animals. It is only after their vital forces are weakened by disease or the rigors of a severe winter and by insufficient and unwholesome food. In the history of the cholera epidemics which have swept over this country before the comma bacillus was known or dreamed of, the disease suddenly burst upon communities with great virulence, and left as suddenly as it came, after expending its force, leaving no trace behind, save the deserted homes and widows and orphans bereft of their natural protectors. No efforts were made to destroy the comma bacillus save general sanitary policing, which, according to our present lights, was wholly inadequate to prevent a perpetuation of the disease by propagation of the germs. Any research intended to trace diseases to their ultimate causes and apply remedies for their prevention and cure, without giving the factor of vital force its due importance, will result in failure

and disappointment. It is one of the ultimate facts of nature; we know that it exists only from its phenomena manifested in the growth and decay of all organisms; it determines the normal development and duration of life of the organism, of its species, and its perpetuation by reproduction. The limits of that life can not be prolonged, but may be lessened by the many accidents of life and by violation of the laws of its existence. Powers of reproduction are vitiated and weakened by violation of these laws, which are inexorable, and will exact the penalty to the last farthing. A perfectly well constituted organism contains from the germ sufficient force in reserve for its perfect evolution of fetus, infancy, puberty, reproductive period, and vigor of manhood, when it displays its full powers, and declining old age, when the last reserve is called upon, and at the final expenditure of force the vital spark fades gently and becomes extinguished, having accomplished its perfect and complete round. Any inherent defect becomes more pronounced during the evolution of the climacteric periods, of puberty, and decline of reproductive functions, and the puerperal state, from an increased demand upon the vital powers of the organism. It is evident, then, that the ultimate causes of many diseases are due to inherent defects of the organism transmitted by inheritance, which remain latent until some exciting cause develops them. From three years' service in the army during the War of the Rebellion, and several years' service as pension examiner subsequent to the war, I have observed that those soldiers who bore the tremendous hardships and privations of the field without becoming disabled thereby have since become prematurely old and decrepit, some of them without any assignable cause save the premature expenditure of the reserved vital forces; others from faulty nutrition, indicated by degeneration or sclerosis of the spinal cord and arteries and resulting disease of the heart, and chronic rheumatic troubles affecting mostly the spinal and sciatic nerves. It is a noticeable fact that nearly all of the prominent generals of both sides who served through the war have died prematurely.

**Ocular Massage.**—The "Lancet's" Paris correspondent writes to that journal as follows:

A communication was recently made to the Academy of Medicine on this rather novel, or, as it would appear, modification of the ancient use of massage by M. Costomiris, of Athens. He said that if the ancient Greeks employed massage in eye affections it was not by means of the pulp of the finger on the conjunctiva and cornea, such as he had been in the habit of employing for many years. His method was, after evertting the lids, to spread a thickish layer of fine boric-acid powder on the conjunctiva, and then with one of the fingers to rub, in massage fashion, the parts so covered with the powder. He then washes the eye in boric-acid solution, and for the few following days applies a lotion composed of 1 in 200 of nitrate of silver to prevent the inflammation which sometimes follows the manipulation. He next rubs the outer surface of the lids in the same way, which he finds lessens any pain caused by the internal massage. It is as well in every case to begin with a short and very light friction, then to increase it and again decrease it, and this should be repeated once daily and continued for two or three weeks after cure. M. Costomiris speaks very highly of this method in the treatment of granular lids or follicular conjunctivitis, in parenchymatous keratitis, in hypopyon, in infiltrations, and in abscesses or ulcers of the cornea; but in deep-seated ocular mischief he can not recommend it.

NEW YORK, SATURDAY, OCTOBER 12, 1889.

"GYNAIA."

In a recent issue of the "Pacific Medical Journal" there was published a review of a monograph by Dr. Steinerkopf which affords abundant food for reflection. To this article we are indebted for all the facts as to the nature and treatment of the disease which has been described by its discoverer, and which he has named "gynaia," defining it as "the simulated existence of feminine moral qualities in the person of a man"; for the original brochure has been inaccessible to us. But enough is related by our contemporary to place Dr. Steinerkopf's right to the title of *savant* beyond doubt, despite the unfortunate fact that in callow student-life he affiliated with the misguided followers of the cult founded by Hahnemann. But, even if he is a medical heretic, he at least is consistent in his practice, for he is an enthusiastic exponent of "high dilution" therapeutics, though stopping short of "olfaction."

The discovery made by Dr. Steinerkopf is that what has been called effeminacy is in reality a disease which is curable, and not a concomitant of congenital anorchidia or a resultant of an early training analogous to the subalar rearing of the offspring of a uniparous hen, when occurring in a male. This disease, "gynaia," is characterized by the exhibition of timidity, aversion to tobacco and to dogs of non-personal allegiance, manners of ratiocination untrammeled by the friction exerted by logic, and other qualities commonly observed in the typical human female. Given the symptoms, the proper treatment to be followed was plain; and to a homœopathic high dilutionist the selection of the specific remedy was a mere bagatelle. The only stumbling-block in the way was the difficulty of diluting femininity to that degree of attenuation needed to prevent it from aggravating the disease. It is a well-known fact that the most important scientific discoveries have been made through sudden and accidental suggestions afforded by trivial and common occurrences. The case in question was no exception to the rule, for the nonplussed scientist saw in an "allopathic" journal a would-be crushing statement, emanating from the venomous malice of a ribald scoffer, to the effect that the fiftieth dilution of "lachesis" contained an amount of the alleged drug which would be present in a mixture of a single drop of the mother tincture with the whole Atlantic Ocean. This apology for a sally of inexpensive wit was to Dr. Steinerkopf what the falling apple was to Newton, the unaccustomed bath to Archimedes, and the post-mortem kick of the frog's leg to Galvani; for the statement revealed the hidden path which was to lead to success. In brief, the moment at last presented itself when a solitary girl was bathing in the surf at a sea-side resort under Dr. Steinerkopf's observation;

and, as her bathing-suit was ultra-Parisian in scope, an exceptionally favorable chance to obtain the requisite dilution of the drug was offered. From a bucketful of water secured at that time, the essence of manliness, retired hoop-skirts, boots, other inorganic matter, and domestic animals were eliminated, and a sterilized solution of chemically pure femininity was obtained. This was labeled "*puella domestica, seu officinalis, seu aestiva,* 50th," as, in spite of the attractive appearance of the crude drug, the doctor was too intent on his purpose, and perhaps on the bathing-suit, to be able to recognize it when attired in conventional raiment, thereby being unable to discover the exact variety of "*puella*" in his preparation. Whatever the variety, it was the correct remedy, as in both "provings" and curative power it surpassed his wildest dreams. His own "proving" of the drug resulted in the temporary acquisition of feelings and habits to which he had before been an entire stranger. He could only sit down in comfort when one of his feet was interposed between the seat and his own person; when a fellow-bachelor crony came later than usual to the *Gasthaus* in which they had for years met nightly, Dr. Steinerkopf burst into passionate tears and upbraided his friend for his heartless conduct with "that woman" who had kept him away; he experienced singular feelings of uncertainty as to the location of and method of access to his pockets, and carried all his journals and specimens in those placed in the skirts of his coat; he regarded with horror the progress of baldness in his own case, and was actually on his way to a perruquier's when the effect of the drug passed away. After another dose he sought to put on his trowsers by the same series of movements and by the same route as those by which he donned his shirt.

The foregoing symptoms are only a few of those observed, and all, when due to disease, vanished before the might of the drug. Though not as yet proved, it is reasonable to expect that the remedy will be equally effectual in those maladies cognate to "gynaia," and will mitigate the chromatic disagreement of shirt and collar, as well as lessen the evidences of intracranial baldness, that are so often observed in such cases. May it not promote absorption of the pre-ocular disc of window-glass that serves to dim the vision of a patient to the looks cast upon him by intelligent men, or to create a desire for other diet than that composed of the heads of walking-sticks? In the interests of posterity let this drug be administered to the *jeunesse dorée*, in the hope that the race of intellectual invertebrates will become extinct, and that hereafter the scions of a virile family stock will show an atavism reflecting the renaissance of ancestral manhood and not the development of an androgynous fungus on the family tree. Then may these anthropoid things, after an amoeboid existence has terminated by the yielding up of a hebetudinous ghost by the same oozy exosmosis that marks the passing of a life-weary oyster, be known only through clay-bank intaglios or masses of adipocere unearthened by the coming race. Who knows but that they might thus fulfill their destiny by bearing fossil testimony that Darwin was no wild dreamer in his search for a "connecting link" as the missing key-stone of his evolution arch, and furnish a much-needed subject for

contention between the Church and the science of a century hence. We can not urge too strongly upon the profession the advisability of following up this discovery of Dr. Steinerkopf's, for true philanthropy demands that our descendants should be spared, as far as may be, the shame and disgrace of this blight of emasculation-mildew from which we suffer. The possibilities are too great to be ignored.

#### THE DANGER OF SUCKING THE TRACHEOTOMY-TUBE.

To the "Lancet," animadverting upon this danger, a correspondent of that journal replies that, if anybody who can swim is justified in trying to save a fellow-creature from drowning by jumping into deep water, it must be allowed that a surgeon is justified in sucking a tracheotomy-tube in order to clear a blocked trachea or the large bronchi. Such action, the writer says, must depend upon the personal character of the operator, and whether or not he has "near and dear relatives dependent upon him," since no instrument is so effective as the mouth, and the dangers of infection can be effectually overcome by rapidly placing one's self under the influence of mercury.

As an exhibition of false sentiment, bad logic, and thoroughly dangerous practice, this should not be allowed to pass unnoticed. According to the first and fundamental law of moral philosophy, "man's first duty is to himself." From this dictum there is no appeal, whether we may have others dependent upon us or not; although it may seem selfish at the first glance, there are many cogent reasons why, even in the matter under present consideration, it is particularly true, and therefore not to be disregarded. Logically, the situation would have been more accurately portrayed if the writer had likened it to a case of drowning in which the would-be rescuer could not swim.

Practically, an ordinary piston syringe, to the nozzle of which is affixed a short piece of rubber tubing, is an admirable substitute for the operator's mouth, and an instrument which should constitute a part of the armament of every tracheotomist.

As to the risk to the operator of sucking the trachea, the application of a razor to the throat would be a more agreeable if not a more certain means of suicide. We can recall a score of cases where valuable lives have been directly sacrificed by it, while a sharp attack with a tardy convalescence of six months has been the writer's personal experience in the matter. Indeed, in a somewhat large experience, he has never known of an instance in which the act has not been followed by some reaction in the operator's throat.

In Billington's admirable work on diphtheria, it is a pleasure to note the views expressed by that dispassionate author upon this very question. "Diphtheria," he says, "is communicated in a variety of ways. The first of these is by direct contact, or the deposition of diphtheritic matter on the mucous membrane, or upon wounds of the skin. Examples of this mode of transmission are furnished by numerous well-known instances in which physicians have contracted the disease by sucking out tracheotomy-tubes, or by receiving the secretions of the patient in the mouth or nares. . . . The demonstration

afforded by the instances referred to is not at all weakened by the fact that many other physicians have sucked out tracheotomy-tubes and have received diphtheritic secretions in their mouths and nares, or that others have kissed infants affected with diphtheria, or that M. Peter and others have painted their own fauces with solutions of false membrane, without diphtheria resulting. . . . A limited number of positive examples of the communication of diphtheria by direct contact, among many negative ones, is all the proof of its occurrence that could be rationally demanded." Such practices, therefore, as admit of the possibility of bringing the diphtheritic poison into contact with the mucous membrane of the throat are absolutely reprehensible and not to be countenanced.

#### MINOR PARAGRAPHS.

##### MORTALITY FROM "CHRISTIAN SCIENCE."

A LEADER of the so-called "Christian Scientists" has been arrested in Brooklyn, on the charge of manslaughter. The charge against him states that he contributed to the death of a young woman, not over twenty-four years old, who, until about a week before her death, had apparently been in blooming health. She was taken sick with a fever, probably typhoid, on a Friday, and on the following Thursday was dead. All proper medical care was denied the sick woman. A physician was called in by the accused, in whose household the patient lived, "to comply with the law," as she said. Religious observances were performed about the sick-bed for some days, as the sole means of cure. And, even after death had taken place, the prayers and other ritual were continued in order to call upon the deceased to "arise again in the flesh." This imposture was even in progress at the time when the arresting officer reached the house of the accused, and the body had already been placed in the ice-box used by undertakers. The leader, in this instance, belongs to an ignorant and superstitious class of society, and his followers are from the same class. The hold of this novelty or "fad" upon the "better element" in our cities has been relaxed, and now the poorer and more ignorant are beginning to suffer from it. As is sure to be the case with regard to every manifestation of quackery, the poor and defenseless suffer the most from it. Since the arrest above referred to another death by neglect has been reported from among the same coterie of deluded people.

##### LONDON POST-GRADUATE COURSES.

It has always been a reproach to London, says the "British Medical Journal," that the unrivaled clinical material of its numerous hospitals is not fully utilized for the purposes of medical education. It is not that teaching power is wanting; on the contrary, the metropolitan schools could furnish among them a body of men thoroughly fitted to make London the center of the medical world, as it undoubtedly ought to be. Owing to want of organization, however, a large amount both of material and teaching power is wasted. Nowhere is the loss of potential educative energy more evident than in the hospitals to which no medical school is attached. It is therefore with peculiar satisfaction that we hail the announcement that the medical staffs of the Brompton Consumption Hospital, the Hospital for Sick Children, Great Ormond Street, the Hospital for the Paralyzed and Epileptic, Queen Square, the Moorfields Ophthalmic Hospital, and the Hospital for Diseases of the Skin, Blackfriars, have decided to unite their forces, and give courses of instruction to qualified medical men in the various important branches

of medical science and practice which these institutions represent. The teaching is intended to be thoroughly practical, and the convenience of men engaged in the active exercise of their profession has been studied in the arrangement of the hours at which the courses will be held.

#### FOOD ANALYSIS IN THE RUSSIAN ARMY.

THE Russian Ministry of War has found it necessary to submit the army ration to a closer inspection and analysis than has been hitherto adopted, on account of the frequency of scurvy and other dietetic diseases among the soldiers. It has been decided to furnish to each army corps an ambulatory laboratory with chemists, who must report upon the quality of the food delivered by the commissariat.

#### CRURAL VACCINATION.

THE "Medical Press and Circular" has an item, taken from some unnamed French source, which raises the question as to the best place on the body for the insertion of vaccine. A French physician has done a sufficient number of vaccinations upon the leg to be able to say that that member is superior to the arm—in his experience. They were all cases of re-vaccination in school-children. His proportion of failures he states to have been, in the arm, 53·8, and in the leg 45·5 per cent.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 8, 1889:

DISEASES.	Week ending Oct. 1.		Week ending Oct. 8.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	55	11	69	11
Scarlet fever.....	34	3	33	6
Cerebro-spinal meningitis.....	1	1	0	0
Measles.....	13	2	18	1
Diphtheria.....	55	14	67	19

**The Health of Johnstown.**—There was a limited prevalence of typhoid fever during September at Johnstown, and there are now twenty-two cases of that disease at the hospital of the Red Cross Association. Those who have had the fever are, for the most part, from among the transient population of the town. Sickness and death are not infrequent, however, among the townspeople proper, their causes in many instances being referable to the great calamity.

**A New College of Pharmacy.**—The Kings County Pharmaceutical Society has had under consideration plans for the establishment of a college of pharmacy in Brooklyn. It is reported that the preliminaries have all been agreed upon, and that before many months a fully equipped school will have been launched.

**The Manhattan Eye and Ear Hospital.**—Dr. W. M. Leszinsky has resigned from his position on the medical staff.

#### Society Meetings for the Coming Week:

**MONDAY, October 14th:** New York Academy of Medicine (Section in Surgery); New York Ophthalmological Society (private); New York Medico-historical Society (private); New York Academy of Sciences (Section in Chemistry and Technology); Lenox Medical and Surgical Society (private); Boston Society for Medical Improvement; Gynaecological

Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private); Baltimore Medical Association.

**TUESDAY, October 15th:** New York Academy of Medicine (Section in Theory and Practice of Medicine); New York Obstetrical Society (private); Medical Society of the County of Kings; Ogdensburg Medical Association; Medical Societies of the Counties of St. Lawrence (semi-annual) and Westchester (White Plains), N. Y.; Hunterdon, N. J., County Medical Society (Flemington); Baltimore Academy of Medicine.

**WEDNESDAY, October 16th:** Northwestern Medical and Surgical Society of New York (private); Harlem Medical Association of the City of New York; Medical Society of the County of Allegany (quarterly), N. Y.; New Jersey Academy of Medicine (Newark); Philadelphia County Medical Society.

**THURSDAY, October 17th:** New York Academy of Medicine; New Bedford, Mass., Society for Medical Improvement.

**FRIDAY, October 18th:** Chicago Gynaecological Society (annual); Baltimore Clinical Society.

**SATURDAY, October 19th:** Clinical Society of the New York Post-graduate Medical School and Hospital.

## Letters to the Editor.

#### PULMONARY CONSUMPTION.

DEVIL'S LAKE, NORTH DAKOTA, September 17, 1889.

To the Editor of the New York Medical Journal:

SIR: So much has been written upon consumption that it seems like presumption to attempt anything further, and yet the subject is far from exhausted, nor is its status entirely satisfactory to the practical physician.

The *Bacillus tuberculosis* is acknowledged by all as an entity, by many as the sole *causa morbi* of tuberculosis, by the few and more conservative as a mere sequenee or at most as one only of two factors causing the disease. Our fathers taught that in certain individuals there was a diathesis either inherited or acquired. What did they mean by a diathesis? Simply this: if a rattlesnake bites a non-venomous snake, a dog, or a rabbit, certain morbid phenomena result. If the venom is examined microscopically, it will be found swarming with bacteria having a wonderful power under certain conditions to promote putrefaction. If, however, this venom is injected into a rattlesnake, there will be no effect other than traumatic. The non-venomous reptile, therefore, has a physiological condition, or, as our fathers would say, diathesis, entirely differing from the rattlesnake's. This diathesis can be inherited. To understand how this occurs, let us briefly review the three or four well-known laws governing the generation of plants and animals. These laws are as follows: 1. A plant can place no constituent in the seed not possessed in itself. 2. All parts of the plant are subservient and contribute to the production of the seed. 3. The seed contains all the constituents of the parent plant or plants, and these constituents have a ratio to the constituents of the parent plant. 4. The seed under certain conditions has the power to draw *similia ad simile*. The first law is evident and needs no example to substantiate or illustrate it. In proof of the second law is the well-known fact that, if cattle are dehorned for generation after generation, horns will at last fail to grow upon the progeny. Under this law it must not be supposed that a constituent comes from a part like a rill from a mountain to

be deposited in the *gone*, but that there exists a constituent in the economy to nourish any given part and from this a modicum is laid down drawing to itself similia, and thus the plant or animal generated has a similar part.

In proof of the second law also is the fact that, if a part or an organ is augmented or distorted through successive generations, the augmentation or distortion will appear in the offspring. The story of the *Macrocephali* is a case in point. The dehorned cattle, the bald-headed man, and the eyeless fish are all illustrative. In conformity to this law it appears to me, I will digress to say, impossible that a disease like syphilis can be transmitted. The germ upon which the disease depends is one fact or has its own separate organic existence. It is an invader and lives at the expense of the recipient and can never become an organized constituent of the sufferer. It can therefore no more be deposited in the *gone* than the worm in the body of a tree can be transmitted to the seed thereof. The child becomes diseased by contact as the father or mother did. I have myself seen children perfectly healthy born of syphilitic parents. On the other hand, the healthy child of diseased parents afterward contracting the disease will suffer slightly less than if the parents had been pure.

The worm in the tree is there because it finds that which is pleasant to itself and sustaining to life. This substance it removes more or less from the tree, and as a consequence trees generated from worm-eaten trees contain less of those constituents agreeable to the worm, and thus the genera are protected. Small-pox among people who have been vaccinated or suffered the disease becomes comparatively mild, but when the North American Indian, secluded from the virus through a great but unknown number of years, finally meets the microbe, the destruction is terrible. To illustrate the third law, one may examine the seed of the maple. This will be found a miniature tree, differing from the parents only in the quantity of constituents. Grafting is a beautiful illustration of the fourth law. The graft, containing only ingredients of the tree from which it was taken, accepts only like constituents in its augment from the tree upon which it is placed. The fruit, therefore, is like that of the parent tree.

I have briefly reviewed these laws, not that I think they are not well known and understood, but simply to recall them to mind and that a clearer conception may be had of the term diathesis. Reverting now to phthisis, it will be noticed that those who say that the bacillus is the sole *causa morbi*, also affirm that it has the power of multiplying; that where at first there were only a few, soon there are many. Now, to assert this is to admit the reception of an augment by the bacilli. What is this augment? Whence does it come? Why does it exist in A but not in B? And is it possible for tubercular bacilli, having *per se* the *vis vitæ* to sustain, to do this and generate themselves without it? Is it not true that, if we knew the nature of this augment and could withdraw it from the human economy, the bacilli must of necessity perish? We may not now be able with the microscope or by direct experiment to demonstrate the exact nature of this pabulum; but, as the astronomer by reasoning from cause to effect predicts the position of an unknown celestial body long prior to its discovery and location by the telescope, so, too, by the same process of reasoning, the physician may and often does discover the hidden origin of disease. There is a law of pathology that, if an apocrosis occurs in an organized body, resulting in a stasis of the substance separated, in whatever part or organ the stasis occurs there will be morbid manifestations. A stone in the bladder, the pus in an abscess, and the deposit in scrofulosis, all exemplify the law. There is also another law, that, if the apocrosis is abnormal in amount, in the part or organ from whence it comes there will

be abnormal manifestations, either of the part or of its functions. Anæmia and dilatation of the heart are illustrative. In the latter the thinness of the heart walls is not wholly due to outward pressure, but partly to overwork, the waste of tissue going on more rapidly than repair. Applying these two laws to phthisis, the morbid manifestations of the stasis are apparent to all, and by just as much as these are the easier of detection, by so much the thoughtless physician directs his attention thereto. Under the second law we find that the abnormal evidences are most persistently and constantly noted in the nervous system, and infer that the apocrosis therefrom is the pabulum or augment upon which the bacillus thrives and has its being. I may point to the crystals of cholesterin found in the deposit, which are now known to be a part of the detritus from the nervous system; but other evidences of a clinical nature, inasmuch as they are familiar to all experienced physicians, I need not repeat. There is, however, one remark of Watson's which is very impressive—viz., precocity of mind and intellect, while it delights the fondness of the parent, awakens the fears of the more far-seeing physician. It is well known that mental activity will produce asitia, nor did this fact escape Shakespeare, who makes Cæsar exclaim: "Let me have men about me that are fat, sleek-headed men, and such as sleep o' nights. Yon Cassius has a lean and hungry look. He thinks too much." *Vice versa*, asitia will produce nervous irritation, and thus the diathesis may be temporarily acquired, as after fevers, from confinement and impure air, or from the actual want of food.

In the latter case the prognosis is much better than in the former, for, if the diathesis is inherited, it will exist though we make our patient fat, whereas, if it is acquired, we have only to remove the cause and the diathesis will vanish with everything depending upon it, including the bacilli. It will be noticed, too, that the inherited diathesis was detected by our fathers long prior to the advent of the second fact, or the one which, united with the former, produces the disease proper. This goes far to prove the initial point to be in the nervous system, as in the precocious child mentioned by Watson. The diathesis acquired through generations of mental worry is, of course, transmitted to the offspring exactly as the *Macrocephali* passed down to their children their distorted heads, and, when once acquired, is so abhorrent to Nature that she stamps it out as soon as possible, even at the expense of destroying some of her most beautiful works. We can not hope to thwart Nature in her purposes, but, having discovered the bacillus, can we thereby do anything to assist her, as Jenner did with the modified virus of small-pox? Of course, by secluding phthisical persons we may protect those having a temporary diathesis; but what of those in whom it is permanent? Here is a field for experiment, though, for one, I fear the result will be unsatisfactory. In treatment, that physician is most successful who can remove quickly the asitia and nervous excitability. When the condition is congenital, narcotics that do not interfere with nutrition are very useful. In a recent case I was furnished the fluid extract of lactucarium by Parke, Davis, & Co., of Detroit. It proved satisfactory, having the beneficial without the ill effects usual to narcotics. In sending a patient from home, not so much asepsis as freedom from care and a climate affording the greatest possible number of days in which exercise can be had in the open air, is the desideratum. When there is fever, exercise should cease and be resumed when the fever has been subdued. Another very important point in management is this: No patient should be accepted for treatment until he fully understands his situation—that it is a fight for life, and that the medication and hygienic rules must be submitted to through a possible period of years.

W. T. O'DONNELL, M. D.

## Proceedings of Societies.

### ASSOCIATION OF AMERICAN PHYSICIANS.

*Fourth Annual Meeting, held in Washington, D. C., on Wednesday, Thursday, and Friday, September 18, 19, and 20, 1889.*

The President, Dr. FRANCIS MINOT, of Boston, in the Chair.

(Concluded from page 380.)

**A Case of Slow Pulse.**—Dr. D. W. PRENTISS, of Washington, introduced a patient as a subject of clinical interest whose pulse-rate for the past two years had ranged from thirteen to forty in a minute. He was a man of about fifty-eight, said to be without organic cardiac lesion and to enjoy good health. The cause had been ascribed to tobacco or malarial poisoning, or perhaps both. The interest in the case turned on the pathology. It was a moot point whether the slowness of the pulse resulted from overstimulation of the inhibitory nerve, from paralysis of the sympathetic, or from lesion of the nerve centers.

**The Relation between Chlorosis, Simple Anæmia, and Pernicious Anæmia.**—Dr. F. P. HENRY, of Philadelphia, read a paper on this subject. He said that the title of his paper might be criticised on the ground that it assumed certain relations to exist between these various affections of the blood. To such exceptions it might be replied that the selection of such a title was the expression of the universal medical belief that these affections were allied, and it was in the highest degree improbable that such a unanimous verdict could be reversed. Considering, then, first the question of pernicious anæmia, the exact status of which was of fundamental importance, it was admitted by all that most of the clinical features of this disease also obtain in numerous other affections, and notably so in atrophy of the gastric glands and cancer. Those, however, who argued most strongly in support of the theory that it was an independent disease, excluded from the category of pernicious anæmia all cases in which an anatomical lesion was found in any organ. This struck him as most unscientific, because an independent disease was one which rested upon a constant anatomical basis, or was invariably produced by the same specific agent. Hunter had endeavored to establish pernicious anæmia as an independent disease by the demonstration of an excess of iron in the liver in cases of that affection, and had regarded that as an essential anatomical feature of pernicious anæmia. The work of Hunter had been of great value, and he had certainly demonstrated the existence of an excessive haemolysis in that disease. In the author's opinion, however, this haemolysis was a consequence of defective haemogenesis. In support of this theory there were certain facts which showed the red corpuscles of pernicious anæmia as abnormally weak and perishable. Chlorosis was universally admitted as being due to defective haemogenesis, and he therefore regarded it and pernicious anæmia as closely related affections. Transition from one affection to the other had been observed by himself and others. His conclusions therefore were (1) that pernicious anæmia is a process, not a disease; (2) that it is closely related to chlorosis; (3) that it may be the terminal stage of other diseases, and especially of cancer of the stomach and atrophy of the gastric glands. Leucocythaemia and Hodgkin's disease—in that they are always associated with lesions of the blood-making organs, spleen, lymph-glands, bone-marrow, etc.—might be regarded as independent diseases, or rather different stages of the same disease, for transitional processes had been recorded.

**The Relation of Anæmia to Chlorosis.**—This paper, by Dr. F. FORCHHEIMER, of Cincinnati, was read, in the absence of the author, by Dr. Pepper. It opened with the statement that the first thing which came up to confuse, in consideration

of the subject, was the difficulty in finding apt and comprehensive definitions for the two diseases. Immermann began his definition as follows: "The conception of the term anæmia is somewhat indefinite in its elasticity," going from this into an elaborate definition, drawing as a final conclusion the inference that, partly from clinical and partly from direct (analytical) evidence, we are justified in stating that anæmia is that condition in which there is a diminution of red blood-corpuscles, as well as of the albumins of the plasma in the blood (*hypalbuminosis*). Again, Strümpell had stated that the essential element in anæmia was a diminution in the red corpuscles, or so-called oligocythaemia, further stating that oligocythaemia was not invariably accompanied by a diminution in the amount of serum albumin (*hypalbuminosis*). The conflicting ideas as to the proper definition of anæmia were clear when compared with those on chlorosis. One writer had said: "I believe chlorosis to be a form of anæmia depending upon similar changes, and therefore to be considered as falling under the head of idiopathic anæmia." Zender conceived chlorosis to consist in defective formation of red blood-corpuscles, both quantitatively as well as qualitatively, adding that, as iron was diminished in the blood and not excreted, the fault must lie in defective absorption. Then other authors, like Strümpell, defined anæmia as oligocythaemia, stating that chlorosis was a mild form of essential anæmia, such as is common to females at the time of puberty. Something approaching a sharp, distinctive definition had been enunciated by Duncan, who appeared to be the first to make the distinctive feature, oligochromæmia, characteristic for chlorosis—that was to say, that in chlorosis we found the individual red corpuscle deficient in haemoglobin. It would readily be seen that a deficiency in haemoglobin would exist in any condition in which the number of red corpuscles is diminished, and this would be called anæmia according to definitions herewith accepted. But the red corpuscles being normal as to quantity, and the haemoglobin being at the same time diminished, one would be justified in concluding that each individual red corpuscle carried too little haemoglobin, and either condition would be called chlorosis. Perhaps, unfortunately for this condition, the term chlorosis was essentially a clinical one, by far the greater number of reported cases being probably no chlorosis at all. This error obtained both abroad and at home. In this country the author of the paper had seen an American girl who had been compelled to stay in St. Petersburg for several years. She had been there pronounced chlorotic by an eminent physician. Examination of her blood had revealed oligocythaemia (about 70 per cent.) and a proportionate oligochromæmia. The girl had been very anæmic, but, according to the conception he asked for the term, she had not been chlorotic. The fact that oligocythaemia and oligochromæmia might occur in the same individual made the term chloranæmia justifiable. As to causation, it would be found that almost every cause put down for anæmia would hold good for chlorosis. Generally, it might be stated that sex, age, a peculiar composition of the blood, and certain vascular anomalies were held characteristic of chlorosis.

But in regard to the chlorosis of males one must be warned against the too ready acceptance of cases of anæmia as chlorosis. The fact urged that these cases were relieved by energetic chalybeate treatment was urged in favor of the chlorosis theory, but then in the so-called cases of school anæmia we expected good results after removal from school and the administration of iron. He considered the relation of the symptoms of anæmia to chlorosis depended upon the conditions of the blood and the anatomical substrata. Given, then, a case of anæmia in which there was only a reduction of haemoglobin as a result of oligocythaemia, and a case of chlorosis in which there was a reduction of haemoglobin as a result of oligochromæmia,

and metabolism in both these cases would be approximately the same. True, the patient with chlorosis might have a different facies; as the essence of the affection lay in the oligochromæmia, the amount of reduction in haemoglobin, if due to oligocythaemia only, would be so great as to become a physical impossibility inconsistent with life. But if, in anaemia, we had oligocythaemia as well as hypalbuminosis, said to co-exist in the majority of cases, then the metabolism must be different from that of a pure case of oligochromæmia. As a result of reduction in haemoglobin there was reduction in the process of oxidation in the body; at the same time the waste products were carried off and sufficient food carried to the tissues by the plasma of the blood, which suffered no change. In this way the nutrition was not generally interfered with; indeed, there might be increased deposit of material in chlorosis because oxidation was not sufficient to utilize the albumin of the plasma. The result of this suboxidation would be a deposit of fat, a point which Immermann spoke of as the "nucleus" of the clinical difference between anaemia and chlorosis. As to symptoms, if Virchow's anatomical lesions were accepted as belonging only to chlorosis, then there existed no difference between the symptoms of the two diseases. Symptoms on the part of the nervous system had been made one of the characteristics for chlorosis, but hysteria and allied conditions were of such common occurrence nowadays that it was unreasonable to make any one condition responsible for them. The author concluded his paper by referring to the therapeutic side of the question. Although the indiscriminate use of iron in anaemia must be deprecated, yet, upon the whole, iron was looked to as a specific in anaemia as well as in chlorosis. While not willing, then, to separate anaemia from chlorosis, we were justified in the statement that iron ought to be given in every case of chlorosis on account of the rapidity of the chalybeate effect.

Dr. WILLIAM OSLER, of Baltimore, said that he was sorry to take issue with Dr. Henry. He had devoted a considerable amount of time to blood work. He must continue, as the result of his work and observation, to regard chlorosis as one of the essentials of anaemia and as a disease absolutely distinct from pernicious anaemia. He had never seen a well-defined case of chlorosis in the male. With respect to progressive pernicious anaemia, we had not facts enough at command to formulate an opinion as to whether it was a separate disease or simply a symptom of several other affections.

Dr. PEPPER said that he was not prepared to admit the analogy between chlorosis and pernicious anaemia, for want of essential data.

**Gastric Neurasthenia.**—Dr. G. M. GARLAND, of Boston, read a paper dealing at length with the subjects of dyspepsia nervosa, anorexia nervosa, and vomitus nervosus. The writer cited in detail cases from his own practice. The paper evidenced careful and exhaustive study of his subject, with much clinical acumen as to objective findings and the various phenomena incident to his own cases. The sum and substance of his conclusions, based as they were necessarily upon the scanty knowledge and bewildering hypotheses as to the specialization of the nerve-supply to the stomach, resolved themselves into a tersely expressed opinion to the effect that the secretion of hydrochloric acid in the stomach must be governed by a special system of nerves which had a definite center of departure. Like other similar systems, these nerves appeared at times to become functionally deranged, when they performed their work with a reckless disregard of the comfort of their possessors.

**Primary Cancer of the Gall Bladder and Ducts.**—Dr. JOHN H. MUSSER, of Philadelphia, in his paper on the subject stated that he had arrived at the following conclusions in respect to this disease: 1. Primary cancer was not so rare a dis-

ease as we had been led to believe. 2. It occurred in females three times as often as in males. 3. The larger number of cases occurred before sixty, and it was not a disease of later life, as had been stated. 4. Gallstones were an exciting cause, especially in a person predisposed to this affection. 5. The organ was not generally much enlarged except occasionally by the secondary pressure of dilatation. 6. Metastasis was not widespread. It occurred by contiguity after involvement of neighboring organs. 7. Adhesions to adjacent organs and ulceration and perforation were not uncommon. 8. Pain, jaundice, emaciation, cachexia, and the presence of a tumor were observed in a large number of cases, while indigestion, vomiting, constipation, diarrhoea, and ascites were of more frequent occurrence than supposed, and were important associated phenomena by means of which the disease was recognized. 9. Pain in sixty-two per cent., at first hardly definite, became localized to the right hypochondrium, and was lancinating. 10. Jaundice appeared in sixty-nine per cent. of the cases, gradually increasing in intensity. 11. The progress of the disease was continuous to a fatal termination. 12. Complications were due to occlusion of the ducts, ulceration and perforation of the gall bladder, secondary growths in various organs, etc. 13. The duration of the disease was about six months, and two thirds shorter in its course generally than any other cancer of internal organs. 14. Death took place from exhaustion, biliary obstruction, metastasis, or peritonitis.

**How far may a Cow become Tuberculous before the Milk becomes Dangerous as a Food Supply?**—This was the title of a valuable and interesting paper contributed by Dr. H. C. ERNST, of Jamaica Plain, Mass. The author had been and still was engaged in the conduct of a long series of elaborately planned and accurately executed experiments upon cows for the purpose of truthfully formulating an answer to a question of vital import to this and all communities. Koch's theory had been that the danger was limited to milk coming from cows with tuberculosis of the lacteal tract. The speaker's conclusions, as the result of work done so far, which it would take still another year to amplify and complete, were as follows: 1. That the milk from cows affected with tuberculosis in any part of the body might contain the virus of the disease. 2. That the virus was present whether there was disease of the udder or not. 3. That there was no ground for the assertion that there must be a lesion of the udder before the milk could contain the infection of tuberculosis. 4. That, on the contrary, the bacilli of tuberculosis were present and active in a very large proportion of cases in the milk of cows affected with tuberculosis, but with no discoverable lesion of the udder.

Dr. H. F. FORMAN, of Philadelphia, read a paper on the **Anatomical and Physiological Relations of Lesions of the Heart and Kidneys.**

**The Frequency with which Lead is Found in the Urine.**—Dr. JAMES J. PUTNAM, of Boston, read a paper supplementing that on a similar subject last year. He said that the conclusions which his investigations seemed provisionally to justify were as follows:

1. That it was not probable that lead was to be detected in the urine of more than fifty per cent., at most, of persons not presenting symptoms of disease, and the finding of lead in a larger percentage for any special group of cases would be presumptive evidence that lead was connected, directly or indirectly, with the production of the symptoms.

2. That lead was an occasional cause of pure neurasthenic symptoms, and the presence of a fine muscular tremor strengthened the probability of this diagnosis.

3. That workers in rubber were liable to suffer from lead poisoning.

He then went on to state the results of observations and analyses, and illustrated his subject by microscopical sections depicting the morbid changes in the spinal cord consequent upon lead poisoning. He stated, however, that there was obviously a danger in seeking to account for pathological conditions of obscure origin that arose in the presence of an agent like lead. We might too readily, by including symptoms due to some other cause, obscure instead of illuminating the true clinical picture. The summing up of one of the author's cases typically exemplifying the theory that lead might act as an indirect cause of spinal sclerosis by causing general anaemia and exciting hypertrophy of small vessels ran thus:

A man in middle life, living under comfortable circumstances, suffered for two years with paresthesia, anaesthesia, and progressive muscular weakness, with focal symptoms. He had exaggerated knee-jerk, ankle clonus, and a moderate diminution of electrical reactions. These symptoms were associated with very marked paleness of the skin, which was of a light-yellow cast. General emaciation and weakness ensued, the whole increasing steadily and terminating in complete paraplegia, incontinence of urine, slight cerebral symptoms of a general character, and death apparently from exhaustion.

To explain all this, there were found anatomically, besides generalized anaemia, which the author was not in a position to refer to as a definite cause, a combined sclerosis of the posterior and lateral columns of the spinal cord, and, representing a later process, a sudden breaking down of the tissues at the seat of the older sclerosis; also, beyond the limits of these areas, more or less hyaline hypertrophy of the vessels, degeneration of the ganglion cells of all the groups in the middle of the lower dorsal region, diminishing in intensity above and below. There was also a marked degeneration of the posterior nerve roots of the dorsal and lumbar portions and, to a lesser extent, the anterior roots, and this process was not characterized by signs of acute inflammation, except, to some extent, at the level of the greatest active change. There were to be found also indications of some degeneration of the muscular and cutaneous nerves, though far less than would be expected had the whole process been primarily one of neuritis. The patient's occupation had exposed him to chronic lead poisoning, and lead had been twice found in his urine.

Dr. F. GERVAIS ROBINSON, of St. Louis, read a paper on **The Contagium of Diphtheria**.

**Hot-air Inhalations in Tuberculosis.**—A paper on this subject, contributed by E. L. TRUDEAU, of Saranac Lake, N. Y., aimed a telling and merciless blow at the recently vaunted and loudly heralded method of Weigert. The clinical evidence had brought no positive proof in favor of the treatment, and from the bacteriological research the following facts were noted:

In all the cases the bacilli which were present before treatment remained in the sputum, and no effect was produced on this important element of the disease. The allegation of diminished violence was tested by inoculations made on rabbits before, during, and after treatment. The sputum of one of the patients who improved was found, fifteen weeks after the uninterrupted daily breathing of hot air, to produce tuberculosis in the animals injected as promptly and to a similar extent as that injected before the treatment had been instituted.

**Conclusions.**—(1) The therapeutic value of hot-air inhalations in phthisis was doubtful; (2) the evidence obtained by the bacteriological study of the cases recorded did not confirm the assumption that inhalations of heated air could either prevent the growth of the tubercle bacillus in the lungs of living individuals or diminish the violence of this microbe when it had gained access to them.

**Election of Members.**—The following-named gentlemen were elected members: Dr. William G. Thompson, Dr. William H. Thomson, and Dr. J. West Roosevelt, of New York; Dr. Charles Carey and Dr. Charles G. Stockton, of Buffalo; Dr. Vietor C. Vaughan and Dr. Heneage Gibbes, of Ann Arbor, Mich.; Dr. Charles W. Purdy, of Chicago; Dr. Starling Loving, of Columbus, O.; Dr. W. H. Geddings, of Aiken, S. C.; Dr. William C. Dabney, of Charlottesville, Va.; Dr. B. F. Westbrook, of Brooklyn; and Dr. Henry P. Walcott, of Cambridge, Mass.

**Officers for the Ensuing Year.**—The following officers were elected: President, Dr. S. C. Busey, of Washington; first vice-president, Dr. William Pepper, of Philadelphia; second vice-president, Dr. Henry M. Lyman, of Chicago; recorder, Dr. I. Minis Hays, of Philadelphia; secretary, Dr. Henry Hun, of Albany; treasurer, Dr. W. W. Johnston, of Washington; member of council, Dr. G. Baumgarten, of St. Louis; representative on the Executive Committee of the Congress of American Physicians and Surgeons, Dr. William Pepper.

**The Next Annual Meeting.**—Dr. BUSEY asked that the date of the next meeting he fixed between the 30th of May and the 15th of June, 1890. This was agreed to and no more exact date was fixed.

## Book Notices.

*The Pathology, Clinical History, and Diagnosis of Affections of the Mediastinum other than those of the Heart and Aorta. With Tables giving the Clinical History of Five Hundred and Twenty Cases. Being an Essay to which was awarded the Fothergillian Medal of the Medical Society of London, March, 1888. By HOBART AMORY HARE, B. Sc., M. D., etc. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. 9 to 150.*

This is a very carefully prepared and valuable monograph, on a subject that has received but little attention. Affections of the mediastinum are among the rarest and most difficult to diagnose, and are confined, for the most part, to the neoplasms found in this region and to mediastinal suppuration. In this essay five hundred and twenty cases of mediastinal disease are tabulated under ten different heads, including mediastinal cancer, sarcoma, lymphoma, fibroma, haematoma, abscess, non-suppurative inflammation, dermoid cysts, hydatid cysts, and other various forms of mediastinal disease. Nearly half of all the cases come under the head of cancer or that of sarcoma; one hundred and fifteen are cases of mediastinal abscess, and the remainder are made up of small numbers of cases of various forms of disease. The pathology, aetiology, and symptomatology of the more common forms of disease found here are taken up separately, and the book concludes with a short summary embodying the most important deductions to be made from the study. These are: 1. That cancer is found in the mediastinal spaces more frequently than any other affection. 2. That abscess is the morbid process next in frequency of occurrence. 3. That sarcoma occupies the third position as to frequency. 4. That lymphomata occupy the fourth place, but are much rarer than the others mentioned. 5. That the anterior mediastinum is affected far more frequently than the two other spaces. 6. That most mediastinal growths occur in adults. 7. That more males than females are affected by mediastinal disease, be that disease what it may. 8. That cancer and sarcoma of these spaces are necessarily fatal. 9. That abscess is recovered from in about forty per cent. of the cases.

It seems probable that from these tables carcinoma appears to occur more frequently than is really the case, for in a large proportion of the cases reported in this monograph the diagnosis was not confirmed by microscopical examination. While there can, perhaps, be no doubt that primary cancer does occur in this region, still, it is equally certain that sarcoma or lymphoma is far more frequent than cancer. The characters of the tissue contained in the mediastinum are such as become most frequently the site of development of lymphomata or sarcomata and not of carcinomata.

The award of the Fothergillian medal for this essay is ample proof of the careful and scholarly character of the work. It will well repay a careful perusal.

*Transactions of the Royal Academy of Medicine in Ireland.*

Vol. VI. Edited by WILLIAM THOMSON, M. A., F. R. C. S., General Secretary, etc. Dublin: Fannin and Company, 1888. Pp. xxxv-482.

THIS volume, like those that have preceded it, contains a large number of exceedingly interesting and important papers, many of them profusely illustrated. Among those read in the Section in Surgery may be mentioned one on "Enterectomy and Enterorrhaphy," by Mr. J. S. McArdle, surgeon to St. Vincent's Hospital; a "Report of a Case of Epidural Haemorrhage with Secondary Trephining," by Mr. W. Thornley Stoker; and one on "The Treatment of Advanced Conditions of Equino-varus," by Mr. R. L. Swan. Among those read in the Section in Medicine, there is a paper on "The Fever of Over-exertion," by Dr. J. F. Knott, of more than usual interest, and also one by the same writer on "Hereditary in Purpura Haemorrhagica." There are reports of an interesting case of a rare form of mental disease, the *Gräbelsucht* of the Germans; gastric epilepsy; foreign body in the oesophagus; and traumatic aphasia. A careful article on "The Distribution of Enteric Fever in Dublin and its Causes" is contributed by Dr. J. W. Grimshaw and Sir Charles A. Cameron; and one on "Epidemic Dysentery and its Aetiology," by Mr. Conolly Norman. There are also some careful notes on "Anatomical Variations and Anomalies," and several interesting papers on obstetrical and gynaecological subjects. The illustrations are excellent, and the book has been thoroughly and carefully edited.

*Contribution à l'étude des corps étrangères des voies aériennes.*

Par le Dr. E. J. MOURE, Professeur libre de laryngologie, otologie et rhinologie, etc. (Communication faite à la Société de médecine et de chirurgie de Bordeaux.) Paris: Octave Doin, 1889. Pp. 5-24.

In this interesting study the author concludes that the use of sternutatories and emetics is inadvisable, sometimes favoring the deeper penetration of the foreign bodies into the air-passages; and considers that the popular treatment of suspending the sufferer by the heels, thus favoring the displacement of the object by gravity, is more desirable. In the latter procedure chloroforming the patient may be advantageous, to prevent laryngeal reflexes and consequent spasm of the glottis. He condemns blind groping in the larynx with the forceps or finger, as local anaesthesia with cocaine will allow of exploration with the laryngoscope. If the physician's hand is not sufficiently sure to seize bodies in the ventricles of Morgagni or between the vocal cords with a forceps, he advises tracheotomy rather than thyrotoxy. Of course, tracheotomy is advised for bodies that are below the larynx, in the trachea or bronchi.

For obvious reasons operative interference in such cases should not be delayed; and, if the body is not found at the operation, the cannula may provoke attacks of coughing and the body be easily expelled.

BOOKS AND PAMPHLETS RECEIVED.

Ophthalmology and Ophthalmoscopy for Practitioners and Students of Medicine. By Dr. Hermann Schmidt-Rimpler, Professor of Ophthalmology and Director of the Ophthalmological Clinic in Marburg. Translated from the Third German Revised Edition. Edited by D. B. St. John Roosa, M. D., LL. D., Professor of Diseases of the Eye and Ear in the New York Post-graduate Medical School, etc. One Hundred and Eighty-three Woodcuts and Three Colored Plates. New York: William Wood & Company, 1889. Pp. xv-3 to 571.

Outlines of the Clinical Chemistry of the Urine. By C. A. MacMunn, M. A., M. D. (Dub.). With Sixty-four Woodcuts and Plate of Spectra. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. xvi-254. [Price, \$3.]

A Manual of Minor Surgery and Bandaging, for the Use of House-Surgeons, Dressers, and Junior Practitioners. By Christopher Heath, F. R. C. S., Surgeon to University College Hospital and Holme Professor of Clinical Surgery in University College, London, etc. Ninth Edition. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. xvi-361. [Price, \$2.]

On the Healing of Aseptic Bone Cavities by Implantation of Antiseptic Decalcified Bone. By N. Senn, M. D., Ph. D., etc. [Reprinted from the "American Journal of the Medical Sciences."]

The Effect of the Entrance of Air into the Circulation. By H. A. Hare, M. D. [Reprinted from the "Therapeutic Gazette."]

The Disposal of the Dead. By John M. Peacocke, M. D., Brooklyn, N. Y. [Reprinted from the "Brooklyn Medical Journal."]

Rapid Dilatation of the Cervix Uteri. [Reprinted from the "Transactions of the Ninth International Medical Congress."]—Surgical Treatment for Laceration of the Perinæum and Pelvic Floor. [Reprinted from the "Transactions of the American Association of Obstetricians and Gynaecologists."]—A Successful Vaginal Hysterectomy for Carcinoma Uteri. [Reprinted from the "Transactions of the Southern Surgical and Gynaecological Society."]—The Pathology of Ectopic Pregnancy and Pelvic Haematocoele. [Reprinted from the "American Journal of Obstetrics and Diseases of Women and Children."] By W. H. Wathen, M. D., Louisville, Ky.

A Report upon Two Hundred Experimental Cases of Injection of the Brown-Séquard Testicular Secretion. By H. C. Brainerd, M. S., M. D., Cleveland, O.

Note on Some Forms of Purpura Rheumatica. By William A. Edwards, M. D., San Diego, Cal. [Reprinted from the "University Medical Magazine."]

Cirrhosis of the Pancreas; or, Pancreatic Anæmia. By C. W. Earle, M. D., Chicago, Ill. [Reprinted from the "Transactions of the Thirty-fourth Annual Meeting of the Illinois State Medical Society."]

The Responsibilities and Duties of the Medical Profession regarding Alcoholic and Opium Inebriety. Address of President C. W. Earle, delivered at the Thirty-ninth Annual Meeting of the Illinois State Medical Society, May 21, 1889.

The Treatment (not Preventive) of Puerperal Fever. By C. W. Earle, M. D., Chicago. [Reprinted from the "Chicago Medical Journal and Examiner."]

Cephaloëmatoma of the New-born. By C. W. Earle, M. D., Chicago. [Reprinted from the "Journal of the American Medical Association."]

Retained Débris as One of the Causes of Puerperal Fever. The Intra-uterine Douche and Curette. By C. W. Earle, M. D., Chicago. (Read before the Chicago Gynaecological Society.)

Antiseptic Obstetrics. By C. W. Earle, M. D., Chicago. [Reprinted from the "Transactions of the Thirty-seventh Annual Meeting of the Illinois State Medical Society."]

The Influence of Sewerage and Water Pollution on the Prevalence and Severity of Diphtheria. By C. W. Earle, M. D., Chicago. [Reprinted from the "Archives of Pediatrics."]

Observations in Vienna. The General Hospital, Billroth, Carl Braun, Bandl, and Others. By C. W. Earle, A. M., M. D. [Reprinted from the "Western Medical Reporter."]

Infant Feeding. By C. W. Earle, M. D., Chicago. [Reprinted from the "Journal of the American Medical Association."]

Lavori dei congressi di medicina interna. Primo congresso tenuto

in Roma nell' Ottobre 1888. Pubblicazione fatta per mandato del comitato ordinatore del Professore Edoardo Maragliano, Ordinario di clinica medica nella R. Università di Genova.

eczema usually began on the second day, taking its origin at the site of the wound and being accompanied by rise of temperature of the skin, swelling of the neighboring lymphatics, loss of appetite, headache, and vomiting. The solution used was 1 to 1,000. Examination of the urine showed that it contained phenol.

**Formula for Iodol Preparations.**—The following are given ("Mntshft. f. p. Dermat," 1889, No. 9): 1. A solution: Iodol, 1 part; alcohol, 16 parts; and glycerin, 34 parts. 2. Iodol gauze: Iodol, resin, and glycerin, each 1 part; alcohol, 10 parts. 3. Collodion with iodol: Iodol, 10 parts; alcohol (94 per cent.), 16 parts; ether, 64 parts; pyroxylin, 4 parts; castor-oil, 6 parts.

**A New Ointment Base** is proposed by Wells ("Pharm. Post," abst. "Montshft. f. p. Dermat," 1889, No. 9) and is made by melting three pounds of fresh goose fat in an enameled pan, passing it through muslin, and stirring into the mass while still warm half a pound of cacao butter. The mass is to be stirred with a wooden spoon till cool. It is asserted that this ointment is very readily absorbed.

**A "Minimal Cautery."**—One of the happy accidents that so often suggest useful inventions has recently befallen Dr. P. Taenzer, who stumbled ("Monatshft. f. p. Dermat," 1889, viii, 401, No. 9) upon the fact that by touching the needle attached to the negative pole of the battery and inserted into a hair follicle, with the opposite pole, the hair would be permanently destroyed. Here the action is not electrolytic but rather galvano-caustic, but so indirect and mild as to cause minimal damage to the skin, producing a scarcely perceptible scar. This put the doctor upon the idea of making a cautery to which he gave the name of "*Minimalbrenner*." It is made as follows: A piece of medium-sized copper wire about three inches long is fastened into the end of a glass rod about ten inches long by melting the glass. Its free end is then sharpened as fine as possible by filing, and about it is wrapped a fine platinum thread in spiral turns, beginning about half an inch from the point and ending about an inch and a quarter from the end of the glass rod. Both ends of the platinum wire are fastened to the conductors from the battery. The conductors are then bound down to the sides of the glass rod. The current passing through the instrument will cause the platinum thread to glow, and the copper needle will become very hot but not glowing, causing a minimal amount of cauterization. The instrument is used by making multiple punctures, and the operation is well borne. The proper degree of heat is shown by the instrument being easily withdrawn after the puncture. It is useful for a great many purposes, as for the treatment of nævus, lupus erythematous, and the like.

**Hydroxylamine in Psoriasis.**—Fabry, an assistant physician in Doutelepont's wards in Bonn, repeats ("Arch. f. Dermat. u. Syph," 1889, xxi, Heft 2, p. 203) the warning as to the poisonous qualities of this comparatively new drug, but thinks that its use upon the skin is quite safe under proper precautions. In psoriasis he thinks that its absorption is least to be feared. In the treatment of this disease he used either a spirituous solution (B Hydroxylamine, gr. vj-vij; alcohol, ʒ iij; calcium carbonate, enough to neutralize) or an aqueous solution (one part to one thousand, with enough calcium carbonate to neutralize). The first solution is to be used with a brush, and the second is to be applied on wet cloths. Before using either preparation the scales are first to be gotten rid of by prolonged baths, rubbing with green soap, and inunctions of ten-per-cent. zinc ointment. As a rule, pyrogallol or chrysarobin was used on one half of the body to make a comparative test of the newer remedy, as used upon the other half. For a few days after the first application of the remedy there was marked increased redness of the spots and surroundings. Soon, however, there was a paling of the spots, then only pigmentation, then an absolutely normal condition of the skin. When a ten-per-cent. solution of the remedy was used, the epidermis was raised in large lamella, and flat bullæ, containing a small amount of serum, appeared, which soon dried up. The normal skin showed the same phenomena. Hydroxylamine proves itself to be a very irritating substance, its irritant action varying with different skins. It is necessary in some cases to use a solution not stronger than one to five hundred and increase strength p. r. n. The drug produces great burning and pain in some individuals, so that its use has to be stopped. The paintings are to be repeated twice a day; the compresses to be renewed every two hours, and only applied to small areas at a time. The urine

## Reports on the Progress of Medicine.

### CUTANEOUS AND VENEREAL DISEASES.

BY GEORGE THOMAS JACKSON, M. D.

**Concerning some New Dermatological Remedies.**—Salol, oxynaphthoic acid, salicylate of mercury, and anthrarobin are the new remedies which Schwimmer reports upon ("Wien. med. Wochnshft., 1889, Nos. 3 et seq.). Salol he used in one hundred cases. Twenty-five of these were simple venereal ulcers, of which twenty-three were healed and two were not. The average duration of treatment of those that got well was twenty-six days, the longest duration having been fifty days, and the shortest twenty-six days. Fifteen cases were of chancroids with bubo. The results were various, some easing doing well and some being uninfluenced, the latter being those in which suppuration was profuse. Thirty-five initial lesions were treated with the drug. In some cases remarkably prompt healing was effected, the normal condition being reached in two to three weeks. He found that the best results were attained by powdering the floor of the ulcer with salol and covering the edges with mercurial plaster. In ten cases of ulcerating syphilides the drug was found to be useful applied in powder. In fifteen cases of simple ulcer of the leg, salol failed to cure one. Schwimmer concludes from these experiments that salol may be used as a substitute for iodiform, though not so efficacious in all forms of venereal ulcers, especially as it is devoid of smell. It is best applied as a powder—two parts to one of starch. Oxynaphthoic acid is a white, odorless powder of bitter taste which is insoluble in water, but freely soluble in warm glycerin and ethereal and fatty oils. This was tried in venereal ulcers, scabies and other animal parasitic affections, and prurigo. In ten cases of venereal ulcers the results were unsatisfactory. In scabies its action was so prompt that Schwimmer now uses it as his only remedy, employing an ointment of ten parts each of oxynaphthoic acid, white chalk, and green soap to eighty or one hundred parts of lard. It causes no irritation to the skin, and cures in three or four days. No constitutional effect was noticed. The ointment is rubbed into the affected parts and then starch is powdered on. This is repeated twice daily, and a bath is taken at the end of the fourth day. In prurigo it lessened the itching, and healed the exorciations in a five- or ten-percent. ointment. The salicylate of mercury was used as an injection of one one hundredth of one per cent. strength in twenty-five cases of gonorrhœa, but was not satisfactory. In venereal ulcers it was used as an ointment in the strength of about two grains to the ounce, with fairly satisfactory results. It was tried in seventy cases of constitutional syphilis, and showed itself as a valuable remedy. It soon enters into the circulation and is prone to cause stomatitis. It was administered both as a powder and pill, and in the following combinations: B Salicylate of mercury, 7½ grains; tincture of opium, 1½ drop; white sugar, 45 grains. To be mixed and divided into ten powders; one to be given twice a day. B Salicylate of mercury, 15 grains; tincture of opium, 3 drops; extract of gentian, a sufficient quantity. To be mixed and divided into twenty pills; one to be given two or three times a day. Besides causing stomatitis, it also may give rise to erythema and urticaria. Anthrarobin was used in twelve cases of psoriasis, four of herpes tonsurans, six of eczema marginatum, and two of pityriasis versicolor. In psoriasis it was found of little use, being much less active than chrysarobin, pyrogallol, or white precipitate. In the parasitic diseases it acts promptly in a ten-per-cent. solution in collodion.

**Creolin Eczema.**—Dr. Wackez, of Munich, has given this much-praised remedy a trial in seventeen cases of slight wounds of children, and reports ("Therapeutische Monatshft., June, 1889, p. 264) that in ten cases the wounds healed by first intention, while in seven cases there was an outbreak of eczema soon after beginning its use. The

is to be watched for the appearance in it of albumin, and symptoms of poisoning carefully noted. Relapses occur after its use just the same as after all other remedies. The advantages of hydroxylamine are that it does not irritate the skin as much as pyrogallol or chrysarobin, that it is cheap, that it does not stain the under-clothing, and that it is quite as rapid in its curative effects as the drugs just named. It took from four to six weeks to remove all traces of the disease in an inveterate case. It should always be remembered that, should symptoms of irritation show themselves, the remedy must be stopped, and some soothing application made until the irritation is reduced, when the remedy may be resumed.

**"Dermatoneuroses Indicatrices."**—By this term Leloir means ("Ann. derm. et syph." 1889, x, No. 5) that a number of eruptions depend upon nervous diseases, and appear as forerunners of grave manifestations on the part of the nervous system. They may be indicative of affections of the spinal medulla, or of cerebral affections, or of the peripheral nervous system. They may take the form of erythematous or oedematous lesions, or of haemorrhages, or of papules and vesicles like an outbreak of eczema, or bullous eruptions, zoster-like or ulcerative lesions, or hypertrophic or atrophic, or pigmentary. Examples of many of these lesions having appeared for a greater or lesser length of time before the appearance of other nervous phenomena are given. Remembering this, in many cases we may well neglect to treat the skin and address ourselves directly to the nervous system.

**Alopecia Neurotica** is that form of baldness which occurs in a most irregular manner, sometimes unilateral, sometimes in circumscribed, variously shaped and sized areas which shade off into the surrounding parts. It occurs after cerebral disturbances, injuries to peripheral nerves, psychoses, neuroses, atrophies, or other trophic disturbances. Sometimes the bald tracts follow the well-known course of a nerve. Schütz now reports ("Münch. med. Wochenschr.", 1889, xxxvi, 124) six cases of this disease. Of these, one patient was wounded in the back of the head with a barber's shears, the injury being shortly followed by hair-fall. The second received a fall upon the right forehead, followed by unconsciousness. Two weeks after the injury the hair fell from the right side of the head in streaks. Treatment: Galvanism, salt-water baths, washing the head twice daily with spiritus saponis kalinus, followed by rubbing in an ointment of veratrine (one to fifteen). The hair did not grow in for nearly three years. The third had no history of injury. The fourth case was limited to one side of the head, and occurred with attacks of phlyctenular conjunctivitis. In the fifth case both the scalp and chin were affected. The patient was a nervous and hypochondriacal man, and had a good deal of headache and burning of the scalp and chin. The sixth case was a symmetrical one of the beard, with a great deal of itching. All but two of the patients were boys, and all were weak and nervous. The reaction of the skin of the affected areas was normal. In most of the cases the bald space was linear in shape, enlarging especially on its peripheral end, forming a three-cornered figure.

**Rejuvenescence of the Hair of the Head and Beard.**—A case of this rare occurrence is reported ("Lancet," July 20, 1889, p. 113) by Dr. O'Neil, the subject being a man sixty-five years of age, who was under the author's care for paralysis and accompanying cerebral disturbance. He had been both bald and gray for many years, when during his sixty-second year his hair began to grow in the bald places, and brown hair began to replace the gray. At last his hair had regained its youthful fullness and color. He had been addicted to the use of chlorodyne for some six months previous to the regeneration of the hair, and he and his friends ascribed the hair growth to the excessive use of the drug.

**The Treatment of Hypertrichosis**, as recommended by Jamison, of London ("The Practitioner," 1889, xlvi, 1), consists in the free use of ethylate of sodium. It seems specially applicable to large, hairy naevi. The case reported was that of a child first operated on at three months of age, and several years were employed in the treatment. After five years the case is reported as cured and without disfigurement. It was a hairy mole of the whole of the right side of the forehead. The operation was done under chloroform.

**Trichomyces Nodosa a Bacillary Disease of the Hair.**—This disease is, according to R. G. Patteson ("Brit. Med. Jour.", 1889, i, 1166), "a peculiar condition, generally nodose in character, affecting the hairs

of the axilla and scrotum, and due to the growth and encapsulation in the cortical layers of the shaft of a small rod-shaped bacterium." The author thinks that the disease may take on different appearances at times, such differences depending upon varying and individual conditions of heat and moisture and personal habits of life. It is probably the same disease that Paxton described in 1869, and that Wilson called "leptothrax" in 1878. It has been confounded with trichorrhexis nodosa. Eberth, in Virchow's "Archiv," Bd. lxii, p. 504, was the first even to approximate to a correct description of the bacteria causing the disease. It is due to a short rod bacterium, the colonies of which, lying between the superficial cortical layers and enveloping themselves in a firm, homogeneous capsule, cause respectively the splitting of the fibers, and the nodes and surface irregularities which are so characteristic of the disease. To the naked eye the hairs present an abnormally dry and dull appearance. They feel rough and knotted. They look as if they had been steamed. The roughness is due to the projection from the sides of the shaft of numerous very minute concretions, which may assume a nodular or diffuse form. The diffuse form may extend along nearly the whole length of the shaft, with narrow intervals of sound hair. The nodular form consists of small rounded masses, generally most thickly placed on the terminal third of the shaft, and usually separated by considerable intervals of sound hair. Both forms may be present on the same hair. They are firmly adherent, and can only be scraped off with injury to the hair. The hairs are not brittle, have little tendency to break at the nodes, and, as a rule, end in fine points beyond the disease. Occasionally they do break through a node, and the end splits up into fibers. It may affect any part of the hair. Nodes are seldom found except on the peripheral part of the hair. If the disease travels up toward the bulb it assumes the diffuse form. It never penetrates the follicle. The bacilli are deposited from without on the ends of the hair and travel up until they find a fit habitat, when they begin their attack and form aggregations or nodes. At the junction of the outer and middle thirds of the hair the nodes are separated at longer intervals, or may become diffuse, gradually disappearing as the follicle is reached. The development of the bacilli can best be studied at the part nearest the follicle. The maceration caused by the warmth and moisture of the affected parts loosens the epidermal scales of the hair and allows of entrance of the bacilli. These lie at first in small pits or depressions, and, as they develop, cause by their growth a longitudinal splitting of the cortical fibers, and finally a rupture and curling up of the terminal ends. At the same time a hard, homogeneous, granular substance is produced, which lies between and around the bacteria, and forms the nodes into which the curled ends of the ruptured fibers can be seen projecting. This substance serves as a splint and prevents fracture. It is exactly similar to the substance produced by lice, is of a pale-yellow color, and stains a deep brown with iodine and a dark purple with methyl-violet. The nodular form is rarely seen on the scrotum, where it is not uncommon to have no outstanding masses, but a superficial burrowing of the shaft by the bacilli. In some cases the concretions are placed laterally. The bacilli are short, fine rods with slightly rounded ends, two or three times as long as broad, and about one fourth the diameter of a red blood-corpuscle. They stain readily with aniline dyes, but best by Gram's method. They are non-motile, exhibiting only molecular movement. They are sometimes joined together, but do not form long threads. They are not culturable by ordinary methods.

**The Favus Fungus.**—Some two years ago Quincke detailed his experiments in the cultivation of the favus fungus, and showed that there were three species, which he named  $\alpha$ ,  $\beta$ ,  $\gamma$  fungi. These results have been reported in our columns. Now Elsenberg, of Warsaw, details ("Archiv f. Derm. u. Syph." 1889, xxi, Heft 2, p. 179) his experiments in the same direction, and comes to the conclusion that, though there are seemingly two varieties of the favus fungus, they are in reality one and the same fungus.

**Treatment of Chloasma.**—Besnier affirms ("Jour. de méd." Paris 1889, May, p. 202) that chloasma can be made to disappear by the following treatment: The part is to be scrubbed with green soap until it is somewhat reddened. Then equal parts of mercurial ointment and vaseline are to be worn all night spread on muslin and covered with rubber cloth. This is to be washed off with warm water in the morn-

ing, and during the day an ointment composed of carbonate of bismuth and kaolin, each 3 ij, and vaseline, 3 j, is to be worn.

**The Histology of Rhinoscleroma** is put forth at much length by Dr. V. Mibelli in the "Mouatshefte f. prakt. Dermatologie," 1889, vol. viii, No. 12. The study was made upon material obtained from a patient of the doctor's, an Italiāu. He found the most pronounced alterations in rhinoscleroma, represented by an unusually soft, almost fluid tissue, which was the most characteristic material found in the disease. This is not found everywhere, but mostly deep down in the coverings of the nose next to the cartilage. About it is always placed a more or less indurated cutaneous tissue, and it is the hardness of this which gives us the clinical idea of the disease. Little islands of this soft substance being scattered through the whole diseased parts, gives us a very varying picture when seen on section. The skin follicles are sometimes destroyed, sometimes intact and normal. The sweat-glands are generally wanting, though their ducts may be found either intact, or widened, or with their walls thickened. The blood-vessels have about their walls and within them an infiltration of round cells, but these are usually normal in appearance. In some places the lumen of the vessels is narrowed, and in some entirely obliterated, while in others there is well-marked endarteritis obliterans. The lymphatics are greatly dilated. It would seem that the skin and the outer parts of the nasal mucous membrane become only secondarily and very gradually diseased from the deeper-lying parts. The characteristic cells of rhinoscleroma are uniformly round, strongly refractive to light, and contain a coarsely granulated, sharply contoured protoplasm, and a large oval or round, light-colored nucleus. In the neighborhood of these cells are often seen larger round cells, with clear, finely granulated, irregularly contoured protoplasm, and with a less bright nucleus. Rhinoscleroma bacilli (enveloped in a capsule) are found in this protoplasm. It is probable that the damage caused by the bacilli in this disease is due far more to their mere presence and growth than to any poisonous products generated by them. [This article contains much of interest to the histologist, but, unhappily, does not lend itself easily to the purposes of the abstractor.]

**The Treatment of Lupus**, as now practiced in Hamburg, is, according to Clasen ("Monatshft. f. prakt. Dermatologie," 1889, Bd. viii, No. 11), the following: The Paquelin cautery is first used to destroy the lupus tissue, the patient being under chloroform. Upon the fresh tissue surface is penciled or rubbed a solution of corrosive sublimate, gr. 25; carbolic acid, 3 jss.; and ether, 3 j. M. Then a plaster muslin is applied, either of salicylic acid, five drachms, and birch creasote, ten drachms to the yard, or of salicylic acid, five drachms, guaiacol, two drachms and a half to the ounce, the plaster being cut a little larger than the surface to which it is to be applied. The whole is covered with a zinc paste and a bandage. The dressing is changed every twenty-four hours, the surface of the wound being washed off and penciled with cocaine, and suspicious points bored out before the plaster is reapplied. A cure is effected in two or three weeks. For the plaster-muslin may be substituted an ointment of twenty parts of salicylic acid and forty parts each of creasote and cerate, which is to be spread upon doubled muslin and covered with a solution of gutta percha. Where it is impracticable to use any energetic treatment, the cure can be effected by the use of the salicyl-creasote ointment during the night, and by painting with an eighty-per-cent. solution of silicate of potassium in linseed-oil during the day. If the lupus patch is very much inflamed, it should be painted with a watery solution of ichthylol during the night, and simply anointed with the ointment during the day.

**Acquired Leprosy as seen in England.**—Hutchinson believes ("Brit. Med. Jour.," June 29, 1889, *et seq.*) that the poison of leprosy is a specific one, and that the disease is acquired, not by contagion, or climate, or quality of food, but by the ingestion of "some very special kind of poison of rare occurrence taken in connection with food." The bacillus of Hansen may possibly be the bearer of the poison. He would direct subsequent investigations to the food question and the special poison therein residing. The disease may be arrested by change of climate to a region where it is not endemic. Some twelve cases of leprosy are cited to show that the eating of fish plays an important part in the dietary of leprous patients. They had all acquired the disease in countries in which leprosy was endemic.

**A Case of Leprosy apparently arrested** is reported by Cottle ("Brit. Med. Jour.," July 6, 1889, p. 12). The subject had resided for twenty-four years in Jamaica, and the disease appeared some seven months after his return to England. The treatment used was chaulmoogra-oil, in doses of from twenty to ninety minims three times a day. Improvement began under doses of sixty minims t. i. d., and in about one year he had hardly any symptom of his disease. The oil was taken continuously for nearly ten years, and the patient is still under observation with no return of his disease.

**The Cure of a Case of Leprosy** is reported by Dr. Sandreczky, of Jerusalem, in the "Monatshft. f. prakt. Dermatologie," 1889, No. 11. It was that of a child of eight years, in whose family and connections leprosy had never occurred. He was under treatment for four years, and it was directed upon general principles, such as fresh air and exercise, massage, iron and quinine; bathing with green soap, sulphur, iron, or salt, the water being very hot and the bath being followed by free sweating under proper covering. The tubercles were treated with chrysarobin, green soap, or iodine without any effect. After two years of general treatment marked improvement showed itself. There has been no relapse, and all signs of the disease have disappeared excepting the atrophy of the hands, which is, of course, permanent. The doctor does not believe that the disease is contagious, and says that that is the view held by the inhabitants of the country.

**The Chrome-Water Treatment of Syphilis.**—Dr. Güntz, of Dresden, again brings to the notice of the medical profession the virtues of this, his method, of treating syphilis ("Allgemein. Wieg. Med.-Zeit.," 1889, No. 14 *et seq.*). The impossibility of finding any universal remedy for the disease is granted, and then the oft-repeated failure of mercury to accomplish a cure is fully dwelt upon, while it is not denied that often it does excellently well. But, alas! it sometimes is in itself responsible for the death of the patient! This it does by causing a disintegration of the tissues. Against this chrome-water works, and, when used with discretion, it will save from death many a person with malignant syphilis. Chrome-water gives the patient a blooming appearance, in marked contrast to the "cheesy" look of him who imbibes mercury. The weight of the patient is reduced, but when its use is combined with that of salt-water baths, extreme thinness is not attained. Never does "that dangerous fatty degeneration" take place that is so often seen with quicksilver after many months or years of small doses. While eighty-two per cent. of the patients treated with mercury suffer from relapses, chrome-water is often abortive in the stage of the initial lesion. It is always efficient. Under its use syphilitic parents beget sound children. You can get this wonder-working water of a certain apothecary in Dresden, and there, too, you may find its enthusiastic inventor.

**A Study of Syphilis contracted at Advanced Age** has been made by Renault ("Ann. de derm. et syph.," 1889, No. 3, p. 165). The subjects were individuals forty-five years old or over, and the number of them is comparatively small. The period of incubation of the chancre is probably somewhat longer than in younger subjects. The accompanying adenitis is somewhat slower to appear, say from the twentieth day to the seventh week. The initial lesion is likewise slower in its development and remarkably hard. It takes six or seven weeks to heal, or about one third longer than in the younger man. It also shows a decided tendency to enlarge and become phagedenic, and may even become gangrenous. Its diagnosis is often difficult, especially from cancer when located upon the face, and then we must await further developments. The syphilitic fever is often well marked and of typhoid character, or it may simulate an attack of acute rheumatism. The diagnosis is difficult and we must await further manifestations. The relative time of outbreak of the secondary eruptions is not well determined, but probably the interval between the initial lesion and the eruption is longer than in earlier life. The roseola is usually slight and sometimes limited to certain regions, so as to be readily overlooked. The squamous syphilide is very rare. The papulo-tubercular syphilide appears early. The papulo-squamous syphilide is often so covered with scales that it has the appearance of psoriasis. It is also obstinate to treatment, prone to relapse, and at times is followed by purpuric spots. Tertiary lesions appear early in many cases. Mucous patches tend to ulcerate. Multiple adenopathies are the rule. Gummy tumors are frequent, ulcerate somewhat, and heal slowly. Neuroses are common and

appear early. Deafness and ocular disorders are more common than in earlier years, and set in early. Anæmia is marked, as is also cachexia. There is hardly any intermediate stage between the so-called secondary and tertiary periods. The most frequent tertiary manifestations are the tuberculo-ulcerous syphilitide and the purely ulcerative. They are characterized by—1. Confluence, tending to invade the whole surface of the body at the same time. 2. Their appearance and changes. They are habitually covered with crusts, and tend, according to some observers, to take on a cancerous change in certain locations. 3. Gravity. The ulcers tend to become large and deep. They become phagedenic or gangrenous, and often lay bare the muscles. 4. Tenacity. They are extremely rebellious to treatment. Indeed, the prognosis of syphilis contracted at an advanced age is bad, and should make the physician use all his skill. This depends upon the fact that old age is naturally the time when retrogressive changes take place and vitality is lowered. Our treatment of these cases should be directed against both the virus and the debility incident to age. Tonics should be given along with the mercurial and iodine, and it is usually best to combine the iodide of potassium with the mercury. Unhappily, mercury in these cases is very liable to provoke salivation, stomatitis, and diarrhoea, and its use must be stopped on their appearance. On account of the tendency to diarrhoea it is desirable to use an astringent with the mercury.

## Miscellany.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the abstract of sanitary reports received by him during the week ending October 4th :

CITIES.	Week ending—	Estimated population,	Total deaths from all causes.	DEATHS FROM—								
				Cholera.	Yellow fever.	Small-pox.	Varioloid.	Variola.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.
New York, N. Y.	Sept. 28.	1,582,975	641	...	7	3	17	1	12	...	...	...
Philadelphia, Pa.	Sept. 28.	1,040,245	312	...	15	2	3	...	2	...	...	...

**Creolin Injections in Dysentery.**—“Dr. Sosovski has found large enemas of dilute creolin very useful in dysentery. He employed a one-half-per-cent. solution injected into the bowel twice or sometimes three or four times daily, the quantity used for each enema being generally about five pints. The patients did not experience any burning

sensation or abdominal pain. The treatment was employed in sixteen cases, not one of which proved fatal, although a considerable number of patients succumbed to the disease during the same epidemic. In two cases the disease was arrested after the second enema, in nine cases the bloody stools ceased on the third day, in two cases on the fifth day, in one on the sixth, and in one on the ninth. The remaining case, though more obstinate, ultimately recovered completely. In addition to these, two children under a year old were treated successfully by means of creolin enemas. Again, another Russian physician, Dr. Kolkoloff, has used a one-per-cent. solution in a number of cases of adults with complete success.”—*Lancet.*

## ANSWERS TO CORRESPONDENTS.

No. 291.—Those by Chambers and Fothergill.

No. 292.—Its publication seems to have been suspended.

No. 293.—The manœuvre of bringing the shaft of the instrument away from the groin and carrying it up over the linea alba.

No. 294.—Cases have been reported in which the period of incubation seemed to have been less than twenty-four hours.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of “original contributions” are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters’ hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer’s name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author’s name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies’ regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

## Original Communications.

## TUBAL PREGNANCY.\*

By WILLIAM T. LUSK, M. D.

**CASE I. Tubal Pregnancy; Rupture; Laparotomy; Recovery.**—On the 19th of November, 1888, I was summoned in haste to the bedside of Mrs. S., nineteen years of age, who was suffering from shock and intense anaemia.

Of her history I learned that she had been three years married, and that a year previous she had given birth to a dead child at term. Since her confinement she had suffered from profuse leucorrhœa and pain in the right inguinal region. The patient had passed two menstrual periods, but had had no subjective symptoms of pregnancy. On the 10th of November she noticed a sero-sanguinolent discharge from the vagina. On the 11th she was seized with cramps associated with faintness, with nausea, and at times with vomiting. There was no intestinal disturbance to which the abdominal pains could be referred. Similar attacks, but of less intensity, occurred daily, usually in the morning hour, up to the 18th inst. On that date the pains had been unusually severe, when suddenly Mrs. S. became exsanguinated, and syncope ensued, which lasted about twenty minutes. On recovering consciousness she felt chilly and restless, with constant nausea and vomiting.

At Dr. Janeway's suggestion, on the evening of the 19th inst. I was sent for by Dr. Agan, the family physician. As I have stated, I found the patient excessively anaemic; vomiting was constant; pulse was 140; the abdominal pains had ceased. On vaginal examination, the uterus was found to be pressed somewhat to the left. To the sides and posterior to the uterus irregular masses of a soft consistency could be felt, which obscured the palpation of the uterine appendages.

The diagnosis was ruptured tubal pregnancy with intra-peritoneal haemorrhage, a diagnosis which was further confirmed by the expulsion of a decidual membrane on the 20th inst. Laparotomy was recommended, and the next day, in spite of the patient's feeble condition, she was conveyed by ambulance to St. Vincent's Hospital. She arrived in a state of prostration, which seemed to afford little hope of a rally. During the night Dr. Mitchell, the house physician, watched at her bedside and administered hourly an ounce of whisky and five drops of tincture of digitalis every two hours. By eight in the morning the patient's condition had greatly improved. Her pulse had fallen to 100 and possessed more volume.

At 10 A. M. the patient was carried to the operating-room. Operation was performed under ether with the usual antiseptic precautions. When the peritoneum was incised a stream of dark fluid blood, probably not less than two quarts in quantity, gushed out. On introducing the hand, I found the pelvic cavity filled with clots, which were carefully removed. The tube on the left side was enlarged near the fimbriated extremity. On lifting it out of the abdomen the hemorrhage was seen to proceed from a sac in the broad ligament, which had ruptured into the peritoneal cavity. A strong silk ligature (Staffordshire knot) was made to include the tube, sac, and ovary on the left side. The ligatured mass was removed by the thermo-cautery, and the pedicle dropped. The right tube and ovary appeared perfectly healthy. The abdominal cavity was then irrigated with Thiersch's solution, was rapidly sponged, and a large

drainage tube was introduced. The usual antiseptic dressings were employed. The operation lasted about forty-five minutes. By noon the patient had rallied and expressed herself as feeling perfectly comfortable. In the afternoon, while vomiting, so large an amount of bloody fluid was forced from the drainage tube that at first it was feared a fresh bleeding had taken place. It was noticed, however, that, as regarded her general condition, the patient was progressively improving; so it was decided to await events in place of reopening the abdomen. The next morning the quantity of fluid removed from the tube at each change of dressings had fallen to a drachm or two, and was more serous in character. However, it was four days before all color had disappeared and the tube was finally removed.

It is to be assumed that the bloody discharge was due to imperfect siphoning of fluid from the abdomen after irrigation, and not to an after-haemorrhage. The sudden expulsion of the retained fluid during the act of vomiting was, I believe, a lucky accident, which contributed to smooth the path of convalescence.

In the afternoon of the first and in that of the second day the temperature rose to 101° F., with a pulse of 116; with these exceptions, the temperature remained below 100°. The pulse for a few days at times was in the neighborhood of 100 (generally less). At the end of the week it possessed about the normal frequency.

At 2.30 P. M. of the day of operation a teaspoonful of strong tea was given to the patient by mouth every ten minutes, and one quarter of a teaspoonful of brandy every twenty minutes. By rectum, brandy  $\frac{3}{4}$  j. tr. opii gtt. xv. aq.  $\frac{3}{4}$  iij, was given every four hours. (The patient had no pain. The opium was given solely on account of the cerebral anaemia, and was discontinued at the end of twenty-four hours.)

After the effects of the ether wore off all vomiting ceased. The patient was thirsty and took carbonated waters freely by the mouth. On the third day she took two ounces of brandy and two ounces of milk every two hours in addition to the rectal enemata. On the fourth day toast, boiled rice, eggs, coffee, and tea were given, and were eaten with relish. Convalescence was uninterrupted. The patient slept well; all the natural functions were normally performed, and she rapidly regained color. On December 4th the patient was permitted to sit up in a chair. On December 17th the external wound and the sinus resulting from the tube had entirely healed, and the patient returned to her home. A month later she was able to go to a ball and dance all the evening with enjoyment. Her health since the operation has been better than at any time previous in her life.

The illustration herewith presented represents a longitudinal section through the specimen after it had been subjected to a hardening process by Dr. Dunham, of the Carnegie Laboratory. A certain amount of shrinkage has taken place, so that the specimen is perhaps not more than three fourths its original size. The embryo corresponds to about the sixth week. A clot surrounds the walls of the ovum, and above has so far thinned the tubal walls that it appears to be covered by peritoneum only. Rupture, however, had taken place below. At first a haematoma had formed between the folds of the broad ligament. The distension caused by the effused blood had converted the posterior layer at the point of pressure into a sac in which at the

\* Read before the New York State Medical Association, September 25, 1889.

time of operation an opening was found of about the size of a man's thumb. The clots in this sac were much softer than that which surrounded the ovum.

stated that she had menstruated last about six weeks previous, and had supposed herself pregnant. The undoubted occurrence of intraperitoneal haemorrhage led to the strong suspicion of ruptured tubal pregnancy. There had been, however, no antecedent symptoms—*i. e.*, no colicky pains, no sero-sanguinolent discharge, no expulsion of decidua. The presence of clots in the pelvis obscured the palpation of the pelvic organs. Still Dr. Janeway and Dr. McSweeney and myself believed that we could recognize an enlargement of about the size of an egg in the course of the left tube.

On the morning of June 2d the patient was conveyed by ambulance to St. Vincent's hospital. Stimulants were freely administered. Lapar-

otomy was performed in the afternoon. Unfortunately, no formal notes were taken at the time, but the history of the operation was a repetition of that of the case already given. The abdominal cavity contained a large amount of fluid blood, the pelvis was filled with clots, and the tube on the left side was found ruptured on its posterior surface above the folds of the broad ligament. The rupture was caused by an ovum which presumably had attained four weeks of development. Through the rent the villi were beautifully apparent.

FIG. 1.

If we attempt to follow the sequence of events in this case it would appear that haemorrhage into the tube occurred first, and corresponded to the symptoms experienced on the 11th of November, when the patient suffered from cramps, faintness, and nausea. The thinning of the tubal walls was such that the non-occurrence of intraperitoneal rupture at that time was almost in the nature of a miracle. Possibly the timely formation of the clot served as a protection. If the rupture of the tube was coincident with the occurrence of the first haemorrhage, the separation of the folds of the broad ligament and the formation of the pouch probably took place gradually. Until the 18th inst. the patient experienced cramp-like pains, but she kept her color and had no symptoms that made her feel apprehensive. The sudden anaemia and prolonged unconsciousness at that date marked the rupture of the sac and the pouring of the blood into the peritoneal cavity. Subsequently the feeble heart action and the formation of clots in the pelvis doubtless served as a temporary check to the bleeding from the opened vessels.

**CASE II. Tubal Pregnancy; Rupture; Laparotomy; Death from Bright's Disease on the Eighth Day.**—Mrs. K., aged thirty-six, had given birth to nine children at term, and had had two miscarriages. Her labors had all been easy ones. Her general health previous to the occurrence which was the cause of my first visit had been good. There was no history of constitutional trouble, nor had she been conscious in the past of any pelvic suffering. On the 31st of May, without warning, she was seized with a violent attack of pain, followed by blanching of the surface, and syncope which lasted for several hours. For a time Dr. McSweeney, the family physician, had little hope that restoration could be effected, but she finally rallied. The next day (June 1st) Dr. Janeway and myself were invited by Dr. McSweeney to see Mrs. K. with him in consultation. We found her extremely anaemic, with blanched lips, rapid, feeble pulse, and great prostration, but not suffering greatly from pain. She

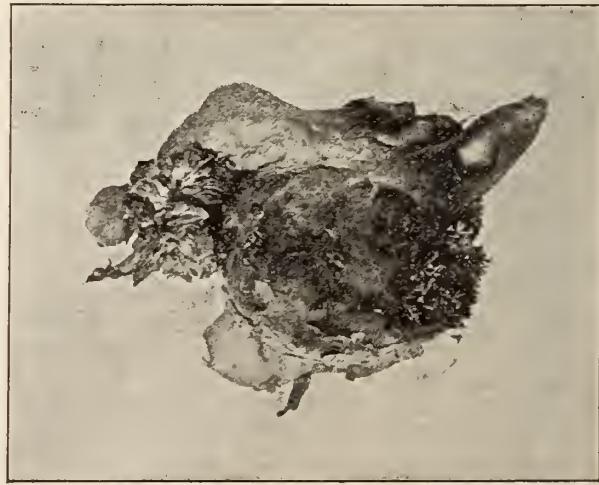

FIG. 2.

The operation was unusually free from difficulty and lasted hardly more than a half-hour. The patient rallied well. In the evening her general condition was most promising, save in one respect—viz., the water passed in the afternoon contained over fifty per cent. of albumin. During the succeeding days there was little or no fever (temperature rose to 103° F. for a brief period on the second day), there was no pain, the appetite was good, but the albuminuria persisted. Still, the general progress of the case was so favorable that recovery was regarded as cer-

tain. On Saturday (seventh day), however, the urine, which had previously ranged between eighteen and thirty ounces, began to diminish in quantity, and in a short time sank to a few drachms, which became solid on boiling. Death from uræmia occurred on the eighth day.

These two cases illustrate the ordinary history of tubal pregnancy. In both, without antecedent symptoms, at an early period of gestation rupture with haemorrhage takes place; in the one instance the blood primarily making its way between the folds of the broad ligament, in the other pouring suddenly, without check, directly into the peritoneal cavity. They are simply additions to the long list already furnished by Mr. Lawson Tait upon which he has based his scheme of ectopic gestations.

In Mr. Tait's belief, all cases of extra-uterine pregnancy are *ab initio* of tubal origin. When the ovum develops in the free part of the tube, rupture, he holds, occurs at or before the fourteenth week. If rupture occurs at once into the abdominal cavity, death ensues from haemorrhage, or later from suppuration of the sac and peritonitis; if rupture takes place in the lower portion of the tube between the folds of the broad ligament, the ovum may develop to full term; may die and be absorbed as an extraperitoneal haematocele; may suppurate and be discharged at or near the navel, or through the bladder, the vagina, or intestinal tract; may remain quiescent as a lithopaedion; or may become an abdominal pregnancy by secondary rupture. In the tubo-uterine form death occurs from intraperitoneal rupture before the fifth month. Mr. Tait denies the possibility of a primary abdominal pregnancy. The ovarian form he regards as possible but not proved.

There is no question as to the utility of Mr. Tait's scheme. It is based upon his exceptional personal experience and has received substantial support from the observations of others. It has stimulated active inquiry, and has given proper direction to pathological study; but the subject of ectopic pregnancy is still too new to make it possible for any scheme to be regarded as a finality.

The most interesting outcome of Mr. Tait's work has been the change of view as regards the existence of primary abdominal pregnancy. An overhauling of museum specimens, long believed to establish this variety, has so far furnished very nearly negative results, and there is at present a very general agreement that the reported cases are at least open to grave suspicion. It is not *a priori* likely that an ovum immediately after fecundation is capable of forming nutrient connections with the peritoneum. It is not theory, however, but facts with which we are called upon to deal. The discovery of an ovum growing in the peritoneal cavity with the tubes and ovaries demonstrably intact would suffice to establish the abdominal variety. In the early months, before the anatomical conditions are obscured by secondary changes, there is no pretense that such proof has been obtained. In more advanced stages a good many cases of assumed abdominal pregnancy have been placed in evidence. These, so far as my investigations permit me to judge, are divisible into two classes:

- Cases where the tubes are reported as intact, but in which there exists a direct communication between the tube

upon the affected side and the sac cavity. Thus, Treub, of Leipsic, recently reports the following instance:

Patient menstruated last about the middle of April, 1887; peritonitic pains, with symptoms of internal haemorrhage, on the 12th of June. At the end of July the same symptoms occurred but were more violent. Ballottement was distinct by the end of September. Life was felt a week later. There were no foetal movements after November 24th. Septic symptoms developed, and laparotomy was performed January 22, 1888, when the patient was nearly moribund. Death ensued the following night.

At the autopsy the annexa on the right side were normal. The left tube measured ten centimetres and a half, which corresponded to the length of the right tube. It was pervious throughout its entire extent. The fimbriated outer end communicated with the sac. There was no apparent distension of the abdominal end of the tube. The sac of the ovum was adherent to the posterior surface of the uterus and of the broad ligament, to a few coils of intestines, to the sigmoid flexure, and to the rectum.

Abdominal pregnancy was assumed by Treub because the tube had its normal length and its natural direction, while the placenta was attached to the posterior sac wall, which contained no muscular elements, even in the vicinity of the tube; but it is much more natural to suppose that a fecundated ovum occupying the infundibulum ruptured the tube walls at an early period of its growth, and thence continued its development between the folds of the broad ligament. It will be remembered that there were unmistakable symptoms of internal haemorrhage in June and in July. The length of the left tube does not affect the question, as Werth\* furnishes cases of unmistakable intraligamentous development where the same feature was noted.

2. Cases where the tubes are reported as intact and not in communication with the sac. Few of these merit criticism. Lately, however, new interest has been excited as to the possibility of primary abdominal pregnancy by a case operated upon in 1879 by Professor Müller,† of Bern. Extra-uterine and intra-uterine pregnancy existed at the same time. At the eighth month spontaneous expulsion of the intra-uterine fetus took place. The extra-uterine ovum was removed by laparotomy. Death ensued from haemorrhage. The post-mortem investigation was conducted by Walker who, in a carefully prepared essay, concludes that the case was a typical one of abdominal pregnancy. The tubes and ovaries were in contact, but not adherent to the sac. The latter had started originally from the bottom of the *cul-de-sac* of Douglas, and only in the course of its subsequent development had reached the uterine appendages. The correctness of the author's deductions has not, however, passed unchallenged, most of the recent reviewers regarding the history as indicating a tubal origin.

\* Werth, "Beiträge zur Anatomie und zur operativen Behandlung der Extrauterinschwangerchaft," 1887. *Vide* table A, containing sixteen cases of intraligamentous tubal pregnancy. In No. 9, Scott's case, the length of the tube was given at six inches; in No. 12, Dreesen's case, at fifteen centimetres; in No. 15, Martyn's case, the statement is made that the tube was enormously increased in length.

† *Vide* L. Bruhl, "Zur Kasuistik der Extrauterinschwangerschaft," "Arch. f. Gynaek.," vol. xxx, p. 70, and Walker, "Der Bau der Eihäute bei graviditas abdominalis," Virchow's "Arch.," vol. cvii.

Schlectendahl\* reports the discovery of an ovum near the spleen, containing a fetus measuring fifteen centimetres in length, in a woman who had died from internal hemorrhage. The sac was the size of a man's fist, and was surrounded by adherent intestines. The uterus and tubes appeared normal. The value of this case as evidence on behalf of abdominal pregnancy has been denied, but the facts related by Schlectendahl certainly call for explanation.

There is little question as to the occasional occurrence of ovarian pregnancy. The specimen discovered by Patenko † in the Pathologico-Anatomical Museum of St. Petersburg seems to answer all the requirements of a demonstration. The right ovary was of the size of a hen's egg, and contained a cyst with smooth walls filled with serum. In this he found a body of a yellow color, of the size of a hazel-nut, which contained cylindrical and flat bones. The most careful microscopical examination established the fact that the bones were those of a fetus, and not merely the chance products of a dermoid cyst. The presence of corpora lutea and follicles in the walls of the envelope proved that the body was an ovary. The tube on the corresponding side was nowhere adherent to the sac. The abdominal extremity was closed, and there were no traces of fimbriae.‡

Paltauf# relates a case of extra-uterine pregnancy in which there was a sacculated condition of both tubes which communicated with a cyst of ovarian origin. The ovaries were closely united. By means of the ovarian cyst a complete communication was established between the two tubes. In the large central ovarian cyst a clot was found which contained an embryo corresponding in size to one of from forty-five to forty-eight days' development. The origin of the condition here met with is naturally a matter of speculation.

But these exceptional cases, however interesting, play an unimportant rôle in the history of ectopic pregnancy. It is the tubal form that, not only relatively to the others but actually, is of common occurrence. Its pathology, diagnosis, and treatment are among the pressing questions of the day.

The physiology of conception, so far as known, consists in the discharge of the ovum from the ovary through rupture of a Graafian follicle, its entrance into the Fallopian tube by the mediation of currents created by the ciliated epithelium of the fimbriae, and its propulsion through the tube either by ciliated currents, by peristaltic movements of the tubal walls, or by both forces acting conjointly; while in the

uterine cavity the descent of the ovum is impeded by the upward current produced by the ciliated epithelium of the uterine mucosa. This latter force undoubtedly helps propel the spermatozoa in the direction of the fundus or the cornua. How far the spermatozoa are hindered from entering the tubes by the opposing current is a matter of uncertainty. That it does not necessarily prevent progression is shown by the fact that in certain animals the entire current is in an outward direction. Wyder,\* moreover, reports a case of tubal pregnancy in which he found, in the uterine portion of the tube, ciliated epithelium everywhere present.

As exceptions to the ordinary mechanism, it is possible for an ovum to migrate from the ovary upon one side, cross the pelvis, and enter the tube upon the opposite side; or, possibly, in very rare instances, after entering the uterine cavity, to cross the fundus and find lodgment in the opposite dilated tube.†

In regard to the aetiology of tubal pregnancy, Mr. Tait is unquestionably right in insisting upon the importance of the various forms of chronic salpingitis. Owing to the associated loss of epithelium, the dilatation and other changes in the tube walls, the two active forces which propel the ovum through the tube—viz., ciliated movements and peristalsis—are weakened or destroyed, while free ingress is afforded to the spermatozoa. Or, again, the passage of the ovum may be interfered with by the secondary results of catarrhal inflammations—such as the production of mucous polypi, of adhesions, or of sac-like dilatations. Formerly great stress was laid upon the aetiological importance of flexions and constrictions resulting from old peritoneal adhesions and inflammatory bands. Curiously enough, in recent laparotomies for tubal rupture, this cause has not played an important part. It is not quite clear whether the peritonitis formerly observed so frequently at autopsies was not in most instances secondary. It is, moreover, possible that, as a class, in cases where antecedent peritonitis has existed as a cause, the hemorrhages resulting from rupture, owing to the agglutination of intestines and pelvic organs, are circumscribed, and do not call for surgical measures of relief.

Recent observations have shown that there is a tendency for tubal pregnancy to recur. Thus Herrmann has reported a case where, in performing laparotomy for tubal rupture, he found the remains of an ovum in the other tube. Tait † has reported one and Veit # three cases where, within a year or two after a first operation for tubal rupture, a second laparotomy was rendered necessary because of the occurrence of pregnancy in the tube of the opposite side.

Tubal pregnancy is associated with the formation of a uterine decidua which differs in no wise from the decidua of

\* Schlectendahl, "Ein Fall von graviditas abdominalis," "Frauenarzt," 1887, No. 2.

† Patenko, "Casuistiche Mittheilungen," "Arch. f. Gynaek.," vol. xiv, p. 156.

‡ Mr. Tait, in his recent work on "Ectopic Pregnancy," refers to a specimen described by Dr. Walter as one of primary ovarian pregnancy (sac had ruptured at fifth month, and fetus had escaped into peritoneal cavity), which is now in the Dorpat Museum, and suggests a careful investigation as to its real character. At Werth's request this has since been made by Runge, with a complete confirmation of the significance given to it by Walter in his original publication. Werth, *loc. cit.*, p. 64.

† In a review by Schaeffer ("Arch. f. Gynäk.," vol. xvii, p. 13) the question of the internal migration of the ovum is once more placed in doubt. In addition to the inherent improbability of the occurrence, Schaeffer declares that in all the cases reported the evidence is open to criticism.

# Tait, "British Gynaecological Journal," August, 1888, p. 178.

# Veit, Gesellsch. f. Geburtshilfe und Gynäk. zu Berlin, May 10, 1889.

pregnancy, except that the distinction into three layers is less marked. The decidua of the tube containing the fecundated ovum possesses a cell layer alone, as the tubal mucosa contains few if any glands. There is no serotina, nor is there any maternal portion to the placenta. The club-shaped extremities of the villi are simply imbedded in the muscular walls. Concerning the decidua reflexa opinions are conflicting. Frommel and Winckel maintain its existence. None was discovered by Langhans and Leopold.

In the early months the development of the ovum leads to a spindle-shaped dilatation of the tube, associated with hypertrophy of the muscular walls due to increase in the length and thickness of the individual fibers. As regards the degree of hypertrophy, very great individual variations have been observed. Indeed, in the same sac a thickening at one point may be accompanied by an excessive degree of tenuity due to overdistension at another. Now, the ultimate fate of a tubal pregnancy is in large measure dependent upon these anatomical differences. Unquestionably, early rupture, such as occurred in my two cases, is the rule. Mr. Tait says: "Out of an enormous number of specimens which I have examined, I have entirely failed to satisfy myself that rupture has been delayed later than the twelfth week." It seems to me, however, carrying skepticism too far to refuse credence to the positive observations of others, made apparently with the utmost care and with full knowledge of possible sources of error, which seem to show that a tubal pregnancy may exceptionally reach advanced, or even the full term of pregnancy. At present it seems fair to assume that when the sac which surrounds the ovum is composed of muscular and connective-tissue fibers with an external peritoneal envelope, and directly communicates with the Fallopian tube, the sac walls are of tubal origin. Of course it is not possible to assert that no rupture has taken place in the course of development. It is only known positively that rupture occurring at the site of placental attachment gives rise to hemorrhage fatal to the fetus; and the same is true, with rare exceptions, where rupture occurs at any point of the peritoneal surface. That rupture has first occurred into the cavity of the broad ligament in all the cases which go on to the period of viability does not seem so absolutely certain. The anatomical appearances in some instances at least indicate that the exposure of the fetal membranes here and there through the maternal sac results not so much from laceration as from the gradual separation of the muscular fibers due to excessive stretching.\* In most of the cases in which the pregnancy reaches an advanced stage the development of the tube takes place principally between the folds of the broad ligament. The support furnished the tubal sac by the gradual unfolding of the ligament layers hinders rupture. More rarely pregnancy may go to the period of viability without encroaching upon the intra-ligamentous space. The tumor then rises above the pelvic brim, and is furnished with a species of pedicle consisting of the uterine end of the tube and of the broad ligament.

The first of the above, or the intra-ligamentous form, lies

close to the uterus, which it not infrequently crowds upward and forward. The uterine end of the tube varies greatly in length. The fimbriated extremity is unrecognizable. Usually no traces of the ovary are found. In the so-called pedicled form the uterus is crowded to one side or retroverted. The uterine end of the tube is usually long and thickened. The corresponding ovary has generally been discovered. In both cases the relations of the sac are often obscured by adhesions to adjacent viscera. In the second half of pregnancy rupture of the sac and the escape of the fetus into the peritoneal cavity may occur without noticeable hemorrhage or without interruption of pregnancy. As the pressure is removed by the escape of the amniotic fluid, the placental borders curl inward so as to furnish a cup-like space, while the membranes sink downward and cover the upper placental surface. The fetus in these cases may occupy the abdominal cavity, or a sac may be formed by the agglutination of the adjacent viscera.

Werth has reported a case in which death of the embryo occurred in the second month, and was followed by hemorrhage which poured through the abdominal end of the tube into the pelvic cavity and gave rise to intraperitoneal hematocle. Similar observations have been made by Veit and Westermarck. This form Werth terms tubal abortion. In another case described by Wyder the fimbriated extremity of the tube was obliterated, and as a consequence the hemorrhage following the separation of the ovum converted the ampulla of the tube into a blood cyst the size of the fist.\*

In the interstitial form of pregnancy—*i. e.*, where the ovum develops in the uterine portion of the tube—the sac of the ovum forms a whole with the body of the uterus. Of twenty-six such cases collected by Hecker, all ruptured before the sixth month. Tait says that, "so far as known, interstitial pregnancy is uniformly fatal by primary intraperitoneal rupture before the fifth month." Schwarz,† however, reports a case belonging in this category in which the fetus was expelled into the uterine cavity.

The patient was known to be pregnant. Repeated hemorrhages indicated a threatened abortion. To avoid further dangers, the cervix was dilated with the view to empty the uterus. On examination with the finger, the uterine cavity was found empty, but at the uterine opening of the left tube was a piece of membrane which was removed. The next day the finger detected membrane at the same site, and beyond a hard body. The uterus began to contract energetically. On the fifth day a fetus was passed by the vagina, the pains ceased, the tumor largely disappeared, and the patient made a good convalescence.

Martin removed a male fetus 33 centimetres long (six months) from the left uterine cornu. The patient recovered. Duvelius, who examined the specimen, concluded that the ovum had partially grown into the tube and between the folds of the broad ligament. He thought that rupture did not occur owing to the number of the muscular elements in the sac wall.‡

\* *Vide* tables of Werth, "Beiträge zur Anatomie und zur operativen Behandlung der Extrauterinschwangerschaft."

The burning question at this moment connected with tubal pregnancy is that of early diagnosis. Dr. Hanks has recently stated his belief that a diagnosis can be made in ninety-five per cent. of the cases we are called upon to attend. Mr. Tait, on the other hand, thinks "he may be excused for maintaining a somewhat skeptical attitude concerning the correctness of the diagnosis of these gentlemen who speak of making a certain diagnosis before the period of rupture."

The problem seems simple enough. Given pregnancy, and having ascertained that the ovum is not in the uterus, the diagnosis is effected. But we all know that the subjective symptoms of pregnancy are deceptive, and that the pigmentation, the mammary and the utero-vaginal changes are not always so clearly defined in the first three months as to make it safe in every case to positively diagnosticate pregnancy in even the intra-uterine form. The advice to use the sound to demonstrate the vacuity of the uterus in suspected cases has been the cause of many needless abortions. Fortunately, the sound often does no other harm than to add to our sources of error. Twice within the year past gravid patients have been sent to me with the assurance that the repeated introduction of the sound had shown the empty condition of the womb. In one of them, after an anaesthetic was given, it was easy to determine the presence of the head of the child through the cervix at the internal os; in the other, I felt perplexed and asked the opinion of Dr. Thomas. He pronounced it an ordinary pregnancy, and the event has shown that he was correct. Twice within the year, to my knowledge, the abdomen has been opened in this city for supposed extra-uterine gestation, and only ordinary gravidity has been found.

In the main our dependence must be upon local symptoms and local changes. The former consist of the suspension of the menses, often followed, after a brief period, by a bloody discharge, of paroxysmal pains, and of the discharge of the decidua. But the latter is by no means of constant occurrence. Paroxysmal pains are frequent in other forms of tubal disease, and menstrual disturbances are common phenomena in uterine derangements. In my two cases, and in most of the forty-two reported by Mr. Tait, there was no call for a diagnosis until rupture had taken place. As a matter of fact, the occasion for diagnosis must be very exceptional in the large class in which rupture occurs primarily within the peritoneal cavity. In the intra-ligamentous form the case is somewhat different. Here the swelling to the side of the uterus is easily reached through the vagina. We have as distinctive signs a rapidly growing tumor, early fluctuation, and the presence of pulsating vessels over the site of the tumor. Bimanual examination under an anaesthetic, especially if the thumb be introduced into the vagina and two fingers into the rectum, makes it possible to determine that the tumor is independent of the uterus. I believe in such cases that the chances of error are slight. Of course the diagnosis is strengthened by the existence of concomitant symptoms. I do not understand Mr. Tait to deny the possibilities of a diagnosis under such conditions. He differs only in regarding all intra-ligamentous cases as secondary to tubal rupture. Not much dependence is to

be placed upon uterine changes in the early months. These sometimes correspond to those of ordinary utero-gestation, but in the instances I have related in this paper they were insignificant. Neither perceptible enlargement nor cervical softening indicated pregnancy.

After the third month it is not ordinarily difficult to determine the existence of the pregnant state. Ballottement is usually perceptible at an early date, and the foetal heart makes the diagnosis certain; but the greatest care needs to be exercised in the examination of the patient and in the formation of an opinion concerning the extra-uterine situation of the ovum. In a suspected case violence in the attempt to separate the tumor from the uterus may cause sae rupture. Grandin believes the absence of contractions when frictions are applied to the sac of an extra-uterine ovum should prove a most valuable aid to diagnosis. Küstner\* curiously enough maintains that the existence of contractions in tubal pregnancy should distinguish them from other pelvic growths. Evidently here more clinical observations are called for. Mr. Tait cites as a misleading condition an abnormal thinness of the uterine walls. In my own experience, lateral flexion of the uterus often simulates ectopic gestation to a surprising degree. In these cases the fundus containing the ovum lies upon one side of the pelvis. The cervix is crowded to the opposite side. Between the two a deep sulcus is felt. If the patient is hysterical, these deranged relations are exaggerated by contraction of the abdominal muscles. No difficulty in detecting the error is experienced when the patient is completely anaesthetized. Cases of retroflexion of the gravid uterus with incarceration are likewise often difficult to distinguish from extra-uterine pregnancy.

The distinction by physical signs between the tubal, the ovarian, and the secondary abdominal form is scarcely practicable so long as trained anatomists fail to agree concerning them when the abdomen has been opened and the organs are exposed to view.

A review of the subject of diagnosis makes it apparent that many cases of ectopic pregnancy present no symptoms previous to rupture. In another class the existence of a suspicious tumor with few or none of the corroborative signs should lead to a waiting policy, or, when the symptoms are of a threatening character, to an explorative laparotomy. It is well, however, to remember that with reference to this latter procedure recent popular interest in abdominal surgery has a tendency to invest trifling anomalies occurring in gestation with a sinister importance. But there still remains a considerable class where the early diagnosis is scarcely doubtful—as, for instance, that of Hawley,† where the diagnosis made previous to rupture was confirmed by laparotomy.

Upon the fact that in favorable cases certainty of diagnosis is attainable in the early stages of ectopic pregnancy rests the entire argument as to the validity of the treatment by means of galvanism or the faradaic current.

In two cases which I have elsewhere offered in evidence

\* Müller's "Handbuch der Geburtshilfe," vol. ii, part 2, p. 541.

† Hawley, "N. Y. Med. Jour.," June 16, 1888.

there were present the early signs of pregnancy, a rapidly growing tumor to the side of the uterus, pulsating vessels, paroxysmal pains, and in one case discharge of the decidua. In both instances the diagnosis was confirmed by Dr. Thomas, concerning whose cool judgment and great experience there can be no question. In both, the faradaic current was used—the positive pole externally, the negative pole through the vagina for five minutes, and then through the rectum for the same period. This treatment was employed twice daily. After a couple of days the tumor had become noticeably flaccid, and in a week had shrunken to a small size. I have seen both patients many times since. Neither have suffered inconvenience, though in each a body of the size of an English walnut may still be felt. One has since given birth to two children without trouble ensuing. These cases are typical, and many similar ones have been reported. The same treatment employed in the forms of tubal distension due to salpingitis has not, in my experience, proved of avail. The use of the galvanic or faradaic current does not call for special skill. The only arguments against the method, except that the results reported carry with them the evidences of ignorance and folly, are that it is likely to cause rupture and that the retained ovum is liable to excite suppuration. But these eventualities are so rare that they may be left, in case of need, to a subsequent laparotomy. It should be understood that the method under discussion is only available in the first three months, and that no one in this country, as is commonly assumed by foreign critics, advocates electro-puncture. Foreign critics state that the results we claim are impossible. But it is unscientific to condemn them without subjecting the method to experimental tests.

The argument in favor of the early use of galvanism does not in the slightest degree impair the value of laparotomy, which must always remain our most important therapeutical resource. Only seven years ago I wrote as follows:

"As, under careful management, rupture of the tube most often proves fatal, Kiwisch recommended in such cases to make an incision four or five inches in length through the abdominal wall along the linea alba. In order to be sure that internal haemorrhage had really taken place, he advised, when the peritoneum was reached, to first make a small puncture, and to introduce a pipette into the abdominal cavity. If the presence of blood was detected, the peritoneum should then be laid open the length of the abdominal wound, and, after first tying the bleeding vessels, the sac should be removed and the peritoneum carefully cleansed. Strange to say, intelligent as these instructions seem, no one, in these days of abdominal surgery, has so far had the hardihood to carry them into execution. The reasons for this backwardness are probably to be found in the uncertainties of the diagnosis, the risk of finding the sac hopelessly matted to the adjacent viscera, the dislike for operating upon a dying woman, and the fact that a considerable number of spontaneous recoveries occur, either from the mummification of the foetus or by the limitation of the sanguineous effusion and the production of a circumscribed haematocele."

The glory of demonstrating the practicability of the surgical treatment of rupture belongs to Mr. Tait. The sentence I have quoted was hardly printed before he began that magnificent series of operations—according to recent

reports, forty-two cases with but two deaths—which is certainly one of the greatest surgical achievements of the last ten years. Many active workers are now following in his footsteps, and the future saving of life by the employment of laparotomy in this field will be to him an eternal monument of fame.

Laparotomy not only possesses the advantage of being the one measure for the treatment of cases where, as in rupture, death is the common alternative, but it enriches our resources in cases of impending danger. Unlike the employment of galvanism, it presupposes the equipment necessary for laparotomy, and the skill that comes from experience. It possesses this advantage—it leaves nothing to chance. All the possibilities are under the control of human intelligence. Except for the question of ethics, it is available before and after rupture. It can be resorted to for the extirpation of the sac after three months have passed, when galvanism is no longer available. But Mr. Tait maintains that we have no right of our own volition to sacrifice foetal life. That depends. So long as the attempt to remove the foetus after the period of viability was followed by a ghastly record of maternal deaths, it was necessary to recognize the limitations of our skill and seek to preserve the life of the greatest value.

Recent more hopeful experiences challenge us to a revision of older views. Thus, in addition to the memorable case of Jessop, which formerly stood alone in saving the life of both mother and child, we have now those of Martin,\* Lazarewicz,† Olshausen,‡ Breisky,§ Braun von Fernwald,|| John Williams,△ and Eastman,◊ of Indiana, in which the child was alive at the time of operation. In this list Williams alone left the sac *in situ*. Of the others, Olshausen, Breisky, and Eastman removed the sac entire with the placenta. The others controlled haemorrhage by means of ligatures, and brought a portion of the sac outside the abdominal wound.

These later results leave little reason to doubt that, when the anatomical conditions come to be properly realized, human invention will find means to control the dangers of the so-called primary operation for extra-uterine pregnancy, and it too will find its place in the domain of legitimate surgery.

---

**Reunion of Cut-off Fingers.**—Dr. Nikolai P. Engelhardt, of Smolensk, communicates ("Proceedings of the Smolensk Medical Society," 1888) another instructive instance of complete reunion of a cut-off finger. A peasant hacked off with an axe the terminal and middle phalanges of his left forefinger, only a thin palmar cutaneous bridge, measuring not more than one quarter of an inch in breadth, remaining to connect the severed finger with the hand, even the tendons being cut across. Without any delay, the parts were readjusted and sewed together. The wound healed kindly. The injury, however, left, besides a linear scar, immobility of the interphalangeal articulation and some induration about it."—*Medical and Surgical Reporter*.

## CÆSAREAN SECTION IN A CASE OF PRIMARY CARCINOMA OF THE VAGINA.

By JOHN S. HAWLEY, M. D.,

ATTENDING GYNECOLOGIST TO THE NEW YORK HOSPITAL, OUT-PATIENT DEPARTMENT; ASSISTANT SURGEON TO THE NEW YORK CANCER HOSPITAL AND TO THE WOMAN'S HOSPITAL.

THE recent improvements in the technique and the decrease in the mortality of the Casarean section have done much to deliver that time-honored and worthy operation from the obscure recesses of the *oubliette* to which it had been remanded by the greater number of obstetricians, but there is yet extant in the minds of many a deep-seated prejudice against its employment as an operation of election, rather than as a reliable method of granting a merciful euthanasia to an exhausted parturient. True, in times of rare and desperate extremity it was brought forth, furbished up so as to exhibit its brand "*dernier ressort*," and given an opportunity to earn a commutation of its sentence; but this was so hampered by suspicious distrust of the good faith of an attainted felon that its performance, while in a condition due to long inactivity and deficiency of lubricating material, usually led to reincarceration, with an extension of its original sentence. But the world moves, and there is now only a smoldering ash-heap where once was a blazing fire of prejudice. How much influence in the preservation of these half-consumed coals is due to the old fetich-worship of the peritonæum, which adds to its pagan decalogue the prohibition, "Thou shalt not commit abdominal section, nor enter into the peritoneal cavity"; or what may be the exact value as an obstructionist to surgical progress of the blood-stained record of the operation as done in the past—can not easily be determined. But, although it is not disputed that early and unhesitating resort to operation is a prominent factor in that which goes to make the same successful, the practice of waiting until success is well-nigh precluded by ill-judged delay is still followed by many. The sooner it becomes a well-understood and practically accepted principle that, in so far as Cæsarean section is concerned, procrastination will add sneak-thieving to its criminal specialty of temporal larceny and filch from both mother and child the best of their chances for recovery, the sooner will its equitable deserts be granted to the operation, its utility be determined, and the cranioclast be sent to molder where Cæsarean section had been made to vegetate in periodical trances.

The status of the present operation, as modified in scope and technique, is well known, and the consensus of opinion among progressive surgeons is only disturbed by the question of whether or no the uterus should be removed at the same time that witnesses the extraction of the child. This element of discord is not relevant to the subject of this paper, and will not be admitted to a place among more pertinent matters to be considered. But the list of recorded cases in which the improved operation has been performed is sadly in need of re-enforcements if it is to act as the army which is to fight the statistical battles of the procedure; and, although this recruit can not be regarded as an enthusiastic defender of the faith, the fact is in no wise a matter of voluntary choice on its part. The following history of

a case which not long since came under my observation is offered, not as a very valuable, but as a rather unique contribution, for it presents some interesting features and an opportunity for critical comment:

C. D., aged thirty-two, married for twelve years, having borne five children and having had two miscarriages, was sent to the New York Cancer Hospital by Dr. A. P. Dudley, and was admitted into that institution on the service of Dr. Cleveland (which was at the time under my charge) on June 27, 1888. She was then in the fifth month of utero-gestation, the catamenia having last appeared on January 20th. During the previous two months she had suffered from severe pain, referred to the vagina and the hypogastrium, and for the same period had noticed the existence of a very foetid vaginal discharge. Her last pregnancy had resulted in abortion, not quite one year previous. She had had a feeling of malaise and of pain in the head and in the sacral region for three years, dating from her last labor. She had noticed the occurrence of quickening two weeks before, and had felt the movements of the foetus regularly since that time.

She was fairly well nourished and of not unhealthy appearance, though her facial expression and general demeanor bore her out in her statement that she felt very weak and nervous. Her pulse was feeble, very rapid, and of unsteady rhythm. All the external signs of pregnancy of about five months' duration were present, but neither movements nor heart-sounds of the foetus could be detected. Vaginal examination revealed the fact that the lower third of the canal was all but occluded by a soft, friable, cauliflower-like mass, sloughing in spots, from which proceeded a discharge of foetid and characteristic odor, breaking down at the slightest manipulation, with free haemorrhage, and the seat of extreme tenderness. The hard, infiltrated base of this growth involved the lower third of the posterior vaginal wall and the subjacent tissues almost to the rectal mucosa, the posterior border of the *ostium vaginae*, and apparently the deeper periproctal tissues. The vulva, the upper portion and anterior wall of the vagina, and the cervix were free from the diseased action, the tendency of which seemed to be to extend its limits downward rather than circumferentially. The softer portion of the tumor which obstructed the vaginal canal having been scraped away, the affected tissues of the rectovaginal septum were found to be rigid and inelastic, while the extent of infiltration was so great that no hope of radical excision of the growth could be entertained. The mother was certainly past any chance of recovery, and therefore her interests were made subordinate to those of the child in the after-management of the case.

During the ensuing nine weeks the patient's condition became steadily worse. The cancerous cachexia, rapid emaciation, speedy recurrence and extension of the growth, progressive debility and cardiae weakness, all combined to render her condition by the latter part of August one of great exhaustion. Common humanity had demanded the free administration of morphine almost since her admission, for she could not endure the excessive pain. In the middle of July the euretting was repeated, and the discovery was made that the rectal mucosa was involved. Further interference was contra-indicated by the extreme weakness of the patient's condition.

The foetal heart sounds and movements were recognized at about the middle of July, and all the indications pointed to the existence of a vigorous state of foetal vitality until the last week in August, when a marked loss of power, both in movements and heart sounds, was apparent. The mother was in a most critical condition, her pulse ranging from 120 to 150 in rate, and showing such feeble and irregular cardiae action that sudden

heart failure seemed to threaten her life at any moment. The whole aspect presented by her case was as ill-omened a harbinger of impending death as would have been a prophetic vision of a Highland seer in which her form had been seen completely muffled in the folds of the fateful shroud. As sudden death of the mother almost certainly involved that of the child, which had reached a viable age—seven months and a half—I was not willing to run so great a risk as was apparently to be taken by delay, especially as the fetus had manifested the signs of diminishing strength. Therefore, on August 28, 1888, with the kind assistance of Dr. Outerbridge, Dr. McCosh, and the gentlemen of the house staff, I removed by the Cæsarean section a male infant weighing four pounds and eight ounces, well developed for its age and seemingly vigorous. Chloroform anaesthesia was employed for the reason that albuminuria had been discovered in the patient. The incision in the uterine wall was closed with deep and superficial sutures, the former of silk and the latter a continuous fine gut suture including the peritoneal covering only. The uterus contracted firmly and the patient rallied well from the shock of the operation. But, as was expected, the sloughing mass in the vagina played its part of an infectious source of septic poison, and the case was terminated by death on the fourth day. An autopsy revealed the lesions ordinarily found in puerperal metro-peritonitis, but, although a large collection of pus was present between the anterior abdominal wall and that of the uterus, which was found to contain in its cavity and its sinuses a quantity of purulent matter, the incision had closed by primary union, and so completely that the aid of scissors was needed in reopening the uterine cavity through the line of the wound.

The child was placed in an improvised incubator, where it soon adapted itself to its altered environment, breathing well, and soon lifting up its voice in quite a strong appeal for protection of infant industries. I was totally unprepared, therefore, for the news that it had suddenly died, after a gasp or two, some four hours later. Dr. Broun, the house surgeon, informed me that there was a hard lump in its axilla, but he was unable to remove this for examination on account of the vigilant supervision of the father of the infant.

On reviewing the history, in the attempt to decide as to the exact amount of influence on the unsuccessful result exerted by the early resort to operation I can find but one argument, and that a most unstable one, against the practice which was followed. Of course the question refers to the child's life only, as the mother was doomed under any circumstances. Assuming that no valid objection can be made to the choice of the simplest and most rapid method of operation as preferable to laparo-clytrotomy or Porro's operation, the adverse argument can rest alone on the principle that, as every day of intra-uterine life is precious to the fetus, interference should be postponed until the last moment.

But that this case was an evident exception to this rule will be easily demonstrated by taking into consideration the conditions with which I was confronted in making my decision, and which seemed to threaten the transfer of the case to another court, the jurisdiction of which admits of no appeal from its rulings, should I hesitate for any length of time. A mother in the last stage of exhaustion from the combined effects of cachexia, pain, cardiac weakness, morphinism, loss of blood, as well as probable sepsis, and exhibiting all the signs which portend a sudden and impending death; a viable fetus, dependent on diseased, poison-

laden materials from that mother's system for its existence and growth, showing evidences of failing vital power, whose life was in the same danger as that which threatened the mother momentarily—if there is any confidence to be placed in indicative signs, such were the conditions of the problem; and whether it should be solved by action or by trusting to uncertain future possibilities, the welfare of the child being the only object to be gained, was the question to be answered.

I regarded the conditions under which the child was placed as so unfavorable to its adequate nutrition—if not, indeed, tending to the actual production of a dyscrasia or a morbid condition in the child, dependent, as it was, entirely on the pabulum to be derived from a diseased, degenerated, poison-contaminated source of supply which threatened to fail at any time—that its longer subjection to their influence would be simply murderous extinction of its chances for ultimate survival. Moreover, that the malnutrition of its foetal existence would, as a detrimental element, more than counterbalance the disadvantages of premature birth and artificial feeding, I was firmly convinced, even if the danger of its sudden death were not taken into consideration. The undesirable character of its intra-uterine surroundings may be indicated by the enlargement of its axillary gland, if it is admissible to draw the most natural inference as to the nature of that enlargement. Though the result can not be regarded as brilliant, the principle of early resort to operation—that is, before absolute emergency or prolonged efforts at labor have occurred—remains unshaken; nor must it be regarded in any other light than as upheld rather than decried by the facts in this history.

One or two points of interest are presented by the history. The primary union in the wound of the uterine wall under conditions most adverse to aseptic repair is additional evidence in support of the statement made by others that such action is not prevented by septic peritonitis, which is not a direct result of the operation itself. The unusual condition which called for operation in this case is also worthy of mention. Primary carcinoma of the vagina is considered a very rare condition by authorities, only twenty-eight cases having been collected from the whole literature prior to 1883.\* I fancy, however, that this rarity of the condition is dependent more on paucity of reports than of cases observed, for I have seen four unquestionable cases during the past two years, and had met with several other instances of the condition before that time. But in the character of an imperative indication for Cæsarean section it is veritably a rarity, and, as no implication of uterine tissues in the malignant growth was discernible after death, the present case may be regarded as a clinical curio.

At the risk of appearing in the light of a hair-splitting theorist when I mention as a possible cause of the child's sudden death the effects of morphinism, acquired during its foetal life from the mother, I venture to allude to such an explanation of the death from apnoea of even a seven-months baby, as it savors of some plausibility, but do not offer it as anything more than a possibility.

In forming a judgment as to the propriety of the course

\* Hart and Barbour, "Manual of Gynaecology," 1883.

pursued in the treatment of this case, it is necessary to take all the circumstances carefully into consideration as a whole. The case is, to borrow a simile from Oliver Wendell Holmes, "as unseizable, except in its totality, as a billiard-ball"; and, just as one is tentatively rolled over the table for the purpose of testing its freedom from asymmetry of form and irregularities of surface before it is put in play, this is now sent out to be tested and turned in the lathe of others' criticism, so that in any future contest its perfect action may only be invalidated by faulty execution or miscalculation on the part of the player.

## THE SURGICAL TREATMENT OF ERYSIPelas IN CHILDREN.

BY A. SEIBERT, M.D.,

PROFESSOR OF DISEASES OF CHILDREN, NEW YORK POLYCLINIC, AND  
PHYSICIAN TO THE CHILDREN'S DEPARTMENT OF THE GERMAN DISPENSARY.

To open the inflamed skin in erysipelas by means of numerous small incisions made all over the diseased surface, and deep enough to draw blood, has been practiced for some time, and not without success, provided antiseptic lotions (five-per-cent. solutions of carbolic acid, or sublimate, 1 to 2,000) were frequently poured on the dressing. Hypodermatic injections of a two-per-cent. solution of carbolic acid into the healthy skin surrounding the inflamed part have also been in use with varying success. The object in both methods was to bring Fchleisen's coccus of erysipelas, wandering in and along the lymphatics, in direct contact with germicidal fluids. The idea was correct, but its execution deficient in both methods. The incisions in the inflamed cutis closed up too rapidly to admit sufficient antiseptic fluid into its lower layers, and the fluid, brought into the healthy skin bordering on the erysipelas by the hypodermatic needle, found its way too rapidly into the circulation, thus doing no good locally, but often harm constitutionally.

Kraske's method was the first step in the right direction. He made regular incisions on the border of the erysipelas, extending into the healthy skin, and, by crossing these diagonally with others, the incised surface (diseased and healthy) presented an appearance not unlike a rail fence. The object here was to give a good chance to the cocci to get to the surface, and the antiseptic fluid to get to the cocci in the lower layers of the skin, at the same time disinfecting the healthy ground most likely to be invaded next by these germs. To this end the dressing was constantly moistened for the next few days. The results of this method were excellent.

Riedel and Lauenstein ("Deutsch. med. Woch.", March 14, 1889) proposed to improve Kraske's method by locating this fence of incisions entirely in the healthy tissue, about one or two inches away from the border of the erysipelas. This was to avoid possible infection of yet aseptic tissue, and this modification has given better results than any other method as yet practiced. The patients were usually put under an anæsthetic and the whole operation was performed strictly according to the rules of antiseptic surgery.

In three cases of genuine erysipelas in children I have been able to employ this method, and in each case with such success that I may be pardoned for relating them in detail:

Girl, five years old, in private practice. Child had an eruption (varicella); had scratched its legs, causing open sores, and in one of these on the left calf erysipelatous inflammation was set up, beginning with a severe chill and nausea, continuing with high temperature (104° to 105° F.) and other signs of severe illness, and spreading rapidly downward and upward. I saw the child eighteen hours after the chill, and, recognizing its cause immediately, proposed the Riedel-Kraske method. This was flatly refused, because of the anæsthetic. Next day I brought a new vaccination lancet with me, and proposed to make the bloody fence with the little harrow attached to it and without the anæsthetic. This was consented to. The erysipelas had meanwhile spread upward to about an inch above the knee and downward to the ankle joint. I decided to make a fence only around the thigh. After carefully cleansing the whole thigh with soap, water, ether, and a five-per-cent. solution of carbolic acid, and covering the erysipelatous region with a carbolized towel, I firmly grasped the leg, and with long strokes of the harrow managed to open the skin around the thigh to the width of about an inch, and about an inch and a half away from the erysipelas. The longitudinal scratches (which were all deep enough to draw blood) were carefully but quickly crossed diagonally with manifold strokes of the harrow, so as to be sure that all of the surface operated upon was opened. A solution of corrosive sublimate (1 to 2,000) was then rubbed into the wound, and a layer of absorbent cotton applied and fastened with gauze bandages. This dressing was moistened freely with the same solution every fifteen minutes.

The whole operation lasted no more than two minutes. The child's temperature at the time was 105° F., it had vomited all food for two days, and had been awake and delirious most of the previous night. The "fence" was made at 11 P.M. I did not see the child until the next day, when I found it sitting up in bed smiling, with a temperature of 100·5° in the rectum, due to the erysipelatous infiltration remaining in the limb below the "fence." The erysipelas had evidently reached the wounded ring, for on the lower border of the dressing the skin disappeared under it in a red and swollen condition, with a number of blisters spread over it, while on the other side it was as white and cool as could be, and it remained so until seven days later, when I removed the dressing. The temperature never rose again, the appetite returned, the child had slept well, and the subsiding of the severe symptoms had set in about six hours after the little operation.

But I found another patient on that day also sick with the same complaint. The younger sister of the first patient, a very nervous, somewhat anæmic child three years and a half of age, had been attacked the evening before with erysipelas of the right leg, beginning also at a scratch. As the parents consented immediately to the treatment, I was able to make the bloody ring just below the knee, and to thus stay the advance of the erysipelas in that direction. The temperature of the child fell from 104·5° to 101° F. within four hours, the erysipelas traveled down to the toe-nails, but never crossed our fence, the child meanwhile feeling perfectly well.

The third case was that of a baby but thirteen months old. I first saw the child at the children's department of the German Dispensary, on September 10th, when it was brought there for a severe attack of cholera infantum. As it was collapsed, I washed out its stomach. This had the effect of checking the vomiting and of virtually curing the case. But two days later erysipelas

began just above the knee, showing great tendency to spread rapidly upward, thus threatening the child's life. I resolved to operate the next day in spite of the child's weak condition. When I did make the fence the child's condition appeared almost hopeless, the temperature registering 105° F., and the strength of the baby being almost exhausted. As the inflammation had spread anteriorly nearly to Ponpart's ligament, I had to make the ring just below it, coming up from behind half way over the buttock. The mother being a Bohemian and quite unable to understand me, I had to make myself intelligible more by signs than by words, and yet our combined efforts resulted in a complete success, for the next day the baby's temperature was normal and the child made a speedy recovery.

I had the satisfaction of being enabled to present the three children to my class at the New York Polyclinic, and there removed the dressings for the first time, showing exactly the line of demarkation and its remarkable action. I am positive that this method will check and cure every case of erysipelas if employed in time. My three cases demonstrate that my modification of operating with the vaccination-harrow and without an anæsthetic can be easily made use of in children, its advantage being that parents will more readily consent to this treatment.

122 EAST SEVENTEENTH STREET.

## SOME GENERAL SUGGESTIONS IN DERMATOLOGICAL THERAPY.\*

BY SAMUEL SHERWELL, M. D.,  
BROOKLYN.

*1. A Simple Method of treating Scabies.*—The following plan is one I have long used, and for which I claim originality, certainly not as to the antiparasitic element itself, sulphur, which is as old as dermatology; but the manner of employment I have never seen referred to except by Greenough, of Boston, who casually refers to one of the means in a late monograph on the subject of scabies. I have employed and advocated the method as below given for many years, almost to the exclusion of others.

Instead, then, of the use of the odious and, as I believe, totally unnecessary inunctions with possibly rancid and certainly evil-smelling unguents, all that I find needed in my practice is to give a sufficiency of the dry precipitated sulphur to the patient, which I direct him to rub fairly well, but without violence, into the parts of the person where the lesions of the disease are manifest, or most manifest, once a day, preferably on retiring; to also sprinkle or dust a little, say about a small teaspoonful, of the same powder on the sheets or blankets, etc., of the bed—on the clothes, in fact, coming most intimately in contact with the individual. A simple bath of soap and water is ordered, with total change of under-clothing and bed-clothing about twice, at most three times, a week.

This plan seems to obviate all the discomfort, moral as well as physical, felt by the patient during his treatment, which makes him feel so like a leper under the ordinary, and certainly so under the more stringent, treatments, and I

am as certain of good result as in the latter ways. I maintain and believe that the sulphur by this method, with the increased sebaceous secretion of the stimulated skin, makes the best unguent, enough of the unguent, and certainly the least irritant unguent; and as such one far less liable to cause any of the violent eczemas which so often follow the use of the recommended and applied ointments, etc., of the authorities, especially the older ones.

A little spirit of lavender or any other mild perfume may be sprinkled on the linen, etc., to cover the slight sulphurous odor, which in such way is made barely perceptible and is in striking contrast to the pronounced diabolism of the ordinary method. If thought best, occasionally a mild inunction with some bland oil (such as sweet-almond oil) might precede the rubbing on of the sulphur; but I seldom or never find it necessary. Particularly do I recommend my method in cases where perhaps, as is natural, all the family are affected, though the disease is most manifest, as is usual, on only one or two of them. It can readily be perceived how easily all may be treated and yet hardly perceive it. Particularly do I lay stress in these cases upon the dusting of the bed-clothes.

It happens very commonly in my practice that the servant-girl fresh from Scotland, Scandinavia, or some other foreign country, brings it with her from the steerage, and becomes the focus of contamination. On one such set of causes and cases treated within the last fortnight I have now a letter from the family attendant. They were all cured without the slightest trouble. The disease had been present some months. I have treated in all eight cases during the past thirty days in the same manner with a perfect result and no trouble.

In all the foregoing, however, I do not seek to maintain that this mode would be so promptly and rapidly efficacious in those phenomenal cases we read of in literature as the Norway itch, etc., where, from the pachydermatous condition of the patients, a bath of caustic soda would seem to be a good preliminary to any treatment; my plan is adapted to the conditions under which we see the disease here—among families of perfectly, or at least relatively, cleanly habits and persons.

*2. Eczema Ani.*—I do not see in the works of skin authorities generally—when speaking of this exceedingly annoying affection and its accompanying distressing pruritus, both of which may have extended, and usually do, to the genital regions and parts surrounding—enough reference, or at any rate reference stringent enough, to what, in my opinion, is almost always a concomitant, and probably oftenest a cause—viz.: slight fissure of the mucous membrane of the sphincter, or oftener indeed inside the sphincter and well up the bowel.

In these latter cases generally I find the other name for fissure, “painful ulcer of the rectum,” to be a misnomer, as it is often unattended with pain, or at least great pain. I scarcely ever now pretend to treat a marginate eczema of these localities without making a specular examination of the rectum first, and frequently find a lesion of this character, which, with its peculiar irritant secretions, both liquid and gaseous, renders it difficult, if not impossible, for a cure

\* Read before the American Dermatological Association at its thirteenth annual meeting.

to be obtained by external applications alone, or even by slightly deeper excursions beyond the vermillion edge.

Every one knows how a fissure should be treated; but a good many patients, feeling no pain, can not understand the necessity for a surgical operation or procedure, and will not readily submit. In these cases I am in the habit of advising and instituting the use of rubber bougies—the hard variety (they are sold in nests like test-tubes)—and gradually increasing the caliber of the bougie introduced, letting them remain in some five to ten minutes every other night.

In several patients of late—one or two of whom (themselves professional brethren) had been treated before by celebrated specialists, and had been stretched, cut, and cauterized with nitrate of silver—I have found decided proctitis involving a large portion of the bowel; and it is for those cases peculiarly that there seems to be a reason for my speaking here, for their pruritus was something dreadful. It is this state of things that causes the evil secretions I have mentioned above, and a person may medicate the superficial surface of the anus and the adjacent region and, as aforesaid, the surface of the external sphincter for even some distance up, but no good, or very little, will result.

In these cases, after a laxative, preferably saline (I like Startin's tonic with a good deal of sulphate of magnesium), I think it important to have the bowel washed out with an ordinary slight enema, and then a sufficient quantity, say a tablespoonful or so, of the following or a similar mixture thrown up and allowed, if possible, to remain (this is best accomplished naturally at night):

R Acdi borici,	{	.....āā 3 ss.;
Zinci sulphocarbolat.,		
Listerine,	{	.....āā 3 ij;
Glycerin,		
Aque .....		5 iij—5 iv.

In both the cases alluded to I varied this injection with self-insufflations of various powders—sulphur well triturated, boric acid triturated with carbonate of bismuth, etc.—taking care to vary the preparation often, as I find that the mucous membrane resists or resents, as the skin does, absolute uniformity or monotony of a healing agent. The result of this treatment with the bougies was entirely satisfactory, and speedy and welcome cure was attained. A word as to the method of self-insufflation. This was easily managed by one of the gentlemen, an excellent practitioner, by the following means: A long rubber tube (drainage-tube) was attached to a thick glass tube, loaded, and introduced as far as necessary into the bowel, and then by a quick puff emptied. Some mild antiseptic lotions and salves were also used externally, being changed occasionally for the same reason as the powders. In this way recovery became absolute, and, as one declared, freed him from what was making life itself a burden.

3. *Eczema and Sycotic Conditions of the Upper Lip.*—These conditions, too, are ordinarily dismissed with a slight and almost contemptuous reference to irritant discharges from the nasal chambers. I think they merit at least a half dozen lines in those treatises which pretend to be exhaustive, as they are very common, very distressing, and most rebellious unless handled properly; and, in my opinion, the nose and

its lining require as much attention as the lip. This interference may be either medical or surgical as the case may demand, but certainly the mere prescription of a salve or lotion does not cover the ground.

Having a very large auxiliary clinic attached to an eye and ear hospital, I am constantly meeting with strumous infants, children, and those of larger growth, with these forms of dermatitis; always improvement may be obtained by protective and soothing treatment externally, but to facilitate a cure and render it perfect, the nose must be the first object of treatment. In these cases I am inclined to think, as in some cases of eczema ani, that not alone the acrid liquid secretions, but the foul gases from the mucous membranes, act as decided irritant causes.

In all the foregoing recommendations I have purposely been as brief as possible. For instance, in the references made to anal, nose, and upper-lip troubles, many different therapeutic agents, both medical and surgical, may be used by different intelligent practitioners with equally good effect. However, I may perhaps add a closing word on the subject of scabies and its treatment as recommended.

I maintain, as before said, originality; also efficiency and convenience. I think, too, the means used might be recommended as prophylactic in circumstances where large bodies of men are gathered together, as in soldiers', lumberer's, and cow-boys' camps, in winter quarters, etc., for a long time.

I have never seen any dermatitic manifestations from sulphur used in this way with any degree of care. This is one of the most common complications or after-results of the "quick cures" of the itch. To be sure, my method is not so rapid as they are said to be, but is rather a nine-day than a three-day cure; but all other conditions are in its favor.

## SEXUAL PRECOCITY.

BY RICHARD DOUGLAS, M. D.,  
NASHVILLE, TENN.

ABNORMALLY early puberty is quite compatible with good health, says Herrick, in the "Reference Hand-book of the Medical Sciences."

To the contrary, it appears that sexual precocity with its disturbing and demoralizing tendencies is in itself a pronounced disease, repugnant to our finer natures, and appealing most strongly to our sympathies. It robs childhood of its innocence, and youth of its beauty and purity. The one so cursed to "wallow in the carnalities of the world" is at last left a withered victim of premature senility.

If parents could interpret aright the many hints in the budding character which suggest sexual precocity in their children, training and watchful care might do much to correct the affliction they have transmitted. Under favorable surroundings and in ordinary temperaments, childhood merges into puberty and safely into adolescence, unconscious and innocent of all save the purest of feeling. That such a quiescent period is now fast becoming the exception, the forward youth of to-day fully attest. Yet it is most unusual for us to meet with a case so exaggerated as the one

I append. I can find but few in subjects of such tender age in the literature on the matter.

D. is four years and three months old, weighs fifty-four pounds, is three feet ten inches and a half high; the circumference of the head, just above the ears, is nineteen inches. The features are rather large and coarse. The general muscular system is remarkably developed. The penis, scrotum, and testes are of the size of those of an ordinary adult, the penis measuring full three inches in the flaccid state; the prepuce rests half retracted over the glans. The pubes is covered with soft, silky brown hair. The abdomen is quite protuberant.

This child, with such unusual physical development, is mentally sluggish, obstinate, and self-willed. He enters with spirit, however, into the amusements of children. He does not appear to manifest any fondness for the opposite sex, and yet is addicted to that curse, masturbation, which seems to come by intuition with the dawn of puberty. He will take advantage of every opportunity to commit self-abuse. His erections are vigorous. The emission which is sometimes found on his linen is of thin mucus; no spermatozoa are present.

The history of this rather unusual case is somewhat unique. The boy, now something over four years old, was not in any way peculiar or unlike other children up to three years of age, at which time, after wading in a spring branch for several hours, he was seized with a violent chill, followed by extremely high temperature and active delirium. A physician was called, and under his care the boy was quite well again in four days.

Some few weeks after this his mother observed the change in his voice. The gradual development of the sexual organs followed.

It was first known that he masturbated some six months ago. His father died of acute tuberculosis.

I shall not attempt an explanation of this curious perversion. A probable solution of the case is that during the short but severe fever his brain sustained some positive organic lesion which has since acted as an irritant to the sexual nerve centers.

## A CASE OF PRECOCIOUS MENSTRUATION.

By A. J. JAGOE, M. D.,  
HERNANDO, MISS.

ON August 14th a negro named Cobb called on me and stated that his daughter, not yet four years old, has been menstruating for over two years. She was born October, 1885, and in July, 1887, her mother noticed a discharge of mucus from the vagina. He took her to Dr. Westbrook, who prescribed, and in a few days the trouble was gone. Again came the discharge, and again the doctor "cured it," but the thing wouldn't stay cured, but kept returning, until my friend saw a periodicity in the attacks and cures, and informed its mother of the true state of the case. In a short time it became a regular menstrual discharge, normal as to time, quantity, and material. On my request the child was brought before our County Medical Society at its late meeting.

We found a well-grown negro child, very intelligent for her age, breasts fully developed, pubes wearing the adult garb, and the child actually menstruating. The parents are healthy, and forty-five and forty-three years old, respectively. The child is the tenth of their family, and there are two younger.

As none of us doctors here ever saw a case of the sort, and have read of but few, we send it for record.

September 16, 1889.

## THE NEW YORK MEDICAL JOURNAL, *A Weekly Review of Medicine.*

Published by  
D. APPLETON & CO.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, OCTOBER 19, 1889.

### "THE OPEN DOOR OF QUACKERY."

UNDER this title Dr. Eggleston, Dr. Flint, and Dr. Doremus, in the October number of the "North American Review," discuss the regulation of medical practice. So important a subject should be carefully studied, and whatever remedies are suggested should be practical. In the first place, it must be remembered that the National Government can not act in the matter. Dr. Eggleston seems to think it can, under what he calls the "general-welfare clause" of the Constitution. If that is so, then under the same clause it might regulate the kind of seeds to be planted by farmers. Dr. Eggleston's remark that Congress once made a State out of a part of one previously existing, without the consent of the latter, and in violation of the Constitution, does not seem relevant to the subject. The "general-welfare clause" can not be interpreted to mean that Congress shall regulate the practice of medicine in the several States. Possibly "to protect an American industry" the National Government might be persuaded to forbid the entrance of doctors from foreign lands, or to charge a light duty upon them, or regulate inter-State medical requirements; but it can not lawfully forbid every State to graduate doctors in such manner as it may choose, and so make a fool of itself in this matter if it wishes.

In the second place, any effort to regulate medical practice must be so directed as to appeal to the people. They must be made to see that it is best for every one to prevent certain men from obtaining licenses. Our Government is representative in the widest sense. The Government "of the people, by the people, for the people" may be said to be of the average, by and for the average. Good, bad, and indifferent alike are represented. The active forces are the small number of good and the possibly rather larger number of bad men in the country. The great majority belong to the "indifferent" class who do not think much, except in the lines laid down by the good or the bad, and who rarely *act* save under the lead of these.

When seeking to bring about a reform in such a matter as the practice of medicine, it is most important to see just what can be done, not alone what ought to be done. The legislative measures suggested must be constitutional and practical, which can be passed by the legislatures and do good when passed. In the first place, the measures must not be proposed in Congress. In the second, they must be of such a nature that the selfish interests of the majority of the State legislature be not antagonized. Thirdly, if possible, they should appeal to these same selfish interests; and last, but not least, they should be so framed as to accomplish something really raising the standard of practice.

The first point needs no more discussion. In regard to the second, it is possible that a bill might pass the New York Legislature forbidding the chartering of more medical colleges having the power to grant licenses to practice until the population of the State reached, say, twice its present number, or for a certain number of years. Such a measure might somewhat diminish quackery. Possibly, also, a State board of examiners might be appointed. The bill suggested by Dr. Flint, while good in many ways, would be hard to pass, since it provides for an "unsectarian" board. Now, the law ought not to recognize separate "schools" of medicine, but it does. Moreover, most of the people do. Dr. Flint's "unsectarian" board would mean to many a board composed of narrow sectarians whom they would designate as "allopaths." The fact stated by Dr. Flint that "there is but one science of medicine" would seem absurd to a large number of people. They think there are three—"allopathic," "homeopathic," and "eclectic." With the American love of "fair play" and the American "don't-care-a-damn attitude," the average legislator will see no reason why these three "schools" should not have a share in the examining board. The "County Democracy," "Tammany Hall," and "Irving Hall" are recognized as varieties of Democrats. Why are there not three kinds of doctors? Any way, the doctors don't count for much as voters, and it is hardly worth while for the ordinary politician to trouble himself about them; but if a bill is to be passed, he does not see why the "allopaths" should "have all the patronage." Moreover, a good deal of care will be taken by the homeopaths and eclectics and the various quacks that the legislator be clearly shown why the allopaths should not. They are "slow" and "narrow," these "old-school" men. Moreover, no more "monopolies" should be tolerated.

Suppose Dr. Flint's plan should pass the legislature, should we be better off? Of course, the plan would need more elaboration before being presented as a bill, for it is too vaguely worded, and leaves considerable doubt as to what is meant by several phrases; but it or any measure creating a board of examiners would help to sift out some of the worst quacks. Yet, an examining board would not cure the evil, for the reason that no examination can show a candidate's real knowledge or ability. Moreover, any such board, if not well paid, would not command the services of the best men, and, if well paid, would soon become the prey of politicians, medical and lay, who would rapidly destroy its efficiency. Still, a board would do something.

The most important thing, however, is to teach the people that their own interests demand good medical education. It takes long to do this, and it can only be done by again and again reiterating the idea. No law not supported by public opinion can be enforced. This opinion, on the whole, is right. To produce any real result the people must be shown again and again the folly of quackery until they begin to think about the matter. The moment public opinion is in favor of good doctors, it will cause laws to be passed which will check the present evils, and, moreover, will bring pressure to bear upon poor colleges, forcing them to improve.

We must not suggest violations of the Constitution. We must not hold up the idea of an examining board as a cure-all. Dr. Eggleston's statement of the countries in which national boards exist shows the absolute futility of such an idea, since we find Romania, Guatemala, Syria, Turkey, and Egypt among them. While many good doctors may be found in these countries, it will hardly be maintained that the average equal our own, or that our worst are as low as theirs.

It is doubtful whether, on the whole, the public can not take care of its own interests in this matter without the help of special laws. As a rule, the public is pretty shrewd. Whether we wish to pass a law or not, by all means let us explain to the people our own position, and show them what we believe to be best. If we are to have any improvement, it will be by our own efforts. Let us remember, however, that we live in a practical age among a very practical people, and we must not begin by proposing measures which can only be adopted if we accept the liberal ideas implied by the New York assemblyman when he asked, "What is a little thing like the Constitution among friends?"

#### CORONILLA, A NEW CARDIAC REMEDY.

A RECENT number of the "Therapeutic Gazette" gives some interesting facts and deductions in regard to coronilla, lately brought forward as a drug having a special action on the heart.

The *Coronilla scorpioides*, from which the drug is obtained, is an annual plant widely distributed throughout southern France, of the family *Papilionaceæ*, suborder *Coronillæ*. From experiments on animals, Cardot has determined that coronilla arrests the heart in systole. He cites four cases in which its use produced considerable amelioration in various cardiac affections. Recently Schlagdenhauffen, Gley, Reeb, and Spillmann have called attention to the drug. A glucoside has been isolated, termed coronillin, of which the toxic dose for a man weighing a hundred and twenty pounds would be about three quarters of a grain. At the same time Schlagdenhauffen and Reeb maintain that as much as two or three grains of coronillin must be administered to produce any therapeutic effect, or from nine to twenty-two grains of the extract.

Coronilla is said to act especially on the muscular tissue of the heart, increasing its contractility. In seventeen cases of heart disease Spillmann employed it during the asystolic period. In eight of these the remedy gave satisfactory results, while in seven it proved entirely inoperative. A diuretic effect was frequently observed, the daily amount of urine increasing from seven ounces to from two to four quarts. The therapeutic effect of coronilla, administered for three or four days in succession, became apparent in twenty-four or thirty-six hours after the ingestion of the first dose. The drug acts but feebly on the frequency and rhythm of the cardiac pulsations, but it is said to produce an increase in the amplitude of the pulse, an augmentation of diuresis, diminution of oedema, and improvement in respiration. The good effects of coronilla seem to be of the most transient character. In a day after the cessation of its use the patient returns to his previous condition. Thus the

value of coronilla is highly problematical, one author maintaining that three quarters of a grain of coronillin are a toxic dose, and another recommending from three to five grains. Further experiments are essential to test coronilla satisfactorily.

### MINOR PARAGRAPHS.

#### THE SUBCUTANEOUS USE OF ANTIPYRINE IN SCIATICA.

DR. OSHEROVSKY, in the "Proceedings of the Caucasian Medical Society" for 1888, reports upon the treatment of himself and three others, for sciatica, by the subcutaneous injection of a solution of antipyrine, with a small addition of hydrochloride of cocaine. He gave one injection daily of the solution, so that the patient received from six to eight grains of the former and an eighth of a grain of the latter. In his own case three such doses effected a cure. Of the other persons affected, one obtained relief only after three injections, but with two more recovery was accomplished. In another case there was double neuralgia of the thigh, for which he administered seven injections on the right and five on the left side. The remaining patient of his series, who had had left-sided sciatica for two years, obtained temporary relief only from the injections; it became necessary to supplement the treatment with a month's course of faradization, whereupon recovery was effected. Dr. Osheroovsky prefers the subcutaneous use of antipyrine, thinking that only palliative effects follow its internal administration. He holds that a speedier result is thus secured, and by smaller and less frequent doses. He has found no unpleasant accessory results—such as nausea, giddiness, or excitement—from this method of treatment, according to his own experience or in the reported observations of others.

#### FAULTY TITLES TO ARTICLES.

It is a fault in those who write for the journals, medical as well as others, to adopt meaningless headings to articles and paragraphs that have purpose and point. Dr. Billings has more than once shown how difficult it is for those who have indexing work to do to properly handle papers and articles which are indefinitely described by their heading. Nearly every medical man who has had research and collation to do, has found himself hampered by the apparently pointless head-lines of many writings. Of course, a pointless paper must have a meaningless title, but this sort does not commonly find its way into print. What assistance is there to the studious person who finds in the index of a periodical expressions like these, "An Interesting Case," or "A New Plan of Treatment," or "A Step in Advance," or "An Ethical Question," or a thousand others we have met with from time to time, but which we refrain from approaching too closely lest the teachings of this article be taken to have a personal bearing, which they assuredly have not?

#### THE MEDICAL SCHOOLS OF PHILADELPHIA.

THE "Medical News" states that the colleges of that city are increasing their facilities greatly this year. The Polyclinic has a contract under way for the construction of a new college, hospital, and dispensary building, the corner-stone of which will be laid early in November. The University Medical Department has a new Maternity, with a capacity for fifteen confinements each month. This is the one completed wing of the hospital that will not be carried out, in the entirety of its plans, for a year or two. The Jefferson Medical College will soon add another building to the cluster located at Tenth and Sansom Streets; a portion of the new structure will be for hospital en-

largement. A new autopsy building is now going up near the University Hospital for the use of that institution. It contains a theatre, modeled after that at the Johns Hopkins Hospital, for necroscopic demonstrations. These structures will be rather ornate in exterior and replete with every modern improvement within.

#### QUACK MEDICINES IN AUSTRIA.

ACCORDING to the "Occidental Medical Times," the police of Vienna have seized the entire stock of "Warner's Safe Cure," held by the pharmacists of that city. This was done not so much because of the character of the compound as because of the charlatanic advertisements which accompanied the nostrum. The agents for its sale had complied with the Austrian law, which directs that the formula of its composition shall be made known in regard to every proprietary medicine before it can be put on sale in the pharmacies. The "Pharmaceutische Post" is quoted as saying that the fault really lay in the quackish pretensions that were published in relation to the compound. Very severe rulings and examples have recently been made against certain preparations on that account.

#### PHENACETIN IN WHOOPING-COUGH.

NOT long ago we alluded to some favorable experience in the use of phenacetin in whooping-cough that had been recorded in a Munich periodical. From a recent issue of the "Archives of Paediatrics" a confirmatory opinion, by Dr. George C. Irwin, of Seetha, Kansas, may be cited, showing that the drug has proved beneficial in very young infants having pertussis. A child only three months old, with whooping-cough marked by severe hourly spasmoid attacks, got well under half-grain doses of phenacetin, dissolved in ten drops of glycerin. The relief was noticed from the onset of the administration, for on the first night after using it, a few times, at four-hour intervals the child obtained over six hours of good rest. In this case antipyrine, as well as other drugs, had been used without avail.

#### FALLING FROM A HEIGHT.

IN reference to an annotation in the "Lancet" upon this subject, a medical man, formerly a sailor, states that in youth he fell from the topgallant yard of a vessel, a distance of at least 120 feet. Sensation was entirely lost during his transit through the air. It returned slightly on striking the water, sufficiently to enable the lad to strike out (being a good swimmer) and seize a life-buoy. The writer thinks death would have been painless had he fallen on some hard substance; but the assertion that persons die in the act of falling is, he thinks, evidently wrong.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 15, 1889:

DISEASES.	Week ending Oct. 8.		Week ending Oct. 15.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	69	11	77	13
Scarlet fever.....	33	6	40	3
Cerebro-spinal meningitis.....	0	0	1	0
Measles.....	18	1	12	1
Diphtheria.....	67	19	64	20

**An Impostor.**—Members of the profession in the city and State are warned against a plausible stranger, who professes to be a secretary of the "Association of Commercial Travelers,"

and desires to secure the services of a physician to attend members of the association. He shows a thorough familiarity with the "Medical Register," and gives unexceptionable references, on the strength of which he solicits a small advance for the purchase of blank forms. He has already been quite active in this city and may seek other victims.

**The Chicago Medical Library Association** held its first regular meeting on the 4th instant, and Dr. N. S. Davis was elected to its presidency. We wish the movement great success. Nothing short of a large collection of books in a fire-proof domicile will satisfy our ideal of what Chicago should possess.

**Electricity in Extra-uterine Pregnancy.**—Dr. A. H. Buckmaster read a paper, on October 11th, before the Kings County Medical Association, on the many methods of applying electricity to the ectopic fetus. The subject is still under study by Dr. Buckmaster, and his results will be given to the association at a future meeting.

**The American Academy of Medicine** is endeavoring to make as complete a list as possible of the alumni of literary colleges, in the United States and Canada, who have received the degree of M.D. All recipients of both degrees, literary and medical, are requested to forward their names at once to Dr. R. J. Dunglison, Secretary, No. 814 North Sixteenth Street, Philadelphia.

**The Medical Society of the State of New York.**—The next annual meeting will be held in Albany, on the 4th, 5th, and 6th of February, 1890. The Business Committee consists of Dr. G. H. Fox, 18 East Thirty-first Street, New York; Dr. Henry Flood, of Elmira; and Dr. Herman Bendell, of Albany. Persons intending to read papers at the meeting should make application to some member of the committee before January 1st, stating the title of the paper. The time required for the reading of a paper should not exceed fifteen minutes.

**The New York Obstetrical Society.**—At the annual meeting, held on the 15th inst., officers for the ensuing year were elected as follows: President, Dr. J. E. Janvrin; vice-presidents, Dr. H. C. Coe and Dr. R. A. Murray; recording secretary, Dr. A. M. Jacobus; corresponding secretary, Dr. A. H. Buckmaster; treasurer, Dr. J. L. Morrill; pathologist, Dr. J. R. Nilsen.

**Changes of Address.**—Dr. Edward G. Janeway, to No. 36 West Fortieth Street; Dr. J. G. Hirons, to No. 36 West Thirty-third Street.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 29 to October 12, 1889:*

POINDEXTER, JEFFERSON D., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month. S. O. 113, Headquarters Department of Dakota, September 30, 1889.

ADAIR, GEORGE W., Captain and Assistant Surgeon. Leave of absence for one month granted in S. O. 90, Headquarters Department of the Platte, September 25, 1889.

POPE, BENJAMIN F., Major and Surgeon. Relieved from duty at Fort Clark, Texas, and will report for duty to commanding officer, Whipple Barracks, Arizona Territory. Par. 11, S. O. 230, A. G. O., October 3, 1889.

BILLINGS, JOHN S., Major and Surgeon. Detailed as delegate to represent the Medical Department of the Army at the annual meeting of the American Public Health Association to be held at Brooklyn, N. Y., October 22, 1889. Par. 10, S. O. 230, A. G. O., October 3, 1889.

TREMAINE, WILLIAM S., Major and Surgeon. Relieved from temporary duty at Fort Leavenworth, Kansas, and will re-

turn to his home, Buffalo, N. Y. Par. 18, S. O. 230, A. G. O., October 3, 1889.

KENDALL, WILLIAM P., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month. S. O. 93, Department of the Platte, October 2, 1889.

STEINMETZ, WILLIAM R., Captain and Assistant Surgeon. Ordered for examination for promotion. Par. 3, S. O. 236, A. G. O., October 10, 1889.

CARTER, EDWARD C., Captain and Assistant Surgeon. Granted leave of absence for twenty days. Par. 6, S. O. 234, A. G. O., October 8, 1889.

SMITH, A. K., Lieutenant Colonel and Surgeon. Leave of absence extended twenty-one days, on S. C. D. Par. 7, S. O. 234, A. G. O., October 8, 1889.

MUNDAY, BENJAMIN, Captain and Assistant Surgeon. Granted four months' leave of absence. Par. 2, S. O. 233, A. G. O., October 7, 1889.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the two weeks ending October 12, 1889:*

HARMON, GEORGE E. H., Surgeon. Detached from the U. S. Steamer Constellation and ordered to the Naval Academy.

LOWNES, C. H. T., Assistant Surgeon. Detached from the U. S. Steamer Constellation and ordered to the Naval Academy.

WINSLOW, GEORGE F., Surgeon. Ordered to the Marine Rendezvous, Boston.

HENRY, CHARLES P., Assistant Surgeon. Ordered before the Retiring Board for examination.

BRIGHT, G. A., Surgeon. Detached from temporary duty at the Naval Academy and placed on waiting orders.

**Marine-Hospital Service.**—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the six weeks ending October 5, 1889:*

FESSENDEN, C. S. D., Surgeon. Granted leave of absence for thirty days. October 3, 1889.

WYMAN, WALTER, Surgeon. Granted leave of absence for thirty days. September 3 and 21, 1889.

SAUTELLE, H. W., Surgeon. Granted leave of absence for seven days. September 26, 1889.

AUSTIN, H. W., Surgeon. Granted leave of absence for thirty days. September 9, 1889.

GASSAWAY, J. M., Surgeon. When relieved at New Orleans, La., to rejoin station at Cairo, Ill. September 30, 1889.

GOLDSBOROUGH, C. B., Surgeon. Leave of absence extended thirty days on surgeon's certificate of disability. September 16, 1889.

ARMSTRONG, S. T., Passed Assistant Surgeon. Relieved from duty at New York; ordered to command of Service at Cleveland, O. September 17, 1889.

AMES, R. P. M., Passed Assistant Surgeon. Assigned to duty at New Orleans, La., upon expiration of leave of absence. September 30, 1889.

WHITE, J. H., Passed Assistant Surgeon. Leave of absence extended thirty days on surgeon's certificate of disability. September 21, 1889.

NORMAN, SEATON, Assistant Surgeon. Granted leave of absence for thirty days, to take effect when relieved. October 4, 1889.

PETTUS, W. J., Assistant Surgeon. Ordered to Portland, Me., for temporary duty. September 26, 1889. Granted leave of absence for twenty-six days, to take effect when relieved. October 3, 1889.

KINYOUN, J. J., Assistant Surgeon. Granted leave of absence for thirty days. September 21, 1889.

### Society Meetings for the Coming Week:

**MONDAY, October 21st:** New York Academy of Medicine (Section in Ophthalmology and Otology); New York County Medical Association; Medico-chirurgical Society of German Physicians; Hartford, Conn., City Medical Association; Chicago Medical Society.

**TUESDAY, October 22d:** New York Academy of Medicine (Section in Laryngology and Rhinology); New York Dermatological Society (private); Buffalo Obstetrical Society (private); Medical Society of the County of Putnam (quarterly), N. Y.

**WEDNESDAY, October 23d:** New York Surgical Society; New York Pathological Society; American Microscopical Society of the City of New York; Medical Society of the County of Albany; Philadelphia County Medical Society.

**THURSDAY, October 24th:** New York Academy of Medicine (Section in Obstetrics and Diseases of Women and Children); New York Orthopædic Society; Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private).

**FRIDAY, October 25th:** Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

**SATURDAY, October 26th:** New York Medical and Surgical Society (private).

## Proceedings of Societies.

### NEW YORK ACADEMY OF MEDICINE.

*Meeting of October 3, 1889.*

The President, Dr. A. L. LOOMIS, in the Chair.

**The Pathological Anatomy of Chorea.**—Dr. C. L. DANA, in the course of an exhaustive paper on this subject, dealt especially with the pathological anatomy of the nervous centers in chorea. He said that the changes elsewhere, particularly those in the heart, had often been described, and there was a pretty definite agreement that the most uniform condition in patients dying of chorea or with chorea was fibrinous deposits on the valves of the heart, usually the mitral. Osler thought that this occurred in ninety per cent. of cases. He would not take up this particular point, but turn to the nervous side of the question and report a case in his own practice:

William G., single, Swiss, aged eighteen years, had come under his care December 15, 1888; family history unknown. Patient had always been weak and sickly as a child; had no remembrance of having had any of the ordinary children's diseases; gave no rheumatic, venereal, or alcoholic history. He had begun to have choreic movements twelve years ago; cause unknown. The movements had not been severe, and when at the age of twelve he had come to this country he had been able to work and be useful. The patient had suffered from so-called epileptic attacks at occasional intervals for many years. The attacks had at first occurred at night only, but of late had come on during the day also. They had begun with a shrill cry. The patient had to be examined physically in his bed, as he was unable to walk or help himself on account of the violence of the choreic movements. He was somewhat emaciated and anaemic, face dull, expression stupid, but answered questions

intelligently, though his speech was slow and jerky, on account of the movements of his lips and tongue. Over the left parietal bone there was a hole of about the size of a half-dollar made by a trephining operation performed in San Francisco fourteen months before his admittance to the hospital. No history of any form of paralysis. No heart murmurs. Lungs and abdominal viscera normal. Examination of urine negative. The epileptoid attacks at this time were of great violence and frequency and hysteroid in character. Chloral hydrate and stimulant feeding were ordered. On December 20th, five days later, hysterical attacks were less numerous, occurring only at night; chorea jerkings less, so that the patient could feed himself. On December 28th, thirteen days after admission, the attacks had ceased altogether; the chorea was better, the patient sat up, read, and talked, and continued to improve until January 6, 1889, when pneumonia developed, and he died January 8, 1889. The autopsy showed rigor mortis well marked; the body was considerably emaciated; the left lung was beginning to exhibit pneumonic changes. The heart was normal; no vegetations on the valves. The liver and spleen were normal. The kidneys were small, the capsules adherent and thickened. The skull was brachycephalic in shape and extremely thick, measuring seven eighths of an inch on section through the occipital bone. The old trephine hole lay over the left inframarginal gyrus. The dura mater was very adherent; the pia mater was thickened and congested, but not markedly adherent to the cortex. The brain looked normal, except for a very superficial softening seen on the under surface of both temporal lobes. The cord was apparently normal. The brain, the cord, and pieces of the sciatic and in musculo-spiral nerves and of the biceps muscle were saved for further examination. The brain, cord, and nerves were placed in Müller's fluid, which was frequently changed, and at the end of three months for the cord, bulb, and nerves, and five months for the brain, they were placed in alcohol. Sections through the motor convolutions, corpus striatum, optic thalamus, pons, bulb, and cord were made. They were then cut and stained, Weigert's stains being used. The examination of the convolutions and subcortical white matter showed a slight amount of leptoeningitis; the gray matter was considerably injected; the neuroglia cells were not excessively increased. Pyramidal cells mostly normal; an occasional cell might be found undergoing pigmentary degeneration.

The chief changes to be noticed were just beneath the cortex; here the white matter was in some sections honey-combed with little spaces, round, oval, or like long slits. These spaces were either empty or partly filled by blood-vessels. The walls of the blood-vessels were somewhat thickened, though no real arteritis was present. They had, however, been tensely distended, and exudates, including red blood-cells, had been poured out; this had distended and eroded the circumvascular spaces, forming large dilatations similar to those described by DICKINSON. The process, though chronic, could not be looked upon as inflammatory, and it could only be explained by assuming a flabbiness and loss of tonus of the vessel-walls due to prolonged distension, allowing abnormal dilatation and filtration of the vessel contents. There was no hyperplasia of connective tissue and there were no amyloid bodies. At the base and tip of the temporal lobe, where the surface was softened, a severer grade of meningitis was present, and the superficial layers of the cortex showed evidences of disintegration; the ganglion could be seen, but the white matter beneath was more extensively honey-combed, and there was evident increase of neuroglia cells. The basal ganglia and internal capsule did not appear to the naked eye so much involved as the subcortical tissue. The middle portions did not harden well, and only the optic thalamus, the lower part of the internal capsule, and the anterior part of the cau-

date nucleus could be examined microscopically. These parts showed the same honey-combed appearance, though less marked than in sections higher up. There could also be seen the small arterioles which had formed varicose dilatations, which were full of blood. The internal capsule showed more serious disorganization; its fibers were split up by interlacing and dilated blood-vessels, whose walls were thin, degenerated, and ready to drop to pieces. Varicosities of the nerve fibers, such as had been described by Berkley, were found. The corpora quadrigemina were dotted and streaked with dilated capillaries, but showed no large circumvascular spaces. In the crura cerebri, at the level of the third nerve, there was a lesser degree of vascularity than at higher levels; the cells of the nucleus were normal, as also was the descending part of the fifth nerve. In the pons the nucleus and nerves of the fourth pair contained few cells, and some of these seemed to be degenerated. The cells of the motor nucleus of the fifth nerve were normal; their blood-vessels were numerous and dilated, and their walls thicker than those seen in the brain. In the upper medulla a neuro-fibroma of the size of a pea was seen just at the exit of the acoustic nerve on the left side, the fibers of the nerve passing around and through it. The only nerve nuclei in which signs of degeneration could be detected were those of the vagus, including the anterior nucleus and accessorius. The gray matter of the floor of the fourth ventricle was much honey-combed with cavities made by dilated arteries. In the pyramidal tracts there was apparent increase of connective tissue. The neuro-fibroma referred to had not destroyed any parts by pressure. The pia mater of the cord was thickened, somewhat adherent, and filled with distended vessels. In the lateral columns of the cord the vessels were most numerous, but there was none of the honey-combed appearance that was found in the brain and pons. The anterior and posterior roots showed no degenerated fibers. No degenerative or inflammatory changes were found in the sections of other nerves.

*Summary.*—In the brain, chronic leptomeningitis, non-adhesive, and therefore not severe. Diffuse and varicose dilatation of the small arteries, especially of the deeper subcortical matter and capsule. Degenerative changes in the arterial walls; no arteritis. Circumvascular lymph spaces greatly dilated. Cortical cells in most regions normal. The severest changes—vascular, interstitial, and degenerative—were in the lower surface of the temporal lobes, in the internal capsule and adjacent parts of the corpus striatum, especially the lenticular nucleus, and optic thalamus, the antero-internal part. Varicose nerve fibers. Cell degeneration in some of the cranial nerve nuclei. Slight connective-tissue increase in the pyramidal tracts. In the spinal cord, slight lepto-meningitis; congestion of the cord, especially in the lateral columns. Double central canal.

The speaker then reviewed the literature bearing upon his subject, and gave the results deduced from tabulated statistics of pathological findings collected from all available sources. In concluding his elaborate paper, he asked what inferences could be drawn from the pathology. There were at least two things which would determine chorea—the existence of an abnormal state of the blood and an intense cerebral hyperæmia in certain localities of the brain, and a neurotic history. Therefore should we not logically combine a humoral and a neuropathic theory in order to explain chorea? A neurotic child with a tendency to rheumatism or some allied self-intoxication received a fright or a fall. There supervened a vaso-motor paralysis of those motor tracts which in the child were so rapidly developing and so actively used, and therefore so sensitive to strains put upon them. The blood, if impoverished and rheumatically tainted, increased the irritation, and the vascular tonus was gradually

lost and a permanent hyperæmia of the parts would take place. Chorea might be called, therefore, a kind of *Schreck* or traumatic neurosis occurring in children with impoverished or rheumatic blood. He thought, also, that it might be maintained that chorea had an anatomical basis too well marked to be any longer considered simply as a functional disease.

Dr. M. ALLEN STARR thought that the collated facts were most valuable. He had been rather inclined to favor the infection theory in chorea, though he must admit that there were many objections to it. Still, we could not afford to throw it aside without very careful examination. Its acceptance would coincide with what had been said by the author of the paper, because it was well known that a neurotic person in a condition of bad blood would be more susceptible to infection by germs if such really lay at the base of chorea. There were three well-authenticated cases in which the investigators had discovered the existence of micro-organisms, and he thought that every case should be examined for the purpose of obtaining additional evidence. There was no reason why the vascular lesions referred to should not have had micro-organisms as a first cause. Then it was a difficult thing to determine whether the cases in which death occurred and those in which the patients survived were exactly the same in their pathology.

Dr. MARY PUTNAM JACOBI said that two more fatal cases had been reported by an English physician, coinciding with the remark Dr. Dana had made as to the predominance of fatal cases in England. In one of these, in which the autopsy had been recorded in detail, the lesions of the brain consisted largely of a diffused pink color throughout the nerve tissue, but this did not seem to be associated with congestion or dilatation of the vessels. This particular color had been described by a recent writer, and it agreed with Dr. Dana's idea as to the existence of an abnormal condition of the blood as a factor. In Hanford's case lesions had been found in the cervical, dorsal, and lumbar cord, consisting of thrombi of small vessels, foci of haemorrhage, and vascular dilatations. The speaker said she thought that among the other reasons which might be urged against the exclusively infectious origin of the disease was its frequent origin in mental emotion and shock. It seemed impossible that bacteria lay in wait for such cases. Dr. Dana's case seemed to have implied a congenital imperfection of nerve centers.

Dr. W. R. BIRDSALL said he thought that Dr. Dana had certainly added facts to the pathological anatomy of chorea. While, however, he was willing to admit the importance of findings, still the question as to the interpretation of such findings was what we all sought to solve. Were these findings the cause or were they the result of deranged action in nerve centers? Similar lesions were found following a variety of nerve changes—such as epilepsy and other convulsive disorders. The inference, then, was that the findings were the result rather than the cause. A preconvulsive stage had been described, in which it was said there existed a slight disturbance of the nasal mucous membrane. There were other cases which seemed to favor the infection theory. The ocular muscles had been made responsible for a brief period and recognized as a chorea-producing factor in some instances. The majority of cases occurred in childhood, when the voluntary movements were not so well organized and slight disturbances once started might readily be followed by gross changes after a long period.

The PRESIDENT thought that any physician with the large experience of general practice must have noticed the close relation between chorea and infective diseases. That there was a condition in certain subjects—a nervous, hereditary, or acquired condition—which predisposed them to easy unbalancing of the nervous system, seemed to him evident. This occurred very largely in families of considerable neurotic history. But, in ad-

dition to this, it was largely associated with some cardiac phenomena or occurred as a sequel to some infection. He thought that two thirds of the cases of chorea were connected with a rheumatic history. Rheumatic symptoms did not always develop before the chorea, but they did afterward. Whenever he came across a case of chorea he examined the heart, convinced that he should find some lesion or irregularity in that region. He should be loath to regard the pathological lesions just recorded as the cause of chorea. They were seen in so many other diseases differing very little from the pathological records, which we found at one time, of diseases classed as functional. Unless the changes were constant and fixed, there was hardly enough to establish a pathology.

Dr. DANA, in reply, said he had not touched upon the microbic theory. He had been inclined to favor it when first advanced, and had only failed to enlarge upon it in his paper because it was so very far from being sufficiently demonstrated to afford a basis for any definite statements. He regretted that the president had not told them in what classes of disease the identical pathological changes alluded to occurred. He thought the findings of Sydenham pretty uniform, while those cited by Dr. Jaeger were very much the same as already reported by Dickenson. Whether these changes were the cause of chorea depended upon what we understood by the term "cause." He did not suppose that the changes took place without some primary cause. He had not spoken of these pathological changes as the primary cause.

#### AMERICAN DERMATOLOGICAL ASSOCIATION.

*Thirteenth Annual Meeting, held at Boston, on Tuesday, Wednesday, and Thursday, September 17, 18, and 19, 1889.*

The President, Dr. I. E. GRAHAM, of Toronto, in the Chair.

**The Prevention of Skin Diseases** was the subject of the annual address by the PRESIDENT. The speaker made special reference to the form of prevention which the passing of sanitary laws made necessary. He instanced scabies as a disease in which much might be done to prevent contagion if proper and stringent laws were passed. He alluded to the fact that White, of Boston, in an address before the association several years ago, had urged the advisability of having the school-children examined at regular intervals in reference to this disease. A similar course might be followed with advantage in the case of children who were admitted to charitable institutions. Tinea tonsurans was mentioned as another disease whose spread might be much lessened were such examinations carefully carried out. The same truth held even more forcibly with reference to two other diseases—viz., syphilis and leprosy. The former disease numbered its innocent victims by thousands, and yet few well-directed attempts had been made to eradicate it. In those countries where laws had been enacted to such an end little had really been accomplished. Public sentiment had not been roused to the need of such action. Where attempts had been made to have periodical inspection and registration, the ends had been defeated by clandestine prostitution; and yet, if such registration were possible, we might reasonably suppose that the ravages of the disease would be lessened. At the present time it was unwise to advocate any legal measures, since the larger portion of the community was directly opposed to such a plan. The speaker would suggest two methods by which a partial control might be gained—viz., early diagnosis, and proper facilities for treating such patients in our large general hospitals. They should be received into special wards in hospitals rather than into special hospitals. They should be treated with the same consideration as all other patients, so that they might not hesi-

tate to apply for admission. It was often said that the public money should not be used in this way, but it should be considered that in allowing these patients to remain at large there was a still greater danger. A third way of preventing syphilis was by the careful examination of all wet-nurses. In Moscow, where such a system was enforced, 17 per cent. of the applicants for registration exhibited suspicious signs, and 4 per cent. were undoubtedly affected with syphilis. The regular examination of soldiers and sailors, together with care in regard to inoculation by vaccination or in circumcision, was alluded to as of interest in this connection.

The reader questioned whether there were not grounds for alarm at the present time in reference to the spread of leprosy in this country. What means of protection, if any, should be taken against it? There was no question about the contagiousness of the disease, as proved by its rapid spread in the Hawaiian Islands, by the inoculation of persons previously healthy, and by the fact that a *Bacillus lepræ* had been discovered. The germs had been introduced with food, and possibly also by inhalation. Formerly hereditary transmission was considered the only method; but probably it was the predisposition which was inherited. Cleanliness seemed to be a preventive, but in the most favored nations there were certain individuals who became affected. Thus far our own country was not greatly crowded in population, but on the Pacific coast the Chinese were recently becoming very extensively invaded. It would appear that if one leper was allowed to live in a crowded district, the disease was found to be spreading in a very few years. In this country it might perhaps spread insidiously, and be widely scattered before we were aware of it. In India there were said to be a quarter of a million of cases, and in this country it was reported to have increased fivefold within the last ten years. There were two methods of prophylaxis against leprosy—viz., the prevention of new cases coming in, and the isolation and care of those already here. All immigrants should be examined, and those with leprosy sent back to their homes. Doubtful ones should be placed under observation for two or three years at least. The only successful method of controlling the disease was by the segregation of the lepers and their complete separation. That such a step was difficult was shown by the history of the laws in New Brunswick. It was almost impossible to have the patients enter the hospital. When we considered that the disease was now found in the Canadian provinces, in the Southern States and in Mexico, in California, and also in the heart of the country, there seemed to be a good opportunity for its wider spread among us.

In closing his remarks, the president suggested that it was advisable to have the meetings of the association in the large centers of population, so that rare cases of disease might more commonly be seen and shown. He suggested the desirability of limiting the discussion of a single meeting to one or two topics. Allusion was made to the fact that during the past year the first Congress of French dermatologists had met in Paris, and the first meeting of a similar German Congress had been held in Prague, and it was predicted that we might expect abundant fruit in future years as the result of the labors in these organizations.

**Clinical Notes on Herpes Zoster.**—Dr. F. B. GREENOUGH, of Boston, read a paper thus entitled. It comprised statistics drawn from a series of 235 cases of the disease occurring during the past sixteen years at the Boston Dispensary, the total number of patients with skin diseases treated during that time being 17,741. The ratio was therefore a little less than 1·5 per cent.; 45 per cent. had been males. The most frequent age had been from ten to fifteen, which was a surprise to the author. It had been found that the greater proportion of cases had oc-

curred in the spring months, with very little variation in the separate years. The author considered as well proved the intimate connection between the disease and some involvement of the nervous system, as shown by the distribution of the eruption and the occurrence of the neuralgic pains. It was an interesting fact that more pain was felt in proportion as the age of the patient increased. In 17 cases without pain the average age had been nineteen years; in 13 cases of those who suffered pain the average had been twenty-eight years; and in 19 cases where the pain had been mentioned as severe the average age had been forty-four years. In each division, however, there had been individual instances of wide variation from the average.

Another very interesting inquiry related to the question whether the sensitive fibers only of the nerve were affected, or the motor nerves as well. Generally the zoster accompanied the superficial branches, which had no motor fibers. But the author had seen two cases of marked facial paralysis accompanying zoster of the face or head. Both patients had recovered perfectly though slowly. In the second case the herpes had appeared about the left ear, accompanied with marked pain in the ear. It would seem that the direct nervous connection was sufficient to account for the facial paralysis. In one case where the lesions had appeared to pass beyond the median line of the back there had been found to be a spinal curvature. In some cases there had appeared to be a very slight overstepping of the median line over the sternum. Sometimes there had been a haemorrhagic tendency, but such cases had not appeared to be more severe, although they might have caused a little more discomfort. The size or angry appearance of the vesicles made no difference in regard to the amount of cicatrix which would follow. There were certain cases where it was very difficult to distinguish between the progenital or the labial form of herpes and the true zoster. The reader did not think the eruption could be aborted or the disease shortened. Irritation should be avoided, and the vesicles should not be broken. A large diachylon plaster would sometimes be of benefit.

Dr. G. H. Fox, of New York, spoke of the aetiological value of violence in reference to the attacks of herpes. It had been his experience that in almost every case where the history was carefully obtained some injury could be discovered. The relationship was so intimate that he considered it one of cause and effect. In the way of treatment he had found nothing so good as the constant galvanic current. No remedies which he had given seemed to influence the disease, and he had found that many cases would come to a speedy termination without any treatment at all. Some years ago he had given *Rhus toxicodendron* in one case and the eruption had disappeared at once. In subsequent cases, however, the result had been far different. Two or three applications of the current might be sufficient to render the patient entirely comfortable until recovery took place.

Dr. A. R. ROBINSON, of New York, did not think the disease should be strictly classed as a neurosis. It seemed to him that it was an infectious disease, like pneumonia. It had a definite duration, and generally appeared but once in a lifetime. He did not believe that trauma would be a sufficient cause for it. The speaker had seen one case where both sides of the face were affected, occurring during the course of a croupous pneumonia.

Dr. J. ZEISLER, of Chicago, asked in reference to the production of the disease by arsenic. He had lately seen a case of Hodgkin's disease which had been treated with arsenic, where, after the tumors had nearly disappeared, a crop of herpes vesicles had come out in the gluteal and femoral region. The speaker instanced one case where there had been perfect anal-

gesia over one side of the face, and at the same time a prickling and burning sensation over the same portion of skin. Perhaps this would be a corroboration of the statement that sensitive fibers had different terminations in different points in the skin.

Dr. P. A. MORROW, of New York, asked if the hyperesthesia and analgesia had been upon the same surface.

Dr. ZEISLER replied that they had been upon the same area although it was impossible to say that they were at the same exact point.

Dr. MORROW remarked that the temperature sense and pain sense were generally lost at the same time. The observation seemed to him a very interesting one.

Dr. E. B. BRONSON, of New York, said that to him there was an unsolved mystery about the aetiology of the affection. It seemed to occur with a regularity that was opposed to the idea of its infectious nature. There had been epidemics of the disease, and yet it did not seem to depend on the factors—such as season and temperature—which influenced other infectious diseases. The local character of the lesions also militated against the infectious origin. In diphtheria we could see how the poison reached the point where the effects were noticed, but in the case of zoster it was difficult to suppose that the germs could locate themselves in the nervous ganglia. The paralytic phenomena were not easily explained, especially in that form which affected the facial muscles; in the extremities the same result was more easily accounted for. The speaker had seen two of these cases, in one of which the different phenomena had been so closely connected in time that it had seemed as if the same cause had produced both of them. In one case he had thought there might have been an inflammation of the Gasserian ganglion, with extension of the inflammation through the plate of bone which separated it from the intumescentia gangliformis, but perhaps it was more reasonable to suppose that it was reflex in its origin. The speaker had used successfully a solution of gutta percha in chloroform, finally sweeping over the part a wisp of absorbent cotton, a few fibers of which would cling to the surface. It seemed to him that under this mode of treatment the process was sometimes arrested.

Dr. S. SHERWELL, of Brooklyn, believed in the protective dressing, and thought that the continued current was capable of giving great relief. Some patients were of rheumatic tendency, and this should be looked out for.

Dr. W. A. HARDAWAY, of St. Louis, asked about the occurrence of chronic zoster, and related the history of a man of sixty years, who had exhibited an eruption of zoster on both sides of the neck. The speaker believed in galvanism, but was inclined to question whether the whole effect was due to electricity, or whether mental effect might not play some part. He instanced the case of a woman who had been given an application of the electrodes for the relief of a severe attack of supraorbital neuralgia. The result had been a happy one, and the patient had gone away absolutely without pain; he had discovered afterward that he had neglected to immerse the element. The speaker had found nothing so good for the local treatment as a protective dressing in the shape of collodion. He objected to the use of greasy ointments, which macerated the vesicles, so that the tops were rubbed off, and sores were more apt to follow.

Dr. L. D. BULKLEY, of New York, remarked that the disease was seen in almost the same proportion in New York as in Boston, a trifle over one per cent., and remaining the same year after year. It seemed strange that there were so few cases where both sides were affected at the same time. He had seen zoster on the persons of those who had exhibited the scars of a previous attack. He did not believe the affection was a local manifestation of a general disease, but that it was reflex and of

traumatic origin. The reason why it so frequently appeared at the waist was because of the separation of the clothing in both men and women, and the consequent liability to the effects of cold. In one case of lymphoma of the neck there had come on an extensive zoster over the course of the nerves, passing through the growth. It had been a frequent experience with him that persons taking arsenic were affected with the disease. His treatment was to bandage the part as tightly as possible with a swathe on the inside of which a good amount of starch had been sprinkled, and have the whole sewed on. This was left on for a week, and gave great relief, without any other treatment.

Dr. H. G. KLOTZ, of New York, did not agree in the view that made the disease an infective process. Croupous pneumonia, which was an example of such diseases, was sometimes the result of trauma. In two cases of zoster that he had seen the lesions had become gangrenous. Both these patients had had syphilis, and in one of them the disease had been supposed to be a syphilitic ulcer.

Dr. ROBINSON did not mean to assert that an infectious process was necessary for the appearance of the eruption. He had seen a well-marked case of zoster where Pott's disease had been the starting-point of the irritation.

The PRESIDENT reported a fatal result in a case of zoster affecting one side of the face—the cheek and lower lid. On the fourth day the pain attacked the other side of the face, and on the fifth day the patient suddenly died. At the autopsy there was found a softened condition of certain parts of the brain. The Gasserian ganglion and a portion of the fifth nerve were found to be inflamed, and lepto-thrix threads, together with single bacteria, were found in some of the arterioles of the former structure.

Dr. GREENOUGH said that he had no data in reference to the effect of the ingestion of arsenic in the formation of zoster. He considered the coexistence of pain and paralysis as due to the intimate anastomosis between the nerves, although there might be a certain amount of reflex action.

(To be continued.)

#### NEW YORK STATE MEDICAL ASSOCIATION.

*Sixth Annual Meeting, held in New York, September 25, 26, and 27, 1889.*

The President, Dr. W. T. LUSK, of New York, in the Chair.

The meeting being called to order and a number of business matters disposed of, the reading of papers was begun.

**Inversion of the Uterus; Novel Treatment.**—The writer, Dr. G. E. FELL, of Erie County, explained his method of irrigating with warm water, while employing manual pressure, for returning the inverted uterus, citing a case of partial inversion returned in five minutes. In answer to a question, he replied that the history of a previous labor in this case was that the forceps had been used and the uterus pulled bodily into the world, though of this he had known nothing until afterward.

**The Latero-dorsal Posture in Gynaecological Irrigation.**—Dr. FELL also read a paper on this subject. The author made use of what was practically Sims's posture, bringing the buttocks of the patient over the edge of the table or bed.

**Pelvic Cellulitis in Women.**—Dr. W. H. ROBB, of Montgomery County, read a paper on this subject, in which he said that he had selected the term pelvic cellulitis because it conveyed more clearly the nature of the diseased tissue. The cellular tissue of the pelvis did not differ in anatomical structure from other cellular tissue. Much of the lower surface of the peritoneum came directly in contact with the cellular tissue of

the pelvis. No inflammation of any magnitude could well exist in one without affecting the other. The medical profession was divided as to the location and importance of pelvic cellulitis. Some thought the connective tissue of the pelvis never suffered from uncomplicated inflammation. Dr. Gill Wylie had said that if one excluded the diseased glands, tubes, and ovaries, there would be no mysterious inflammations. The author considered that pelvic cellulitis existed as a separate and distinct disease, though the pathology differed in no way from inflammatory processes in the areolar tissue in other parts of the body. The duration of the disease varied much. In one patient it would pass through its stages rapidly, and in another the stage of effusion would last for months or years. The causes of pelvic cellulitis were not infrequently the absorption of septic material. After giving a *résumé* of the symptoms, course, and duration of the disease upon the basis of its usual subdivision into three stages, he went on to indicate the line of treatment which he recommended. In the acute, or first stage, he employed veratrum viride. This he found reduced the pulse, lowered the temperature, and, he believed, would abort many attacks, if given at once and with regularity. If the attacks were following either labor or abortion, he would curette the uterus, then carefully wash out the organ with a one-to-twenty solution of carbolic acid, and introduce iodoform. The treatment of the third stage should be directed to supporting and stimulating the patient. After suppuration occurred, the pus should be removed. If the patient was not suffering from its retention, it was well to wait till it depended to the most favorable point where it could be removed by the use of the knife. The cavity should then be washed out. It was sometimes necessary to follow up tortuous sinuses and make a counter-opening.

Dr. H. O. MARCY, of Boston, said he must take views opposite to those of the author of the paper. After reviewing the physiological function of the connective areolar tissue of the pelvis, he said we had now reached a point when inflammatory processes were pretty well demonstrated as being traceable to some form of micrococcus or bacteria. The tubes, uterus, ovaries, or anything else might be originally involved, the infection finding its way from any of these. The consensus of opinions by the best authorities was that these pelvic inflammations were due to some form of micrococcus. We cured the uterus. Why? To remove this cause. We introduced iodoform. Why? To destroy this factor, which the author of the paper admitted was present. This was simply following along the lines of modern surgery, which endeavored to arrest the progress of infection that came from without. He thought we were simply feeling about for a name to a disease which we ought to know more about.

Dr. E. M. MOORE, of Monroe County, said that he should like to advocate the use of the aspirator in this affection. It gave immediate relief. When we came to drainage we should be dealing with a small cavity instead of a large one. It was, in his opinion, vastly better to aspirate than to employ drainage. With reference to the pathology, Virchow had been disposed to confine it to this very connective tissue everywhere. That the morbid process could extend from operations on the cavity of the uterus had been the speaker's unpleasant experience.

Dr. E. D. FERGUSON, of Rensselaer County, said the operation of aspiration was so simple and so satisfactory that it had a large field of usefulness, but when we came to pelvic surgery it was essential that we should know what we were doing. In other words, by an incision carefully made, layer by layer, it was possible to recognize when we came to parts in the dissection which should be placed on one side and protected. Whether the aspirator or knife was used, he did not think there would be any different effect on the course of the disease, provided

care was taken to keep the cavity free from septic influences. In Dr. Moore's case something had probably been added to the cavity.

Dr. J. CRONYN, of Erie County, referred to subcutaneous injections of morphine as a curative agent as compared with crude opium. Morphine had never in his experience been able to take the place of opium. He advocated its administration with quinine, and, when so used, found that both cinchonism and narcotism were avoided.

Dr. ROBB, in reply, said that, so far as the aspirator was concerned, he had known it to be used where no pus existed, and its simple use not infrequently induced further inflammation. His own opinion would favor opening the abscess freely when it pointed in a suitable position. In regard to the use of veratrum, his experience showed better results than from any other remedy. Opium he often found could not be taken into the stomach, and it was to avoid this that morphine was used subcutaneously when a patient was suffering torture from abdominal pain.

**Laparotomy for Ruptured Pyosalpinx; Error in Diagnosis; Recovery.**—Dr. C. S. Wood, of New York County, reported this case. He thought we owed it to the profession at large as well as to ourselves to report errors. He condemned too reckless a performance of laparotomies, directing his strictures particularly against oophorectomy. Women were unsexed and left in a worse condition than before. Should not we as physicians raise our voices in protest against this great sacrifice of women's ovaries when the diseased condition could often be cured by therapeutic and hygienic treatment alone? The case he had to record was one in which an operation had been indicated and justifiable. Mrs. M., twenty-eight, parentage unknown, of previous good health, had suffered from colicky pains and more or less fever; pain had been intermittent. She had been sent away for a time to Saratoga and had been thereby benefited. On May 9th he was called to see her on account of slight fever. He found some local tenderness and tympanites which were attributed to gastric disturbance. On the following day the pain and tenderness had increased. The symptoms progressed until perityphilitic abscess, in course of formation, was diagnosticated. Routine treatment had been followed. On May 16th he was called in haste. The messenger reported the patient to be dying. On reaching the house, he found her in condition of collapse, bathed in perspiration and unable to lie down, and making constant efforts to vomit. The pulse was rapid and irregular. After quieting her he was told that she had awakened suddenly with nausea and vomiting. This had been followed by a severe chill. The pain was higher up in the bowels than it had been before. Induration was found to be lessened. Being satisfied that there was rupture of a perityphilitic abscess into the peritoneal cavity, and that laparotomy was her only salvation, the writer sent for Dr. Gill Wylie, who, with his brother, performed laparotomy the same day. No abscess was found; there was no tumor and no inflammation in this region; only diffused inflammation and old inflammatory processes evidenced by thickening. A pyosalpinx of the right side, which had ruptured, called for removal of the sac and ovary. Degenerative changes on the opposite side also indicated the same procedure, which was carried out, the patient making a good recovery in the course of four weeks. The speaker thought the case would fairly represent the difficulty frequently met with in accurately diagnosing abdominal diseases. He had learned afterward that his patient some five years before had undergone an abortion, which might have accounted for the conditions found in the pelvis.

Dr. EDIBONIS said that the issue in the case hinged upon the diagnosis between pyosalpinx and perityphilitic abscess. The

tumor of perityphilitic abscess could almost always be found midway on a line drawn from the anterior spine of the ilium to the umbilicus. These abscesses could rarely, if ever, be reached from the vagina until they were of large size. By passing the middle finger of the examining hand into the rectum and the index-finger into the vagina we could reach higher. He had often found a perityphilitic abscess six or seven days old developed enough to enable him to reach it, whereas a pyosalpinx could never be reached in that way.

**Tubal Pregnancy.**—The PRESIDENT read a paper on this subject. (See page 421.)

Dr. WILLIAM GOODELL, of Philadelphia, said that he was not in a position to discuss the dicta of Mr. Tait. As he understood the argument, the ovum was always fecundated in an outlying cavity, and it was through disease of the tubes that the ovum was retained. He did not know that he could entirely accept this. As to the frequency of extra-uterine gestation, it probably occurred much oftener than the profession were willing to accept. Dr. Formad, of Philadelphia, was one of the coroners of that city. He had nineteen specimens of cases of extra-uterine pregnancy. These he had obtained from subjects upon whom he had been called upon, by virtue of his office, to make post-mortem examinations where the women had died suddenly. Then add to these the cases supposed to be haematocele. He could add but little to the statement made by Dr. Lusk as to the pathology. He was disposed to accept the theory that these pregnancies were all tubal originally; they might become intra-ligamentous, and ventral through a second rupture. If an ovule could travel over to the other side, why could it not drop into the cavity of the abdomen? Still he was willing to accept Mr. Tait's opinion that they were tubal. In reference to the intra-ligamentous form, where, after a few weeks, an ovum burst into the broad ligaments between the two layers of the peritonæum, he described it as behaving like an intra-ligamentous cyst, stripping the peritonæum from its various surfaces of reflection. In that way extra-ligamentous gestation came about. It might get in between the layers of the meso-colon or mesorectum, in which case there were often faecal fistulae. In the removal of the intra-ligamentous cysts he had had faecal fistulae result in every case. As to the clinical history, there was usually suppression or irregularity of menstruation, sometimes menorrhagia, or again only a mere dribbling. This latter always led him to believe he had to deal with a case of extra-uterine gestation. The fact that no inflammation was present connected with these symptoms should lead one to suspect mischief. Then, of course, nausea might be present and milk appear in the breasts. There was in natural pregnancy frequent micturition; in extra-uterine pregnancy we were likely to find this still more marked. The main symptom, however, was a tumor on one side of the womb, which might be thereby displaced and which must be readily discovered unless the woman was abnormally fat. If we could discover an enlarged ovary, *a fortiori* we should be able to discover a rapidly growing tumor. He thought it was not necessary to make a diagnosis before rupture. The use of the aspirator should be laid aside. A good many years ago he had caused the loss of a woman's life by aspirating the sac, and, although the method had been warily advocated by Barnes, still the percentage of deaths had been very large, considering the number of cases of operation. He remembered a number of cases in which the cyst had been aspirated and death had resulted.

On the question of electricity, he must differ with Dr. Lusk. If a physician felt confident that a patient had extra-uterine pregnancy, he ought to resort to the knife. Before the speaker had treated three cases of extra-uterine gestation he had believed in electricity. The question had then been in

his mind, what was the best form to use; but, when it came actually to the performance of the operation, he had said to himself, Suppose this foetus was destroyed, what would be the result? Could we remove the adhesions or render the tube impervious? Could we prevent a pyosalpinx? He then showed some specimens from a case in which there had been adhesions to the pelvis and broad ligaments. On the other side the ovary and tube were so adherent that he had been obliged to remove them. He felt that in this case the physician would have been compelled to resort to the knife some months later. Electricity should be used where a patient objected to an operation, or where a physician did not feel himself sufficiently skilled to make the abdominal section. He was satisfied that electricity should not be used for its electrolytic action—that the parts should not be punctured by needles. Most of such cases had ended fatally. His feeling was that if he recognized the condition before rupture, or suspected it, he would operate. Certainly he would do so after rupture had taken place. In all the cases of operation he believed there had not been a single death, except where the patient was *in articulo mortis* at the time. As to what should be done after the child was viable, he had had only one case, which had resulted in death. He would be disposed, from the light of the literature on the subject, to leave the child until it was still more viable, and then operate in one of two ways. He would attempt to remove the whole sac, or else remove it after removing the child. If he found it impossible to remove the sac, he would sew it to the abdominal walls and put in a large drainage-tube. He thought the Porro operation the safest for the woman. The diagnosis was not always possible. He remembered a case that had occurred a long time ago. The first gentleman called had been Dr. H. Agnew, who had diagnosed cellulitis, giving the usual treatment. The woman had had high temperature, local inflammation, metrorrhagia, etc. The speaker was called and made a diagnosis of pelvic peritonitis. But the patient got no better, the people became disgusted, and he was sent away. Shortly after, Dr. Parvin came to him and said: "Doctor, you made a great mistake; that is a case of natural pregnancy." But after a lapse of some weeks Dr. Parvin sent for him. They decided then that the case was one of retroversion of the gravid uterus. Then it flashed across his mind that they had a case of abdominal pregnancy and everything was clear. The head in this case had come down so low in the pelvis that they could feel the sutures in the cranium. The husband would not permit an operation. Both child and woman died. Dr. Parvin made the post-mortem, and this case had led him to write his book. The speaker concluded by citing a number of cases of extra-uterine gestation which had come under his own notice.

Dr. H. O. MAROT said he had come to listen rather than to speak, and was there to learn something upon the question under discussion. He had watched two cases from the beginning to the autopsy, and both had led him to believe they had been *per se* abdominal. For his part he would not use electricity. It belonged to the general practitioner.

Dr. J. E. JANVRIN, of New York County, said that he endorsed the opinion that surgical treatment should be resorted to in cases of tubal pregnancy, and this was especially indicated when rupture had taken place. He regarded the colicky pains as having great import. When a woman was taken with these in connection with other suspicious symptoms, there was generally slight hemorrhage external to the tube which he believed accounted for the pains.

The PRESIDENT said he had not mentioned puncture, but he hoped nobody would ever try it. He had used it once by mistake. He had done this at a clinic, telling the students that they were examining an interesting case of hæmatocele. After

a few weeks a foetus sloughed through the vagina. Luckily, the woman had recovered. Why should not laparotomy be done at once? He had intended this to be the inference from his paper. In case of suspected tubal pregnancy it was good practice, he believed, to perform a laparotomy. The operation was no more dangerous than that for the removal of a Fallopian tube. Galvanism could be used with a comparative degree of safety. The method of employing it was simple, and with it, before three months, we could destroy the foetus, and as a rule it did not cause any trouble. Galvanism in this respect was an effective method of treatment, and he hoped that those not prepared to operate, as would be often the case in the country, and with no medical help available, would use galvanism. He did not think Dr. Janvrin was quite right in supposing there existed any direct association between the colicky pains and hemorrhage and rupture; they were too frequently present in other conditions to be regarded as of special significance.

#### **The Value of Laparotomy in Suppurative Peritonitis.**

—Dr. J. CRONYN, of Erie County, read a paper on this subject. Operative procedures in these cases, he said, had been much lauded within the last few years, and many cases had been reported where great success had resulted, and where it was reasonable to assume the issues would otherwise have been fatal. There were few natural proofs, however, in this relation, and he thought the case he had recorded would be interesting on that account. The child of a Mr. F., of Buffalo, while jumping a rope, in some way had injured the walls of the abdomen. There were no external evidences. The child complained of pain and suffered from tympanitic distension, vomiting, and purging. In thirty-six hours afterward peritonitis was evident. The child, seven years old, was not very strong, and the history of the family and of the parents was certainly scrofulous or tubercular. The child was very pale, and the appearances indicated involvement of the omentum and abdominal veins. Day after day the acute symptoms diminished and diarrhoea had ceased, but the immense distension was most troublesome, rendering breathing exceedingly difficult. On the tenth day there was evident fluctuation. The treatment had been by large poultices and opium. It had been with difficulty that the poultices were borne and applied, as the little one's legs were drawn up. On the twelfth day the propriety of opening the abdomen was suggested to the family as the only way to save the child's life. The writer candidly admitted that he had not urged this very strongly, as he thought the patient likely to die upon the table. On the morning of the fourteenth day he had been afraid the little patient would not live through the day. In the evening he was summoned, the message telling him the child was dying. On reaching the house he found to his surprise that nature had produced the surgical operation. The umbilicus had given way and a gallon of pus had been discharged. A bandage was applied, lactophosphate of calcium, bark, and so on, was ordered, and, to make a long story short, an excellent recovery was made, the patient enjoying better health than before the illness. Could there be plainer proof of the propriety of doing a laparotomy under such circumstances? Nature here had indicated what ought to be done by the surgeon's knife, and probably had done the work better.

Dr. TRUAX, of New York County, said that several cases of suppurative peritonitis had come under his observation in the Harlem Hospital. About six months ago a patient had been admitted to his ward. On examination, he had found the man had peritonitis, and was in a state of collapse. He was apparently a strong, vigorous young man, perhaps twenty years of age. He was too weak to give any history of his disease. Just at that time the visiting surgeon came to the hospital, and the speaker suggested laparotomy and washing out of the abdom-

inal cavity; this was done under thorough antisepsis, but the man never recovered from the shock. A few days after, a young woman had been admitted to the hospital with the same trouble and in the same condition; again the speaker advised laparotomy, and within an hour after her admission it was performed. Notwithstanding all possible care, she died. Some few weeks after, a man about thirty years of age was admitted suffering from peritonitis; he had been sick for several days and was in a state of collapse. Laparotomy was advised. The abdomen was opened and the cavity washed out and the man seemed to revive, and for a few hours hopes were entertained that he would recover; but the next day, about twenty-four hours after the operation, he grew very weak, and, in spite of stimulants, died. This had been the speaker's experience. He admitted that they were all unfavorable cases for operation. He believed that many of these patients could be saved if permission could be obtained to operate when they were strong enough to stand the shock. He had during the last few years had a great many cases of peritonitis, and was bound to confess that uniformly they had turned out unfavorably. Comparatively few of the patients had recovered. He looked upon peritonitis now (meaning general peritonitis) as almost certain death. He had made autopsies in many cases, and found the abdomen filled with pus and in as deplorable a condition as could be well imagined.

A member suggested that Dr. Cronyn's case seemed more like a supraperitoneal abscess.

The PRESIDENT said he thought it well settled that cases of supraperitoneal abscesses should be opened above Poupart's ligament. Circumscribed abscesses, which had been common when he had begun practice, were now hardly known. He had cut down through the abdominal walls, found the sac, stitched it to the sides of the wound, and stuffed the cavity with oakum. In these cases of circumscribed abscesses the prognosis was favorable if large incisions were made, the cavity being well washed out and free drainage secured. The washing out of the abdominal cavity in cases of general peritonitis had failed in his own practice, and he would like to know what had been the experience of others in this respect. Replying to a question as to what formed the intra-abdominal wall of these abscesses, he said he thought it was probably the matting together of the intestines.

Dr. T. H. MANLEY, of New York, said that he had never seen a patient recover whose peritoneum had been opened for general suppurative peritonitis. He had been consulted about one case. It had been decided not to let the patient die without giving him the benefit of so harmless an expedient. So he opened down in the direction of Poupart's ligament on the right side. Pus spurted out in large quantities, serous and grumous fluid, of which as much as a quart was removed. They had just commenced operations on the abdominal cavity when the child died on the table.

Dr. CRONYN said that the gentleman who had hinted that the case he had cited was perhaps only a supraperitoneal abscess must imagine that he (Dr. Cronyn) did not know anything about surgery. He very rarely allowed himself to be led into expressions of opinion until he had well weighed the value of his premises. He explained that there had been evident fluctuation on the twelfth day, and this fluctuation had not been confined to two or three or four inches, but had involved the entire abdomen. As to the propriety of opening the abdominal cavity for peritonitis, he merely thought he would give an instance where nature had opened it.

**The Use of Dispensary and Hospital Material.**—Dr. E. J. C. MINARD, of Kings County, read a paper in which she upheld the utility of free dispensary and hospital material from a

clinical standpoint. Nearly half our girls, she said, entered life in a crippled condition. She emphatically denounced the present methods of education, mental, physical, and domestic, as calculated to stultify girls and render vast numbers of them essentially useless at an age when every part of their organization should be ready to perform its allotted function. She spoke in terms of emphatic approval of the practice of oophorectomy in selected cases. When women got to a condition in which such a measure was indicated they were already unsexed. The disease was one of maturity, and the woman had the right to choose that which would give her perhaps peace and health.

**The Microscope in Diagnosis.**—Dr. G. E. FELL recounted his personal observations, which went to show that in cases of tuberculosis of the lungs, as against other lung affections presenting a train of similar clinical symptoms, an accurate distinction could be made. He also cited several cases bearing directly on this point.

(To be continued.)

## Book Notices.

*Phthisie Laryngée.* Par le Dr. A. GOUGUENHEIM, médecin de l'hôpital Lariboisière et de la clinique laryngologique, etc., et PAUL TISSIER, interne des hôpitaux de Paris. Avec 13 figures dans le texte et 5 planches hors texte dont 3 en chromolithographie. Paris: G. Masson, 1888. Pp. 11-339.

DR. GOUGUENHEIM has presented in this volume the most complete and thorough treatise on the subject ever written, and one to which a hearty welcome can be accorded when we remember that no complete and original work on tubercular laryngitis has been published since the classic treatise of Rousseau and Belloc. In the work before us the author has endeavored to bring forward all new questions connected with the disease, as to its pathological anatomy, its symptomatology, and its therapeutics, to criticize them fairly from the standpoint of his own experience, and to give a truthful picture of the actual condition of our present knowledge of it. He has given a fair exposition of the differences of opinion among various authorities upon certain new theories of the affection, desiring to make these theories as generally understood as possible and thus to gain for them the advantage of discussion and, if possible, of proof. Indeed, the main object of the treatise is to place these questions before the general pathologist and not to allow them to remain strictly within the province of the specialist.

Passing over the excellent chapters which precede that on treatment, we find that the author in every instance, having first given the method under his consideration, frankly appends to it the results of his personal experience with its use. Thus, we find that he attaches little importance to the local application of solutions of menthol; that he has used with success applications of solutions of lactic acid to the surface of laryngeal ulcers; that the submucous injections of lactic acid, advocated by some recent writers, he has found too severe for general use; that the use of the curette, valuable when applied to the extraction of necrosed cartilages, is not satisfactory in the scraping of laryngeal ulcers, and that the galvano-cautery, while of assistance in cases where papillomatous projections or polyp-like masses must be removed, and where avulsion of them might be followed by inoculation of the resulting wound, is otherwise not indicated. Applications of iodoform are highly praised, while iodol the author has found unsatisfactory. Salol he considers inferior to iodoform, and he thinks that boric acid, while bene-

ficial in cases where the ulceration is superficial, does not answer well where it is deep. The prognosis, unfortunately, still remains unfavorable, although by modern methods much may be done to postpone and relieve the distressing symptoms of the disease. The book is well illustrated, the colored lithographs being particularly good, while the press-work is so admirable as to merit attention.

*Hand-book of the Diagnosis and Treatment of Diseases of the Throat, Nose, and Naso-pharynx.* By CARL SEILER, M. D., Instructor in Laryngology and Lecturer on Diseases of the Upper Air-passages in the University of Pennsylvania, etc. Third Edition. Thoroughly revised and greatly enlarged. Illustrated with Two Lithographic Plates containing Ten Figures and One Hundred and One Wood Engravings. Philadelphia: Lea Brothers & Co., 1889. Pp. xii-13 to 373. [Price, \$2.25.]

THE third edition of this excellent hand-book is a decided improvement. The views expressed by the writer are in the main those which have met with general acceptance, and the descriptions of the various methods and manipulations described are concise and clear. The book is well illustrated throughout, the best of the cuts, by the way, being those from drawings furnished by the author himself, several of which are valuable contributions to the old-time stock. Following the sections which deal with the examination of the upper air-passages, there are short chapters on the simpler and more common forms of the diseases of the upper air-passages.

*On the Treatment of Cystic Goitre.* By T. MARK HOVELL, F. R. C. S. E. London: J. & A. Churchill, 1888. Pp. 5-26.

BEARING in mind the frequency of cystic goitre, and the large number of deaths which have resulted from surgical efforts at curing it, Mr. Hovell has called attention to its treatment in a remarkably well written and useful thesis. He quotes the views of the best surgeons of the day upon the subject, and clearly proves that the best method of treatment is that recommended seventeen years ago by Sir Morell Mackenzie—namely, the evacuation of the cyst by means of a small cannula, injection with a solution of perchloride of iron, two drachms of the salt to the ounce of water, the retention of this solution within the cyst until inflammation of its walls has been established, and, finally, the wearing of the cannula until suppuration has ceased. This plan, he believes, possesses decided advantages, since it is simple and effective and far less dangerous than those in common use.

*Congrès pour l'étude de la tuberculose chez l'homme et chez les animaux, 1<sup>re</sup> session—1888.* Président: M. le Professeur CHAUVEAU (de l'institut). Comptes rendus et mémoires. Publié sous la direction de M. le Dr. L. H. PETIT, secrétaire général. Paris: G. Masson, 1889. Pp. 760.

THE large membership in, and number of papers contributed to, the first congress for the study of tuberculosis in man and in animals sufficiently attest the widespread interest in all that concerns this malady. A review of even a modicum of the papers included in this volume is impossible, and certain general points only can be referred to. There was a consensus of opinion that the milk and flesh of tuberculous animals should not be used for food. In this connection Dr. Guinard called attention to the danger of drinking fresh blood at the abattoirs, referring to such a case in which a carcass was found, on dressing it, full of tubercles. Dr. Galtin made some experiments on the employment of fresh blood to clarify wines, that demonstrated that after five days any tubercle bacilli were destroyed. Local

tuberculosis was considered in papers on arthritic, hepatic, and lupous tuberculosis, as well as tuberculosis of the thymus and salivary glands, the meninges, and the mucous membranes, considerable attention being paid to the subject of the introduction of the disease through the alimentary canal. Various methods of treatment were reported, the results, however, promising no nearer solution of this problem than heretofore.

The second congress will be held in Paris in July, 1890, and the following subjects are announced for consideration: 1. The identity of the tuberculosis of man and the tuberculosis of cattle, poultry, and other animals. 2. The bacteriological and pathological associations of tuberculosis. 3. The confinement of tuberculous patients in hospitals. 4. Agents, not injurious to the organism, capable of destroying the bacillus of Koch, from the standpoint of the prophylaxis and treatment of human and animal tuberculosis.

*A Surgical Hand-book; for the Use of Practitioners and Students.* By FRANCIS M. CAIRD, M. B., F. R. C. S. (Ed.), and CHARLES W. CATHCART, M. B., F. R. C. S. (Eng. and Ed.), Assistant Surgeons, Royal Infirmary, Edinburgh. With very Numerous Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. xv-262. [Price, \$2.50.]

This little work is devoted to a practical consideration of the treatment required in minor surgical cases as encountered in daily practice by the surgeon, and of that class of operative procedures demanded in emergencies. Subjects not strictly of a surgical character—such as massage, uralysis, post-mortem examinations, microscopy, etc.—receive also some attention, the minutiae of practical knowledge being generously scattered throughout the whole hook. Fractures and dislocations, with the appliances for their treatment, receive the most attention, and in such manner as to make clear the various methods described. The subject of bandaging is well handled, and is made more extensive in scope than in most treatises with which we are familiar, by including handkerchief dressings and various other improvised affairs not usually mentioned. To the best of our knowledge, it is the only surgical work containing a description of that most efficient, neat, and permanent of the bandages for the extremities, which is applied by making a posterior reverse in a figure-of-eight bandage whenever the latter does not adapt itself smoothly to the limb. The method of Kocher for the reduction of shoulder dislocations is a novelty in our surgical literature other than that of a periodical character, and is to be regarded as an important addition to the list of the other methods described in the work. The numerous explanatory cuts are, in most cases, really deserving of the adjective applied to them, and, though the print is finer than is consistent with absolute comfort in reading, it is clear and well done. The small size and flexible cover of the hook make it very convenient for carrying in the pocket. In fine, the hook is worthy of perusal, and we consider it one of the best of the works that represent the abridged type of medical literature.

*A Text-book of Human Physiology, including Histology and Microscopical Anatomy; with Special Reference to the Requirements of Practical Medicine.* By DR. L. LANDOIS, Professor of Physiology and Director of the Physiological Institute, University of Greifswald. Third American, translated from the Sixth German Edition. With Additions by WILLIAM STIRLING, M. D., Sc. D., etc. With Six Hundred and Ninety-two Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. xxxi-33 to 974. [Price, \$6.50.]

THE third edition of this excellent work appears in a single volume that will make it much more convenient to handle than

the former two-volume edition, and this abridgment has not been at the expense of the matter of the book, for almost two hundred new illustrations have been added, and the work has been amplified in many portions, especially those on the physiology of the circulatory and nervous systems. Dr. Stirling has been a careful editor, and we recall no late investigations in physiology that he has failed to incorporate in the work. All that we said in praise of the former edition is applicable to this, the book fully deserving all the popularity that has been accorded it.

*Synopsis of Human Anatomy*, being a Complete Compend of Anatomy, including the Anatomy of the Viscera, and Numerous Tables. By JAMES K. YOUNG, M. D., Instructor in Orthopaedic Surgery and Assistant Demonstrator of Surgery in the University of Pennsylvania, etc. Philadelphia: F. A. Davis, 1889. Pp. ix-3 to 393. [Price, \$1.40.]

THE title sufficiently indicates the character of this little manual. Every unnecessary word has been excluded, out of regard to the very limited time at the medical student's disposal, and the object of the work is to facilitate the acquisition of this difficult, though essential, subject. It is also good as a reference book for the practitioner, as it presents the facts about which he wishes to refresh his memory in the briefest manner consistent with clearness. It is based mainly on Gray, but other well-known anatomists are quoted. It is well got up and is a valuable book for the purposes indicated.

*Essentials of Pathology and Morbid Anatomy*. By C. E. ARMAND SEMPLE, B. A., M. B. Cantab., L. S. A., M. R. C. P. Lond., etc. With Forty-six Illustrations. Philadelphia: W. B. Saunders, 1889. Pp. xvi-160.

This compend is intended as an introduction to the subject of pathology and morbid anatomy, and to refresh the memory after a more extensive study. For these purposes it is admirably adapted. It is written in a concise manner, and evidently much labor has been expended in condensation. But one criticism occurs to us. The author is very prone to the use of Latin derivatives where Anglo-Saxon would be simpler and therefore more desirable. The cuts are numerous and well executed, and the entire work is got up in a creditable manner.

*A Manual of Instruction for giving Swedish Movement and Massage Treatment*. By Professor HARTVIG NISSEN, Director of the Swedish Health Institute, Washington, D. C., etc. With Twenty-nine Original Wood Engravings. Philadelphia and London: F. A. Davis, 1889. Pp. vii-128. [Price, \$1.]

THIS manual is valuable to the practitioner, as it contains a terse description of a subject but too little understood in this country. It is well written, but is rather too concise. A more extensive work would be better to teach one unaccustomed to the work the exact manner in which to make the movements —*i. e.*, one which dealt with the minutiae, as well as the broad lines upon which this treatment is based. Still, it is sufficient to give a very clear idea of the value of the treatment and of its method of application. The author acknowledges that it will not cure all diseases, and among those of which he speaks as amenable to this treatment there are very few to which we can take exception. Still, we find it difficult to believe that organic heart disease or paralysis due to pressure of a blood-clot upon the brain can be cured by any such treatment. A certain degree of benefit may be obtained, but we are not yet ready to accept statements of greater results. The book is got up very creditably.

#### BOOKS AND PAMPHLETS RECEIVED.

Cyclopædia of the Diseases of Children, Medical and Surgical. The Articles written especially for the Work by American, British, and Canadian Authors. Edited by John M. Keating, M. D. Vol. II. Illustrated. Philadelphia: J. B. Lippincott Company, 1889. Pp. xii-1066. [Price, \$5.]

An Introduction to Pathology and Morbid Anatomy. By T. Henry Green, M. D., Physician to Charing Cross Hospital and to the Hospital for Consumption and Diseases of the Chest, Brompton, etc. Sixth American from the Seventh English Edition, revised and enlarged by Stanley Boyd, M. B., B. S. Lond., F. R. C. S. Eng., Senior Assistant Surgeon to Charing Cross Hospital, etc. Illustrated by One Hundred and Sixty-seven Fine Engravings. Philadelphia: Lea Brothers & Co., 1889. Pp. xx-17 to 539. [Price, \$2.75.]

The Story of the Bacteria and their Relations to Health and Disease. By T. Mitchell Prudden, M. D. New York and London: G. P. Putnam's Sons, 1889. Pp. 143. [Price, 75 cents.]

A Treatise on the Science and Practice of Midwifery. By W. S. Playfair, M. D., LL. D., F. R. C. P., Physician-Accoucheur to H. I. and R. H. the Duchess of Edinburgh; Professor of Obstetric Medicine in King's College, etc. Fifth American from the Seventh English Edition. With Notes and Additions by Robert P. Harris, M. D. With Five Plates and Two Hundred and Seven Illustrations. Philadelphia: Lea Brothers & Co., 1889. Pp. xxv-33 to 671. [Price, \$4.]

Diseases of the Eye. A Practical Treatise for Students of Ophthalmology. By George A. Berry, M. B., F. R. C. S. Ed., Ophthalmic Surgeon, Edinburgh Royal Infirmary, etc. With Colored Illustrations from Original Drawings. Philadelphia: Lea Brothers & Co., 1889. Pp. xvii-670. [Price, \$7.50.]

A Text-book of Physiology. By M. Foster, M. A., M. D., LL. D., F. R. S., Professor of Physiology in the University of Cambridge, etc. With Illustrations. Fifth Edition, largely revised. Part II, comprising Book II. The Tissues of Chemical Action, with their Respective Mechanisms. Nutrition. London and New York: Macmillan & Co., 1889. Pp. xxii-355 to 846. [Price, \$2.60.]

Hygiene and Public Health. By Louis C. Parkes, M. D., D. S. H. Lond. Univ., Fellow of the Sanitary Institute and Member of the Board of Examiners, etc. With Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. xvi-471. [Price, \$2.50.]

La uretrotomía interna en la Isla de Cuba es tan inocente como la dilatación progresiva. Por el Dr. Ignacio G. Plasencia, Médico del hospital civil, etc. Habana: Imprenta "La Antille" de Cacho-Negrete, 1888.

## New Inventions, etc.

### DE BAUN'S OBSTETRICAL ROPES AND HANDLES.

BY EDWIN DE BAUN, M. D.,  
PASSEAC, N. J.

It is a fact that, with but very few exceptions, during the second stage of labor, women require something to pull on; it may be the physician's or assistant's hands, a sheet fastened to the bed, or some other

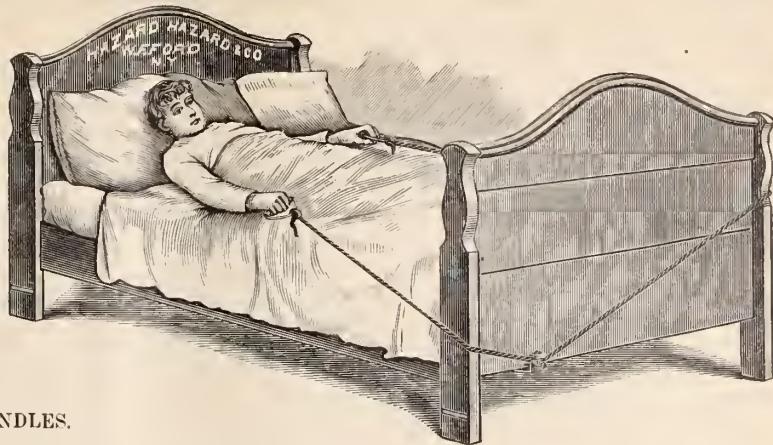

The apparatus disconnected.

contrivance, all of which have proved unsatisfactory to me; and therefore I have devised the use of the *ropes* and *handles*, the mechanism of which the accompanying cuts will in part explain.

I have used these ropes and handles in many cases of confinement, and they have given great satisfaction to both patients and myself. Although the use of them does not hasten labor, yet they give such ease to the patient that one is fully justified in adopting them. Since this apparatus has gained publicity, many of my patients request that I bring it with me.

The rope is of one piece, and runs through the two holes in the end of the clamp in such a manner that as soon as tension is made the rope fastens itself in the clamp and can not be pulled either way. By means of the two loops in each handle, the ropes can be shortened or lengthened to suit the patient.

The clamp is attached to the foot-board of the bed at the most convenient side, then the rope is slipped through the holes in the clamp so as to bring the shorter rope to the side of the bed on which the patient lies. The other end of the rope is then

The patient lying on her back using the handles.

thrown around the opposite side of the bed. Now the handles are adjusted to the proper length for the patient, and the instrument is ready for use, this adjustment requiring but a moment.

The special advantages alleged for this instrument are: The ropes being so fastened to the bed, the patient can lie on her back or either side, or she may change to any position on the bed and still grasp both the handles. She can pull much more evenly than by taking an assistant's hands, and is not so liable to strain herself as she otherwise might be. The handles being smooth and easily grasped, she can hold them for a much longer time without fatigue to herself or an assistant. Then they allow the physician to give what manual aid he may deem necessary during the pains, especially at the close of the second stage, without being hampered by the patient's movements in her often wild desire to grasp something. The handles, being on each side of the patient, do not in any way embarrass the progress of labor, and fewer assistants are necessary at the bedside. All patients using them, especially if the progress of labor is of long duration, are less fatigued and notably in a much more cheerful frame of mind. Taking up very little room, they are very light, and are easily and rapidly adjusted to any bed.

I do not affirm that these ropes and handles hasten labor in any way, nor do I allege for them anything other than the comfort and convenience that they afford both the patient and the physician. Of the sixty-four cases in which I have used these handles I can not recall one instance in which any trouble could be attributed to the use of the same. Nor have I heard of any patient feeling lame or bruised. Of course the disadvantages of the old plan are obvious, although it has been practiced for a long time, yet I think the points in favor of this apparatus may be accepted. But, should only a few adopt my plan, I shall feel fully repaid for my exertions.

Mr. W. F. Ford, of Hazard, Hazard, & Co., New York, has comprehensively and faithfully carried out my ideas.

The patient lying on her side using the handles.

## Miscellany.

**The New York Academy of Medicine.**—At the next meeting of the Section in Ophthalmology and Otology, on Monday evening, the 21st inst., Dr. H. Knapp will present a case of ectaraet extraction; Dr. O. D. Pomeroy, one of microtasia; and Dr. J. E. Weeks, one of coloboma of the choroid; and Dr. Knapp will demonstrate the use of Schweiger's perimeter.

At the next meeting of the Section in Laryngology and Rhinology, on Tuesday evening, the 22d inst., Dr. W. K. Simpson will present a case of a tooth in a bronchus; and Dr. C. H. Knight, one of a tooth-plate in the laryngo-pharynx for sixteen days; and Dr. A. G. Gerster, Dr. R. P. Lincoln, Dr. S. D. Powell, Dr. D. B. Delavan, Dr. O. B. Douglas, Dr. Henry Schweiß, and others will take part in a discussion on "Foreign Bodies in the Air-passages, and their Treatment."

At the next meeting of the Section in Obstetrics and Gynaecology, on Thursday evening, the 24th inst., Dr. R. A. Murray will read a paper on "The Management of Abortion"; Dr. A. P. Dudley will report a case of carcinoma of the uterus and ovary; and Dr. H. C. Coe will read a paper on "A Successful Case of Laparotomy with Supra-vaginal Amputation of the Uterus for Rupture."

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the abstract of sanitary reports received by him during the week ending October 11th:

CITIES.	Week ending—	Estimated population.	Total deaths from all causes.	DEATHS FROM—								
				Cholera.	Yellow fever.	Small-pox.	Varicella.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.

**Sulphur as a Disinfectant.**—"In disinfection by burning sulphur, Dr. Squibb recommends the evaporation of water equal to four times the amount of sulphur burned. To render the disinfection effective, it is necessary that sufficient moisture be present in the atmosphere with which the sulphurous oxide may unite. The water may be evaporated in a shallow dish, heated to boiling. The sulphur, placed in a smaller dish set in the water bath, is moistened with alcohol and ignited. Walls covered with kalsomine or whitewash should be dampened with a brush before the sulphur is burned."—*Medical and Surgical Reporter.*

## THERAPEUTICAL NOTES.

**Ichthyol in Chronic Nephritis.**—According to the "Gazette hebdomadaire de médecine et de chirurgie," M. Blittersdorf has employed ichthyol successfully in daily doses of 15-432 grains of sodium sulpho-ichthyolate in the case of a young girl affected with chronic nephritis for eight months. She had ascites, facial oedema, albuminuria, and amenorrhœa. This remedy provoked an abundant diuresis, caused a reduction of the albuminuria, and gave such relief that the patient could return to her vocation.

**Picrotoxin as an Antidote to Morphine.**—We find in a recent number of the "Lancet" that Professor Bokai, of Klausenberg, considers picrotoxin to be the best antidote to morphine. Paralysis of the respiratory centers is the cause of death in cases of poisoning by morphine, and as picrotoxin administered in small doses tends to increase the action of the respiratory centers, thereby hindering the paralysis, it is evident that picrotoxin will probably prove useful in such cases. Moreover, picrotoxin counteracts the effect of the morphine by stimulating the vaso-constrictor center of the medulla oblongata.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

## Original Communications.

### ON GUNSHOT WOUNDS OF THE ABDOMEN, WITH ESPECIAL REFERENCE TO WOUNDS OF THE INTESTINES.\*

By LEWIS A. STIMSON, M. D.,

SURGEON TO THE NEW YORK, CHAMBERS STREET, AND BELLEVUE HOSPITALS;  
PROFESSOR OF SURGERY IN THE UNIVERSITY OF THE CITY OF NEW YORK.

UNTIL within a period relatively short a discussion of the subject of gunshot wounds in a society of surgeons in civil life would have had an interest almost exclusively academical, and, apart from theoretical considerations and analogy, would have been based in great part upon experience gained at the edge of the battle-field and in the military hospital. But the times have changed, and now, to paraphrase a well-known quotation, Peace hath her military surgery no less renowned than war; and in some varieties of gunshot wounds, such as those of the trunk and head, the office of the military surgeon has diminished, while that of his brother in civil life shows the budding promise of an important development. The reason is not far to seek. On the one side, military fire-arms now discharge their bullets with such velocity that the wounds they inflict upon the viscera are very severe and often beyond hope; while, on the other hand, the possession of parlor rifles and of pistols of small and medium caliber in all classes of the community has become very common, and the injuries inflicted by such, either accidentally or with hostile intent, have correspondingly multiplied. As an indication of this frequency of occurrence of such injuries, I may say that I can recall, without search of the records, twenty cases of serious bullet wounds personally treated by me during the twelve months last past; of these, seven were accidental, three were inflicted with suicidal, and ten with murderous intent. So long, therefore, as pistols are openly sold at prices that place them within the reach of almost every half-grown or adult member of the community, so long as love, anger and despair, greed and want, are strong motives of action, so long as youth is heedless, and so long as the idiot who thinks it is not loaded goes free in the midst of us—so long will gunshot wounds demand our care and attention and deserve our thoughtful study.

All varieties of these injuries have shared in the benefits conferred by modern improvements in the care of wounds and in the stimulus to effort created thereby, but, while in wounds of the extremities the gain has been in the preservation of limbs that would otherwise have been lost, in gunshot wounds of the abdomen the interest is infinitely greater, for the issue is of life or death, and it is beyond dispute that many lives have been already saved by operation during the last five years which would certainly have been lost under the methods of treatment which had previously prevailed. In a collection made by Dr. W. B. Coley, of 124 published and unpublished cases treated by

laparotomy, which is the largest thus far made, and which has been in part published,\* there are 37 recoveries, in many of which the nature of the injuries was such as to furnish ample ground for the belief that, had the operation not been done, the patients would have succumbed. It has, therefore, been fully established that formal laparotomy undertaken to discover and repair gunshot wounds of the intestines may save lives that are in imminent peril; and that, consequently, under certain circumstances, it is a proper and justifiable operation. But from this to the position that in every gunshot wound of the abdomen that is probably perforating, or even in every one that is certainly perforating, a laparotomy should be immediately done, is a long step. It is not enough to have shown that some patients have survived laparotomy; it is not enough to have shown that those who have died without operation could have been saved only by one; it is not enough to have shown that laparotomy for other morbid conditions is daily done with a large measure of success and safety. It must also be shown that it saves a larger proportion of wounded patients than other methods save, and, even if this is done, it must still be ascertained whether we can not discriminate between the different injuries, and recognize those in which it is proper to operate and those in which it is wiser to abstain. Experience alone can supply the materials for an answer to these questions; for the latter we must study individual cases; for the former we must have integral statistics comprising a sufficient number of cases. Lists made up of reported cases contain, as is well known, an undue proportion of successful ones, and I have therefore sought to obtain a list of all the cases that have been treated by laparotomy in the hospitals of New York city. In default of a similar list drawn from a larger area, this will best serve to determine the percentage of success for comparison with the results of other methods. In addition, I shall report three new cases, one of which ended in recovery; and shall further ask your attention to a consideration in some detail of various matters connected with the diagnosis, prognosis, and treatment.

The three new cases are as follows:

CASE I.—C. Z., aged twenty-seven, unmarried, a German, shot himself with suicidal intent, at 3 A. M., on December 6, 1888, with a pistol of .32 caliber. On admission to the Chambers Street Hospital he presented but slight evidences of shock; his temperature was normal, pulse good, and respirations regular but shallow. He complained of severe pain in the abdomen when moved or touched. There was a small blackened wound midway between the umbilicus and the ensiform process, half an inch to the left of the median line.

I saw him at 3.15 P. M. He had vomited once, and had voided a large quantity of very bloody urine. He was very pale, his surface cool, pulse small and quick. His manner was apathetic, he answered questions shortly and unwillingly, and made no complaint of pain except when the abdomen was pressed upon. The abdomen was not distended; it was resonant anteriorly and dull in the flanks; liver dullness normal.

Ether was administered, and the abdomen opened in the median line from the ensiform process to the umbilicus, giving

\* Read before the New York Academy of Medicine, October 17, 1889.

\* Dr. W. B. Coley, "Boston Med. and Surg. Journal," Oct. 18, 1888.

issue to a considerable quantity of bloody serum and a few small blood-clots. On the anterior aspect of the stomach, three inches from the pylorus, a circular perforation was found, and was at once closed with a row of silk Lembert sutures.

On raising the omentum and transverse colon, two perforations, three fourths of an inch in diameter and half an inch apart, were found at the upper end of the jejunum, and were closed with a double row of Lembert sutures, the fold being longitudinal. Just above and to the left of the junction of the duodenum and jejunum was a large ragged wound in the parietal peritoneum, through which blood flowed freely, evidently from a wound of the pancreas; it was closed, and the bleeding checked by deep sutures. In the mesocolon, two inches above the lower end of the duodenum, was a perforation, the bleeding from which was checked by a suture at its lower angle. Finally, a circular perforation of the posterior wall of the stomach was closed with a double row of sutures. A large quantity of liquid and clotted blood was removed from the abdominal cavity.

The ball had evidently first traversed the stomach, then the mesocolon and jejunum, and had then entered the posterior abdominal wall, wounding the pancreas, and undoubtedly the kidney also, as shown by the blood in the urine.

The extent of the injuries and the patient's condition contraindicated further interference. The wound was closed, and he died half an hour afterward. At the autopsy the ball was found to have traversed the left kidney and to have lodged under the skin behind it. No other wounds of the intestine were found.

**CASE II.**—James D., aged thirty-seven, was brought by the ambulance to Chambers Street Hospital at 1.15 A. M. on March 16, 1889. He had been shot a few minutes previously while kneeling upon the ground, his assailant standing over him. The weapon was a pistol of .38 caliber. Condition good; no general pain; marked tenderness above right inguinal region; respiration, 20; pulse, 70; temperature, 98° F. There were two bullet-wounds—one about three inches and a half above the free margin of the ribs and an inch and a half to the left of the median line, the other two inches below the border of the ribs and two inches and a half to the right of the median line. At 4 A. M. he passed six ounces of clear urine.

As I was absent from the city, Dr. Charles H. Wilkin, assistant surgeon of the hospital, was summoned, and he operated at 8 A. M., seven hours after the receipt of the injury.

The wound in the chest was probed and found to pass downward and outward without perforating. In the abdominal wound the probe passed downward in the wall for a distance of three inches, and then entered the abdominal cavity. Median incision six inches long between the pubes and umbilicus, giving issue to considerable bloody serum, containing flakes of lymph and some feces. Six perforations were found at three points in the small intestine—the first pair eighteen inches below the duodenum, the second pair two feet lower down, the third at the lower end of the ileum. The bullet was imbedded in the mesentery, near the cæcum. Each wound was closed with a single row of Lembert sutures; two bleeding points in the omentum were ligated. The cavity was flushed with hot water, and the abdominal incision closed. The patient did well for twenty-four hours, but when I saw him on the following day septicæmia was evidently present. He died at 7.30 A. M. on March 18th, forty-eight hours after the operation. The autopsy showed general peritonitis and congestion of the left lung.

In connection with this case it is proper to state that the operation was performed rapidly and skillfully, that the operator had had a large experience in abdominal surgery, and that all antiseptic precautions were rigidly observed. A

supply of silk and sponges specially prepared for use in laparotomies is kept in the hospital, the instruments are always boiled before an operation, and the assistants are skillful and keenly alive to the possibilities of accidental infection and to the need of constant care and watchfulness. It is to be remembered that feces had escaped into the peritoneal cavity, and that peritonitis had already set in before the operation was undertaken.

**CASE III.**—D. D., aged twenty-eight, a rather fleshy woman, was brought to the Chambers Street Hospital in a cab at 9.15 P. M., April 19, 1889. Six hours previously a man had pressed against her abdomen the muzzle of a Flobert pistol, caliber .22, thought to be unloaded, and discharged it. She had subsequently vomited whenever she had taken anything into the stomach, and complained of much distress in the epigastric region. The ball had passed through a wrapper and chemise without causing any recognizable loss of substance in them, and had entered the abdominal wall two inches and a half to the left of the median line and an inch and a half below the umbilicus, producing a blackened wound a quarter of an inch in diameter with depressed edges.

The patient had walked into the hospital and showed but little shock; her manner was quiet, she talked freely and naturally, and complained only of pain in the pit of the stomach, which she attributed to indigestion, and was confident would be relieved by a plaster. Her body was covered with a fading syphilitic eruption. The abdominal wall was rounded, thickly coated with fat, and its muscles contracted sharply when it was pressed; in other respects its examination was negative.

The operation was begun under ether at 12.15 midnight, nine hours after the receipt of the wound. The course of the bullet was traced by means of a longitudinal incision three inches and a half long, having the wound at its center; it passed backward through two inches of fat and ended in a small slit in the peritoneum, through which blood escaped quite freely from the abdominal cavity.

A second incision, ultimately seven inches long and extending downward from a point three inches above the umbilicus, was next made in the median line, and the omentum, which was firmly adherent to the left ovary and tube, was pushed to the left; the small intestine was contracted and of a dull-red color; a ragged opening three eighths of an inch in diameter, with everted mucous membrane, was found on the surface opposite the mesenteric attachment, and closed with a single row of three Lembert sutures of fine iron-dyed silk; an inch and a half from it, longitudinally, was a second smaller opening, which was closed with a single Lembert suture. The sigmoid flexure, lying in close proximity to the wounded loop of small intestine, showed two wounds immediately opposite each other which the probe showed to be perforating; one, small and round, was at the base of an appendix epiploica in the outer longitudinal band of muscular fibers; the other, larger and ragged, was in the side of an appendix attached to the inner longitudinal muscular bundle; each was closed with a single suture. A wounded artery in the mesentery, midway between its visceral and parietal attachments, which bled profusely, was secured with a catgut ligature. Clotted and liquid blood, estimated at about one quart in amount, was removed, and the peritoneal cavity cleaned with warm sponges. The cavity was not washed. The entire length of the small intestine, which had been turned out of the abdomen and protected with hot towels, was then gone over rapidly in search of other wounds, and, none having been found, returned into the abdomen. It was noted that during the operation they had become distended

to more than double the size they had when first exposed. The omentum had been perforated by the ball, but was not bleeding; its attachment to the internal genitals made the examination and cleansing of the cavity quite difficult. The bullet was not found.

The abdominal wound was then closed by means of stout silk sutures, embracing the entire thickness of the wall except the peritoneum, which latter was closed with several successive continuous sutures of catgut. The tension of the abdominal wall was so great that the peritoneum could not be closed with a single suture, and the method employed was as follows: Silk ligature was passed about two inches below the upper angle of the wound, and drawn tightly enough to permit the peritoneal opening above it to be closed, and two permanent silk sutures to be placed in the interval above it; a second temporary silk suture was then placed a little lower down, the first one relaxed, and the second section of the wound closed in the same manner as the first; and this was repeated until the entire wound was closed except at the lower angle, where a rubber drainage-tube was introduced to Douglas's pouch. Between the sutures three short drainage-tubes were placed to drain the parietal wound.

The incision made to explore the track of the bullet through the wall was closed with silk sutures and drained. The dressing was of iodoform and creoline gauze, absorbent cotton, and a body bandage.

During the first thirty-six hours the patient received no food or drink except water, a teaspoonful at a time, and was kept slightly under the influence of morphine. On the third day (April 22d) the drainage-tube was withdrawn from the abdominal cavity; on the fifth day her menstrual flow appeared and a diarrhoea began, which lasted, with intermissions, until May 2d. On April 27th most of the sutures were removed, and when the wound was again inspected, two days later, the remaining ones were found to have cut out and the sides of the wound to be gaping; it was lightly packed with iodoform gauze, and the edges approximated with strips of adhesive plaster. On May 3d the regular administration of the protiodide of mercury was begun with the object of preventing any harmful influence of the syphilitic virus upon the healing of the wound. On June 6th the wound was entirely healed, and the patient was allowed to leave the bed; and on June 30th she was discharged cured.

A feature of special interest in this case is that, although the bullet was small (caliber .22), it had produced a wound of the small intestine three eighths of an inch in diameter, evidently by entering the gut obliquely, and had so wounded a mesenteric artery as to endanger the patient's life by haemorrhage. I would also call attention to the absence of shock and of all marked symptoms of grave injury. The case was clearly one in which, according to the views held by a number of prominent surgeons, an expectant attitude should have been taken, to await the possible development of grave symptoms, a course which, in my judgment, would have ended fatally by haemorrhage or by septicæmia. The preliminary exploration of the track of the bullet showed perforation of the cavity and the existence of an important haemorrhage, and thus, I think, made the subsequent proceeding imperative.

The operation of freely opening the abdominal cavity to search for and repair gunshot wounds of the intestines is not a new one; it does not even belong solely to the period of antiseptic surgery, but it was performed, and successfully performed, more than fifty years ago. The principles which

lie at its foundation have, of course, been apparent since such wounds were first inflicted; no demonstration was needed to show the desirability of closing the wound in the intestine or the advantage of a free opening in the abdominal wall if sutures were to be applied or if the wound was to be sought, but the fear of making such an opening or of operating upon the intestines was so great, and indeed so well founded as surgery was then done, that surgeons, with but few exceptions, almost down to the present time, practiced and taught abstention, except when the wounded loop of intestine protruded through the opening in the abdominal wall or lay in plain sight beneath it. Under such circumstances they sutured the intestine and returned it, or they promoted the escape of faeces from within the cavity and sought safety in the establishment of a faecal fistula. Occasionally the possibility of advantage in a more active intervention was more or less hesitatingly suggested, and Baudens, in a work published in 1836,\* reported a case operated upon in 1831, which is not only the first instance of the operation we are considering, but which was also said by the editor of the "Medical and Surgical History of the War of the Rebellion" to be, in 1877, "perhaps the only instance of completely successful enterorrhaphy for shot-wound on record." After having recognized a wound of the transverse colon by introducing his finger, he enlarged the abdominal wound, drew the bowel toward it, and told the patient to cough; this was immediately followed by the protrusion of the wounded bowel and by the escape of intestinal gas from the abdominal cavity. He closed the wound with three Lembert sutures, cut their ends short, and returned the intestine. The subsequent course of the case did not differ from that of an ordinary wound of the abdominal wall, and the patient recovered.

He had previously treated a similar case by drawing out the intestine through the abdominal wound and suturing it; the patient died on the third day, and the autopsy showed that a faecal extravasation had taken place from an undetected wound in the cæcum. It seems not unlikely that this experience led him to make the free opening in the next case and to the expression of opinion (p. 324): "I do not fear to place the knife in the perforation made by the projectile in the wall of the abdomen, in order to enlarge it, to pursue into that cavity the examination of the course it has taken, and to apply to the intestinal lesions a prompt and effective remedy."

It will be instructive and clarifying briefly to trace the course of opinion upon this subject during the current century, and then to examine the new material that more recent experience has brought to bear upon the questions involved.

It is to be remembered that the earlier experience is drawn almost wholly from military surgery, and that the bullets were much larger and discharged with a much lower initial velocity than at the present time. The wound of the abdominal wall appears usually to have been large enough at least to permit the introduction of the finger and often to permit spontaneous protrusion of a wounded loop of intestine. In 1799 Larrey passed a ligature through such

\* Baudens, "Clinique des plaies d'armes à feu," 1836, p. 336.

a protruded loop of the ileum which had been divided by a musket-ball, returned it to the abdominal cavity, and fixed it by means of the ligature in the parietal opening, so that the contents of the bowel could freely escape. The patient recovered, and without a permanent faecal fistula. This appears to be the maximum of surgical interference approved at that time and for many years subsequently. The possibility of successfully suturing an incised (not a gunshot) wound of the intestine had been known for over two hundred years, and perhaps very much longer,\* and in the decade between 1820 and 1830 the experiments of Lembert and of Jobert not only brought the subject of enterorrhaphy very prominently to the attention of the profession, but also gave us methods of closing wounds or reuniting divided ends which are still accepted as the best, with only such modifications and additions as the use of absorbable sutures has entailed. Aided by these acquisitions, Baudens treated his two cases as has been described, and favored the preliminary enlargement of the parietal wound. His example was followed in 1848 by Nélaton,† and in 1849 by Pirogoff ‡; the former overlooked one perforation and lost his patient; the latter lost sight of his patient on the fourth day. It does not appear in the accounts that either enlarged the parietal wound, and both quote their eases to support the opinion that it was advisable to resort to enterorrhaphy and not to abstain entirely from operative interference. Pirogoff says: "I regret that in the cases that came under my observation [in the war in the Caucasus] I employed the suture only once, and then in a sort of desperation. I gave up the other wounded as lost; as enterorrhaphy required time and many wounded were awaiting my assistance, I did not use the suture. But just this desperate case proved that much is to be expected from operative interference." Lohmeyer, writing after the Danish War, said that probing of the abdominal wound was indicated only when peritonitis had been set up by the escape of the contents of the intestine from a concealed wound in it and threatened to become fatal, and that then he would follow the example of Baudens and suture the bowel rather than try for a faecal fistula. Legouest, after the Crimean War, expressed similar views, and Demme, after the Italian War of 1859, referred to the treatment only to say that most authors condemned it, and that, in his opinion, it would prove impracticable in the large majority of cases because of the uncertainty of diagnosis. In the War of the Rebellion enterorrhaphy was done in three cases for shot wound of the small intestine by Bentley, Judson, and Gill. In all these cases the wounded gut protruded, and all terminated fatally. Kinloch operated in 1863 in a case of faecal fistula following a gunshot wound received nearly eight months previously. He laid open the peritoneal cavity, excised half an inch of the upper and two inches of the lower portion of the bowel, brought the cut edges into direct apposition with silver sutures, and effected a partial apposition of the serous surfaces

by a few Lembert sutures. The patient recovered, but union failed, and a small faecal fistula persisted.\* At the close of the war the late Dr. Hamilton † wrote: "Be assured the patient will have a better chance for life if we let him entirely alone; and it surprises me that any good surgeon would think otherwise." In 1867, after the Austro-Prussian War, Neudörfer says: "What, then, shall the physician do with a gunshot wound of the bowel? Nothing at all." In the edition of his "Surgery" printed in 1872 the late Dr. Gross, who, thirty years previously, had written strongly and with great authority in favor of enterorrhaphy in incised wounds of the intestine, repeats his approval of it, but adds (vol. ii, p. 667): "These remarks are more especially applicable to incised wounds. In gunshot wounds no benefit, it seems to me, would be likely to accrue from such a course of treatment [*i. e.*, to enlarge the abdominal orifice, to seek for the wounded tube, and to sew up the end], as the bowel is generally pierced in a number of places, and the case, on this account, must, therefore, generally be fatal."

In the same year, after the Franco-German War, Beck argued in favor of a bolder interference, but Eriksen † rejects all operative measures unless the wounded loop protrudes; and if faeces actually escape into the abdominal cavity, he only removes the sutures from the parietal wound and gently separates its edge to afford an outlet. Finally, in 1877, the editor of the "Medical and Surgical History of the War of the Rebellion," after an elaborate review of the subject, says (p. 128): "Reflection . . . leads unavoidably, in the writer's opinion, to a conviction of the propriety of incising the abdominal wall when necessary, in order to expose and sew up the wounded gut concealed within the cavity, whether divided by a cutting instrument or by a shot. The obstacles to success are obvious; but it is a mortal peril which demands an extreme remedy." He adds, in a note, that "over one hundred instances [of enterorrhaphy for incised and gunshot wounds] have already been adduced, with such a large percentage of recoveries that, with every allowance for the suppression of unfortunate results, the evidence is very encouraging"; and he further supports his opinion (note on p. 126) by quoting similar ones contained in letters sent him by Dr. J. S. Billings, Dr. Hunter McGuire, and Dr. N. S. Lincoln. Thus Dr. Billings writes: "When there is reason to suspect intestinal injury, it appears to me to be proper to enlarge the opening, if necessary, to ascertain the nature and amount of injury, . . . to employ sutures or ligatures where needed, and to cut these short and return the injured viscera." Professor McGuire says: "If the shock, thermometer, etc., indicate wound of the bowel, cut down and sew it up." And Professor Lincoln: "In shot wounds of the intestine, unattended by protrusion, unless the perforation may be in

the iliac region, with a reasonable likelihood of implicating the part of the large intestine uncovered by peritoneum, and therefore avoiding the risk of intraperitoneal extravasation, it is the safest course to enlarge the track of the ball and to close the intestinal wound by suture."

These opinions mark the beginning of the change, and doubtless were in some degree inspired by growing confidence in antiseptic surgery. It is noticeable in all that had preceded that the discussion always began with the assumption that a positive diagnosis of wound of the intestine, and often of faecal extravasation into the peritoneal cavity, existed, and the supporters of active interference had gained, even in that class of cases, so few adherents that the instances could almost be counted upon the fingers, and Baudens's enlargement of the parietal wound still remained unique. Of the cases which form so large a proportion of those now encountered in civil practice—cases in which there is at first no evidence of intestinal wound, and in which even the fact of perforation of the abdominal wall is in doubt—there is no mention in the discussions. Apparently it was the universal practice to give opium and await the result. The few cases in which enterorrhaphy had been done were of such a character that it is hard to see now how it could have been avoided; the wounded intestine lay in plain sight at the bottom of a large parietal opening, or was protruded through it. If anything was to be done, what else could it have been? So far as can be judged from reported histories, the line of treatment habitually followed was to administer opium, for the purpose of relieving pain and checking peristalsis, to apply ice to the abdomen, or sometimes to blister the surface to control inflammation, to keep the parietal wound open, and to "maintain the utmost cleanliness," by which attractive phrase was meant the removal from the surface of such faecal and inflammatory discharges as escaped from the interior of the abdomen.

Of the results of this treatment we can form, notwithstanding the vast number of cases reported, only a general idea, because the records probably fail to include a considerable number of fatal cases abandoned upon the field of battle without having received professional care. The Surgeon-General of the United States (*loc. cit.*, p. 202) reports 3,429 cases of penetrating shot-wounds of the abdomen, with visceral injuries, in which the result is known; of these, 421 recovered (12+ per cent.). In addition, there are 19 cases, with 12 recoveries, of penetration without known injury to the viscera. Colonel Otis says (p. 204): "The comparatively small category of cases of recovery after indubitable shot-penetration of the abdomen may be arranged in three divisions. The first and largest group would include the cases of perforation of the large intestine in parts uncovered by peritoneum, followed by recovery with or without abnormal anus. The second, a group so small that the absolutely authenticated examples can be counted on the fingers, comprises the instances of wounds of the solid or membranous viscera, with extravasation of their contents within the peritoneal cavity. In the third division would be placed the cases of recovery after undoubted penetration or perforation of the peritoneal cavity without visceral injury, or, as it would be safer to say, with very slight visceral

injury. On rigorous examination, these also would probably be found few in number." A review of the records of the cases described as recoveries after wound of the large intestine (Cases 235 to 293 and 295 to 299), which must have been included by Colonel Otis in the first of his three divisions, shows little or no reason in any of them for supposing that the intestine was wounded only at a point where it was uncovered by peritoneum, and in a large number of them there seems to be as much reason for supposing that the small intestine was wounded as that the large one was. Thus, in all the cases except five (295 to 299, in which the ball was voided at stool) the ball traversed the abdominal cavity, making its entrance or exit, or both, through the parietal peritoneum, and in a large number of them the wound of entrance or exit was within a few inches of the umbiliens. There is, in my judgment, nothing in them to justify the opinion indicated by his classification that wounds of the large intestine are so much less fatal than those of the small intestine; and, assuming his opinion to be correct, there is nothing in the position of the parietal wounds to enable a surgeon in any similar case to recognize which part of the intestine was wounded. I desire particularly to emphasize this fact, because Colonel Otis's opinion appears to be responsible for the frequently repeated statement that wounds of the small intestine are necessarily fatal, while those of the large intestine are much less dangerous, and the frequent repetition creates the impression that the opinion has been independently formed by many, or that it has a solid and unquestionable foundation. Taking the figures as they are given, they indicate a mortality of gunshot wounds in military practice of about 87 per cent.—say seven patients in every eight—and this, though somewhat larger, is still in substantial accord with the less complete unofficial statistics of individual experience in other wars grouped by Colonel Otis in another table (*loc. cit.*, p. 203): 1,146 cases, with 861 deaths (75 per cent.).

But we are considering the question to-day from the standpoint of civil practice, and we know that the circumstances of those wounded in battle differ greatly in some important respects from those of the wounded received into our civil hospitals. I have therefore collected from the case-books of several of the hospitals of New York the cases treated in them during the ten or fifteen years preceding 1885—a period during which the so-called "do-nothing" plan was habitually followed. The list is as follows:

HOSPITAL.	Cases.	Deaths.	Recoveries.
Chambers Street, 1876-1884 . . . . .	13	11	2
New York, 1884 . . . . .	4	2	2
Bellevue, 1870-1884 . . . . .	8	2	6
Roosevelt, 1872-1885 . . . . .	6	2	4
St. Vincent, 1880-1885 . . . . .	5	3	2
Presbyterian . . . . .	1	..	1
Total. . . . .	37	20	17

The question at once arises, In how many of the cases tabulated as recoveries was the wound actually perforating? and it must be admitted that the question can not be categorically answered. But I have included only those

cases in which the recorded symptoms—pain, vomiting, shock, abdominal distension, and tenderness—were such as would be held to-day by the supporters of active interference to justify an explorative laparotomy, and I think much weight should be given to the deliberate diagnosis of the attending surgeon. In some the diagnosis is absolutely beyond question, as, for example, in one of the Roosevelt Hospital cases in which Dr. Sands vainly sought, by a long incision of the skin, to trace the course of the bullet; two days later faeces escaped through the right inguinal canal, and, after this flow had lasted for some time, recovery followed. Corroborating evidence of the correctness of the diagnosis is, I think, to be found in the fact that, although in the last five years twenty-nine laparotomies have been done in this city for pistol-shot wounds of the abdomen, I have found no record and have not heard of any case in which the operation was undertaken and the wound found not to be penetrating. It seems highly improbable that, in about ten years preceding 1885, there should have been ten or fifteen cases in which an erroneous diagnosis of penetration was made, and that in the five following years there should have been no such mistake. On the other hand, I do not believe that the above thirty-seven cases include all that have occurred here within the period covered by the records, or that the rate of mortality of this table is as high as it would be if the record were complete; but, even if it were increased by the addition to the list of an equal number of fatal cases, its smallness would still, I think, be a surprise to all. Some of our hospital records are well known not to be complete, and a large proportion of the cases that escape recording are those in which death follows promptly after admission to the hospital. The foregoing table, therefore, is offered mainly to show that recovery after a perforating shot-wound of the abdomen, with probable injury of the small intestine, under non-operative treatment, is by no means so great an exception as it is generally alleged to be.

The great majority of these cases are of date subsequent to the publication of the opinions in favor of laparotomy quoted above. In all of them the treatment consisted almost solely in the administration of opium, and in many the parietal wound was washed with some antiseptic solution and then covered with carbolic or iodoform gauze. Surgeons possessed, practically, all the knowledge of the pathology of abdominal shot-wounds, of the various processes by which death is caused or repair effected, and of the methods of operation upon the intestine which they now have. They knew what was necessary or desirable to be done to increase the chances of recovery, but their hands were stayed by the fear that to do what was necessary or desirable was even more dangerous than to leave it undone. The fear had heretofore been well founded, and operations in which the peritoneal cavity was freely opened deservedly ranked among the most serious. But with generalization of the antiseptic method came increased security and confidence, and came also a revision of former notions of what was practicable and permissible, and a great increase in the range of operations. The opening of the peritoneal cavity for the relief of disease was done not only with greatly increased

frequency, but also with great success, and it became only a question of time and opportunity when it should be extended to gunshot injuries. The first operation under the new conditions and new ideas was done by Dr. Sébastopoulou, of Constantinople, in October, 1880, but, as it was not published until 1887,\* it remained without effect upon the opinions and practice of the profession. It was a repetition, and the first repetition if the cases of Nélaton and Pirogoff are excluded, under the protection of antiseptics, of Baudens's operation in 1831.

He was called an hour after the accident to a muscular young man who had been struck at a point midway between the umbilicus and the anterior inferior spine of the right ilium by a small pistol-ball which was thought to have been altered in shape by glancing from a neighboring stone. The wound was nearly an inch long and at once gave issue to a yellowish liquid and blood; pressure forced out clots and gas having an intestinal odor. Although unprovided with instruments or an anæsthetic, the surgeon immediately enlarged the wound to a length of six inches with a stout pair of scissors; about a quart of clotted and liquid blood escaped, followed by the loops of intestine soiled with faeces. On the convexity of one loop was a wound so large and irregular that he thought it best to resect the part and reunite the ends by invagination (Jobert's method), fastening them together by Lembert sutures. The haemorrhage which came from the divided epigastric artery was arrested, the abdomen washed out with a hot carbolic solution, and the abdominal wound closed with silk sutures, which were removed on the eighth day. When seen a year later the patient was again following his calling of wrestler.

The case was similar to those that had formed the basis of the discussions of the preceding half century in this respect—that the existence of a wound of the intestine was certain, and of an extravasation of faeces probable. It was novel in its free incision and in the use of a carbolic solution to cleanse the cavity.

In the following year, 1881, November 1st, Dr. R. A. Kinloch,† of Charleston, S. C., operated upon an adult negro who had been shot eleven hours previously with a pistol of .32 caliber; there was little shock, considerable abdominal tenderness, and pain in the sacral region. The finger introduced through the anus detected a perforation on the posterior wall of the rectum. He opened the abdomen by a median incision between the umbilicus and pubes, closed three perforations of the small intestine with Lembert sutures, and, as he was unable to find the wound in the rectum, he inserted a drainage-tube and closed the abdominal incision about it. The patient died ten hours later, and at the autopsy it was found that a wound of the small intestine had also been overlooked, as well as the one in the rectum.

This was the first case in which the operation was distinctly exploratory—that is, in which the abdomen was freely opened to discover and repair a suspected wound of the intestine; for if the wound previously recognized in the rectum had been the only one intended to be treated, it would hardly have been approached through the anterior abdominal wall. To Dr. Kinloch belongs all the credit that attaches to such priority. Moreover, the idea was not a new

\* Sébastopoulou, "Bull. de la soc. de chir." 1887, p. 274.

† Kinloch, "North Car. Med. Journal," July, 1882, p. 1.

one to him, and the operation was not done simply because others had suggested it. I have above referred to the operation he did in 1863 for the closing of a preternatural anus created by a gunshot wound; in reporting that case, he spoke against "the almost universal practice of abandoning intestinal lesions to nature rather than risk opening the peritoneal cavity." Fourteen years previously\* he had formulated the principle which he applied to this case, and he deserves not only the credit which goes with priority in practice, but also the much greater one which attaches to originality in conception. But—his patient died; and the stamp of success, *iste stultorum magister*, is as necessary to the recognition of the merit of an idea as to that of an individual. The case passed unnoticed, and this, too, notwithstanding the fact that, in a paper read before the New York Academy of Medicine in October, 1881, and published in the "British Medical Journal" in the following December, the late Dr. Marion Sims had spoken strongly in favor of the practice.†

Two years later (September 30, 1883) came the well-known successful case of Kocher. It was published in December, 1883, and an abstract of the case appeared in the "British Medical Journal," July 12, 1884, p. 78, and was copied in the "Am. Journal of the Medical Sciences" in October, 1884, p. 574, and this was followed the next month by Dr. Bull's successful case which was reported to the New York Surgical Society, January, 1885, and has done so much to spread the practice. How great that spread has been is shown by the statistics collected by Dr. W. B. Coley, above quoted. They contain 124 operations, divided as follows according to years: Previous to 1881, 3; 1881-'84, 4; 1885, 9; 1886, 22; 1887, 35; 1888, 32; 1889, 19. One hundred and three of the 124 operations were done in the United States. The mortality is 70 per cent.

The untrustworthiness, in respect of the percentage of mortality, of statistics made up largely of published cases is well known, and is strikingly shown by Dr. Coley's experience and by the results of my own search of the records of New York city. Dr. Coley's first collection, published in October, 1888, contained seventy-four cases with a mortality of about 60 per cent.; his further search has raised the mortality to about 70 per cent., although very few new cases of later date than his publication have been added. His published list contains nine published New York city cases, with three recoveries and six deaths. Only three additional operations—two deaths, one recovery—have since been done here. They are those reported this evening, and yet I have been able to increase the list by unpublished cases from

hospital records to a total of twenty-nine cases, with twenty-five deaths and four recoveries, a mortality of 86·2 per cent.

The details are as follows:

*Cases treated by Laparotomy in New York City.*

HOSPITAL.	Cases.	Deaths.	Recoveries.
Chambers Street .....	12	9	3
New York .....	1	1	..
Presbyterian.....	1	1	..
Bellevue .....	4	4	..
St. Luke's.....	1	1	..
Ninety-ninth Street.....	2	2	..
German.....	2	1	1
Roosevelt .....	3	3	..
St. Vincent.....	2	2	..
Dr. Jersey .....	1	1	..
Total.....	29	25	4

These I believe to be the integral statistics of this operation in the city of New York; certainly no successful cases are likely to have been overlooked. The only statistics of non-operative treatment with which I can compare them are those given above, the record of the War of the Rebellion with a mortality of about 87 per cent., and the cases which I collected from hospital records in this city. I have given my reasons for doubting the completeness of the latter list, and therefore I will select from it for comparison the records of a single hospital which I believe to be nearly, if not absolutely, exact in both classes of cases—those, namely, of the New York Hospital and its branch, the Chambers Street Hospital. The records cover the period from the latter part of 1876 to June, 1889. The cases at Chambers Street were under the care of Dr. Bull (1876-'87), myself (1888-'89), and Dr. Wilkin, assistant surgeon (1886-'89); those at the New York were under the care of Dr. Markoe, Dr. Sands, Dr. Weir, and Dr. Bull.

(To be continued.)

**The Health of Connecticut.**—According to the State Board of Health's "Monthly Bulletin," the total number of deaths reported from 167 towns during the month of September was 1,040, including 3 from scarlet fever, 14 from cerebro-spinal meningitis, 54 from diphtheria and croup, 3 from whooping-cough, 44 from typhoid fever, 16 from malarial fever, and 12 from typho-malarial fever. There were also 116 deaths from consumption, 37 from pneumonia, and 23 from bronchitis.

\* His case was reported in "Am. Jour. of the Med. Sci.," July, 1867.

† On February 9, 1882, Fitzgerald ("Austral. Med. Jour.," v, 1883, 33), and on February 26, 1883, Lloyd ("Brit. Med. Jour.," 1883, i, p. 560), operated unsuccessfully; but neither case belongs fairly in the category of those we are considering. In Fitzgerald's the wound in the side was large and lacerated and caused by a charge of bird-shot; it was enlarged upward and downward, and ten inches of small intestine resected. The patient survived five days. In Lloyd's the operation was not done until three days after the injury, and, strictly speaking, was only to establish drainage in a case of suppurative peritonitis, although a wounded loop of intestine was drawn up and fastened in the abdominal incision.

## THE TREATMENT OF DISEASED TONSILS WHEN UNATTENDED WITH HYPERSTROPHY.\*

BY JOHN O. ROE, M. D.,  
ROCHESTER, N. Y.

It is my purpose in this short paper to call attention to some chronic diseased conditions of the tonsils not characterized by hypertrophy. Such diseased conditions have frequently proved, in my experience, to be of marked clinical importance and to demand appropriate and thorough treatment.

The group of glands between the pillars of the fauces which constitute the faucial tonsils is, as has been stated by Dr. Bosworth,† so small in size when in their normal condition as to be scarcely perceptible on ordinary inspection. The condition of moderate prominence of the tonsil that is commonly seen is not a normal condition, although the tonsils may not be so much diseased as to give rise to any particular disturbance. It is a fact, however, that the tonsils may be and very often are so extensively diseased as to give rise to well-pronounced and often serious local and general disturbances, while at the same time they retain or may be reduced to about the same size as in health, and it is to this condition that the writer wishes to direct particular attention.

This condition of the tonsils has not only not received the attention it demands, but is not even mentioned by the majority of writers on tonsillary diseases, although it has not remained entirely unrecognized.

In conjunction with "Chronic Follicular Tonsillitis," Dr. Cohen ‡ recognizes the fact that the tonsils may be quite extensively diseased without being in a condition of hypertrophy, and Dr. Harrison Allen § has reported five cases of tonsillary disease producing well-marked and persistent symptoms in which the tonsils were small and so hidden behind projecting faucial pillars as to remain unnoticed.

A similar condition has been alluded to by Mr. Lennox Browne || in his brief description of "Chronic Laeunar Tonsillitis," and a case is reported by him similar to those reported by Dr. Allen. Dr. Maxwell,△ of Jacksonville, Fla., has practically recognized certain conditions of the tonsils that form the subject of this paper, but the title of his paper, "Ablation of Tonsils when Smaller than Natural," is misleading, for the reason that it presupposes or implies that tonsils are normally prominent and well-pronounced bodies.

Wagner,◊ in describing chronic catarrh of the lacunæ

in conjunction with atrophy of the tonsils, says: "The cyst-like dilatations of the lacunæ (like comedones) have a clinical importance from the fact that their contents act irritatingly on the contiguous parts, either mechanically or chemically. In this way are produced, and usually repeatedly, the various kinds of tonsillitis, and especially intratonsillar and peritonsillar abscess."

It is interesting to note that for these conditions, which are capable of producing so much mischief, Wagner recommends no treatment whatever, for the reason, he says, that they are seldom detected during life. It is a traditional and a very generally accepted idea that only hypertrophied tonsils require treatment, but the fallacy of this idea will be apparent by a careful consideration of these obscure abnormal conditions of the tonsils, which so often escape observation.

The primary and most common form of disease of the tonsils is hypertrophy. In children it is rare that we find any other than the hypertrophied form of tonsillary disease; but in adults other diseased conditions of the tonsils are of frequent occurrence. It is a recognized fact that hypertrophied tonsils in children become smaller when adolescence is reached; and it is also the common belief that the subsidence of these tonsils indicates a return, not only to their normal size, but to a normal condition. But a careful examination will readily show this belief to be a fallacy; and it is not infrequently the case that these small tonsils will give quite as much annoyance to the patient as he experienced from the tonsils in their enlarged condition. It is almost invariably the case that these small but diseased tonsils in adults follow as a sequel the hypertrophic tonsils of children, and exemplify the importance of removing from the throats of children all tonsils attended by any considerable degree of hypertrophy. All chronic diseased tonsils in adults almost invariably follow a condition of hypertrophy in childhood or youth; but in exceptional cases hypertrophy may not precede the diseased conditions under consideration.

The two forms of chronic diseased tonsils which remain after the subsidence of hypertrophy, or which may exist independent of hypertrophy, are—

1. A chronic disease of the crypts and lacunæ of the tonsil.
2. A fibroid degeneration of the stroma of the tonsil or a cicatricial formation at the base of the tonsil.

The first condition is the result of chronic follicular inflammation of the tonsil, and is almost invariably associated with chronic follicular pharyngitis. The most common form of this is attended by the destructive degeneration of hypertrophied tonsils in children, and is distinctly a diseased condition of the follicles of the tonsils. This slow but progressive destruction of the follicles of the tonsils is the exciting cause of the frequent attacks of suppurative inflammation, which often attends this condition, and which is easily induced by slight exposures or deranged condition of the system. These degenerate tonsils often have the appearance of being hypertrophied when the crypts and lacunæ are filled with the *débris* of the degeneration, which frequently has a very offensive odor and causes the person to have a very bad-smelling breath.

\* Read before the American Laryngological Association at its eleventh annual congress.

◊ Von Ziemssen's "Cyclopædia of the Practice of Medicine," American edition, vol. vi, p. 971.

It is not uncommon to find the surface of diseased tonsils studded with white spots which mark the openings of the lacunæ. These white spots are caused by the material discharged from the crypts and lacunæ of the tonsils and is the chronic inflammatory exudate resulting from the disease of the tonsil. On squeezing this out, it will be found to be of a soft, cheesy consistence, to resemble very much the contents of comedones, and to have an offensive odor, which may be more fully brought out by crushing it. It is usually the case that much deposit of this material is associated with more or less hypertrophy of the stroma of the tonsil, for when the stroma and follicles have undergone further degeneration, this substance is poured out in a fluid form.

The second condition is also the result of the follicular disease, except that, simultaneously with the degeneration of the lymph follicles, there is a deposit of fibrous material in the stroma. The cicatricial formation at the base of the tonsils is the result of the frequent attacks of suppuration around the base of the tonsils which is induced by the follicular disease.

The reason for these conditions being so frequently overlooked is that they usually give rise to little or no discomfort to the patient which he refers to the tonsils themselves; because the disturbances to which they do give rise are usually located in other parts, and are of a reflex character. Another reason for their being so readily overlooked is that, on examining the throat, the diseased condition of the tonsil generally looked for is hypertrophy. This being absent, the real disease of the tonsil remains unsuspected.

The chronic disease of the interior of the tonsil, even when it is attended with considerable discharge, is frequently undetected for the reason that the discharge is so readily cleared away by swallowing or drinking. In other cases the tonsil may be partially or completely hidden behind large and projecting faecal pillars. In the latter case the free exit of the tonsillar discharge may be prevented by the overlapping pillars, thereby causing a distension and dilatation of the crypts and a bulging of the pillars over the tonsils.

In these cases the anterior pillars should be drawn forward with a blunt hook. For this purpose an aneurysm needle or a plain palate retractor is very conveniently adopted. The act of gagging also assists materially in the examination by throwing the tonsils inward and forward, thus exposing them completely to view.

In all cases of obscure disease of the throat the tonsils should be carefully examined. The enlarged crypts and lacunæ may be explored with a probe for enlarged pouches which are so often filled with muco-purulent discharge; and this discharge can be readily demonstrated by simply squeezing it out with the finger. The formation in the tonsil and around its base of cicatricial tissue, which is very often the exciting cause of throat irritation, can also be readily detected with the probe and finger, and can usually be suspected by simply a careful inspection.

The local irritation produced by the diseased condition above described is manifested in a variety of disturbances about the throat and head. The association of this diseased

condition with follicular inflammation of the pharynx renders a removal of the abnormal condition of the tonsils a necessity, before the latter can be cured. Also, disease of the faecal tonsils is frequently the exciting cause of diseased conditions of the other so-called tonsils—the lingual and the pharyngeal tonsils.

It is also frequently manifested in irritation of the larynx and hoarseness; and it is not infrequent that cicatricial formations in and about the tonsils will produce neuralgia of the face, neck, and more or less frequent or persistent neuralgic affections of the ear.

The necessity of treatment of these diseases is therefore evident, not only from the existence of the disease itself, but from the liability of its becoming aggravated by the slightest causes, and also from the accompanying disturbances which it almost invariably produces. The method of treatment in these cases is always local, except in those conditions of the tonsil that depend upon specific disease, or those conditions of chronic inflammation of the circumcellular tissue of the tonsil that accompany rheumatic conditions.

Local applications of medicinal substances in these conditions of the tonsils are practically useless. The application of caustics, such as the Vienna or London paste, may be used in the first form of the disease described, in which the tonsil itself is soft and flabby. In the case of the fibrous or cicatricial formations, the efficacy of the paste is not so great, as the tissue is not readily destroyed by it. The galvanic cautery, which is sometimes employed for the removal of hypertrophied tonsils, may also be employed in these cases. It is, however, far more efficacious in the treatment of disease of the lacunæ and crypts, for the reason that the application of the galvanic cautery tends further to increase the formation of cicatricial tissue.

The treatment *par excellence* in all cases is that of ablation with the knife. In the case of diseased crypts, they may be laid open with a bistoury, and the interior of the crypt thoroughly cauterized with chromic acid or a solid stick of nitrate of silver, or the silver fused on a platinum probe, as proposed by Dr. Cohen. The best plan, however, in these cases is, according to my experience, that of excision. In such case, however, the amygdalotome can not be employed. The method of removing these tonsils is simply to grasp the tonsil with a double tenaculum, draw it forward from its bed, and remove a portion at a time. It is rarely advisable to attempt to remove the whole mass at one cut, for these tonsils are so often attached to the pillars of the fauces that wounding the pillars is liable to take place if care is not exercised. The plan which I adopt in these cases is, first, to anaesthetize the parts as thoroughly as possible with cocaine. This has a double advantage, in that it not only renders the operation less painful, but decreases the liability to haemorrhage. Then with a double tenaculum and a curved blunt-pointed tonsil-knife to remove small portions of the tonsil until all the diseased mass is thoroughly extirpated, usually leaving a deep excavation between the pillars of the fauces. In the case of a cicatricial formation, it should be removed as thoroughly as practicable. In some cases of chronic disease of the crypts of the tonsils it is advisable to remove the outer portion of the tonsil com-

pletely, thus exposing the interior of the crypt, which can be cauterized thoroughly.

In all cases, however, the complete extirpation of the gland when possible is far preferable to any other form of treatment, as nothing but a surface of healthy tissue is left, which heals quickly and permanently. In no instance has the writer observed any troublesome haemorrhage in these operations. This is doubtless due to the fact that in these cases the nutrient vessels going to the tonsils are small or are not so distended as they are when the tonsils are in a condition of hypertrophy.

A large number of cases illustrating the foregoing observations could be cited, but, as the recital of cases is tedious, I will simply state that in every instance excision of these small but diseased tonsils has resulted in a complete cure of the tonsillary disease, and entire relief from all the attendant symptoms of local disturbance and reflected irritation.

## POISONING BY ILLUMINATING GAS.

### HISTORY OF A CASE.

#### RAPID RECOVERY. A RATIONAL TREATMENT.

By WILLIAM C. KLOMAN, M. D.,  
BALTIMORE.

MODERN illuminating gas, the so-called "water gas," is a much more dangerous poison to the human system than the original gas made from coal. Booth ("Encyclopædia of Chemistry") states that illuminating gas made from coal consists, on an average, of light carbureted hydrogen, 57·7; carbonic oxide, 7·7; hydrogen, 21·2, etc., while the modern gas, on the authority of Professor P. B. Wilson, inspector of gas, etc., contains from 20 to 30 per cent. of carbonic oxide, showing an increase of from 300 to 400 per cent. Now, there is every reason to believe that the carbonic oxide is the actual poisonous constituent of illuminating gas.

The practical difference in the poisonous qualities of the two kinds of illuminating gases is best illustrated by the tables of mortality of our Board of Health, which state that prior to January 1, 1881, when the original gas was made from coal, there was but one death from poisoning by this gas during the previous fifty years, while since that period, to October 1, 1889, there have been recorded fifty-one deaths from poisoning by illuminating gas.

The actual nature of poisoning by carbonic oxide is yet a mooted question. Some authorities, such as Claude Bernard, Hoppe-Seyler, and others, believe the symptoms are entirely due to merely a deprivation of oxygen; others, such as Klebs, believe that carbonic oxide has narcotic properties acting on the central nervous system, independent of its power of robbing the blood of oxygen. At any rate, it is established that carbonic oxide has the power of decomposing the oxyhaemoglobin and forming a new compound with the haemoglobin, combining in the same volumetric proportions and forming a new compound which is crystallizable and which can be separated from the blood. This new compound is more stable than oxyhaemoglobin, and is not decomposed by the presence of oxygen. In fact, to the extent of its presence in the blood, it seems to render the

absorption of oxygen impossible, and if the entire quantity of oxyhaemoglobin of the blood is replaced by it, life is no longer possible.

Having recently treated a case of poisoning by this gas, and having successfully treated it by a remedy not heretofore mentioned in connection with the treatment, I have thought it best to introduce the history of the case with the foregoing short *résumé* of the nature of illuminating gas and its effects upon the system.

On September 4, 1889, I was called at 6.30 A. M. to see Diana, a colored girl aged seventeen years, a domestic in the family of Mr. S. She had recently come to the city from Virginia, and was not familiar with the use of gas. She was shown how to turn off the stop-cock and extinguish the flame. She went to bed at about 10 P. M., and was found insensible in her bed at 5 A. M., or soon after. The room-door and window were both closed and the atmosphere filled with the smell of escaping gas. The stop-cock was found partially turned off. Before my arrival she was moved to the adjoining bath-room, where the window was open. I found her lying upon the floor; her limbs were cold and relaxed; I could feel no pulse at the wrist; there was no sign of life except respiration, which was shallow and stertorous. The eyes were partly open, staring and fixed; the conjunctivæ were intensely congested; the pupils moderately dilated and insensible to light; the eyes were also insensible to touch. She was in a profound coma. I at once dissolved one of Sharp & Dohme's hypodermic tablets of nitroglycerin, one fiftieth of a grain, in my hypodermic syringe, and injected the solution into the upper arm. Her body was directed to be covered with blankets. In about two minutes I could feel pulsation at the wrist, and in five minutes her pulse was full and strong. *Pari passu*, the respiratory movement deepened and her limbs began to grow warm. In about fifteen minutes, while yet unconscious, she showed signs of vomiting; I turned her on her side, and she vomited some mucus and partly digested food containing some pieces of tomato. Soon after this she became partly conscious, and, reaction being thoroughly established, I wrote a prescription for æther. sulph., ʒ ss.; elix. ammon. valer., ʒ jss., and directed that during my absence a tea-spoonful diluted with water be administered every second hour. I returned to see her in about three hours, when, to my surprise, Diana walked into the parlor. She told me she was all right except for a slight headache. She also said that she had been constipated for several days, for which I ordered her a purgative. Beyond this she had no medication. Her headache continued for two or three days, but did not interfere with the performance of her duties.

A noteworthy point in this history is the length of time during which the patient was exposed to the inhalation of the gas—a period of not less than seven hours. I was doubtful of this until her recovery, when I questioned her, but found that she recollects nothing from the time she went to bed until she regained consciousness in the morning. It is not possible for me to state how much percentage of gas was in the atmosphere she breathed during the night, for the stop-cock was entirely turned off at once and the door and window of the room were opened before I came. In this connection, however, we must remember that there is a great difference in the susceptibility of different persons to its poisonous influence. Yet, whatever the amount of gas respired, it was evidently enough to render her deeply comatose and very nearly deprive her of life.

I have never heard or read of nitroglycerin being administered for poisoning by illuminating gas, and was moved to do so by the condition of the patient, which presented a profound depression of all the vital functions. I certainly expected to see her powers rally under the influence of this powerful stimulant, yet thought that several days would elapse before her system would throw off the effects of the poison sufficiently to enable her to be convalescent and return to her duties.

I have no explanation to give of the action of the remedy beyond its stimulant qualities, in which I have reason to have the utmost confidence. I regard it as the most powerful stimulant known. In the case under consideration hours would in all probability have elapsed before her system would have rallied under ordinary treatment, if she had rallied at all, since she was entirely unconscious and could not swallow.

I have found nitroglycerin to be an invaluable remedy in all conditions approximating the one found in this case; in traumatic and surgical shock, in the dyspnoea of asthma, and whenever there is great depression of the vital powers it will prove a prompt and reliable stand-by.

I constantly carry the remedy in my hypodermic case in the form of Sharp & Dohme's tablets, which I find to be more soluble than those of any other make which I have tried.

1519 JOHN STREET.

## A CASE OF EMPYEMA.\*

By H. B. SWARTWOUT, M. D.,  
PORT JERVIS, N. Y.

JOSEPH M., aged twenty, small in stature, was treated through the month of March, 1889, for pneumonia. His disease pursuing an unfavorable course, he changed to another physician, who attended him for about a week. He then fell victim to a so-called "Christian scientist," who prayed over him faithfully for some eight weeks, or until June 7th, when I was called to see him. I found him sitting up in bed, cyanosed, with a pulse 130 and feeble, breathing sixty times a minute, and afraid to lie down for fear of suffocation. On removing the shirt, the cause that was producing this alarming condition was fully pictured. The left side was enlarged and extensively oedematous, and in each intercostal space in the axillary line distinct fluctuation was present. The patient was greatly emaciated, and during the preceding four weeks had remained in bed, lying constantly on the left side. He was unable to get up even to attend to the calls of nature.

I introduced a large trocar and cannula in the eighth intercostal space and drew off some three quarts or more of pus; the patient standing that well, the cannula was withdrawn and a curved bistoury inserted, making a free opening, removing a still greater quantity, making in all five quarts. I inserted a rubber drainage-tube and applied oakum dressing. The patient's condition was immediately improved, the cyanosis disappeared, and the respiration dropped to 35 and the pulse to 100.

There were no antiseptics used for the first four days after the operation; then, on account of the high fever and the septic condition of the wound, the cavity was thoroughly irrigated

with a one-per-cent. carbolic-acid solution. The effect of the antiseptic washing, which was repeated every afternoon, was seen immediately. The bad-smelling wound soon assumed an aseptic condition, the temperature fell almost at once and within a week was normal, and has thus remained. The internal treatment was with brandy, quinine, and Phillips's emulsion of cod-liver oil. The use of brandy was discontinued after the first week.

In a week after the operation the patient was able to sit up, in two weeks went out of doors, and on the sixteenth day took a drive of a mile—in fact, his recovery from the date of the removal of the pus was one continuous steady improvement. On June 25th, eighteen days after the operation, the patient complained of passing water too frequently and of a small amount at a time. He had no other unfavorable symptom. I secured a specimen of the urine, and on examination found it pale, dirty yellow, of a specific gravity of 1.020, with albumin in slight amount, of a sickish sweet smell, and emitting on heating a decided carbolic odor. The microscope showed granular renal epithelium, minute oil-globules, and granular and hyaline casts, the latter not being perfectly clear, but interspersed with broken-down granular epithelium. Thinking possibly that this condition of the kidneys was brought about or aggravated by slow carbolic-acid poisoning, I discontinued the acid washings and substituted warm water. Within the next two weeks the kidneys gradually improved without any medication, so that there was no albumin, and, with the exception of an occasional cast, the urine seemed normal in every respect. Hence a still further reason for thinking that this condition of the kidneys was the result of slow carbolic-acid poisoning.

*July 5th.*—Twenty-eight days after operating. For a few days previous to this date the lung expanded rapidly and filled nearly the entire cavity. The only portion remaining vacant was a cavity about three inches in diameter on the anterior side of the chest, extending upward from the opening toward the nipple and bordering on the heart. The diaphragm also ascended and pressed against the tube, so that the tube was with difficulty kept in place, making irrigation next to impossible. This was the last time irrigation was practiced. The tube was gradually removed and the opening allowed to close.

The cavity on the anterior portion was mapped out by the amphoric sound, which was very distinct, and by tympanites on percussion, and was either in the lung substance or circumscribed pneumothorax with a perforation of the lung entering it. My opinion is that it was the latter. At present the amphoric respiration is heard only with the patient in the recumbent posture, a modified vesicular respiration being now discernible over the same portion when the patient is sitting up.

The pulse varies from 80 beats to the minute to 130. I hardly know how to account for this wide difference. In apparently the same condition this difference is noticed, and at times when he appears at his best the pulse is 130. His general condition, while not the best, was not sufficiently weak to cause this variation. It seems to me that the pneumothorax bordering on the heart in some way affects its action, as possibly the cavity does not at all times have the same atmospheric pressure.

*Other Points of Interest in the Case.*—The long standing and extreme gravity of the case when first seen, with favorable recovery. Never hesitate to remove the pus, no matter how alarming the condition. The point of opening is quite important. Had the rule been followed in this case and the opening made in the sixth or seventh interspace instead of the eighth, it would not have been so difficult to irrigate toward the last.

\* Read before the Fifth District Branch of the New York State Medical Association at its seventh special meeting, Port Jervis, August 27, 1889.

Washing out the pleural cavity is a very simple procedure, yet in this subject attacks of spasmodic coughing at times made the outlook quite serious, and the loose false membrane materially interfered. On washing out this patient with carbolic-acid solution, the acid was immediately tasted by him in the expired air and in the mucus raised from the lung. This is not always the case, and may have some bearing on his susceptibility to poisoning. The numerous changes which the chest undergoes, and the amount of the inflammatory exudate, make a physical diagnosis very unsatisfactory. It is difficult to tell exactly what progress the case is making, and just when to discontinue irrigation and to close the opening.

This case illustrates the general rule, where the walls of the cavity are rigid and the lung bound down by fibrous bands and old adhesion; at the third or fourth week they undergo fatty granular degeneration and disappear, allowing the lung to expand and fill the cavity.

In regard to "Christian scientists." Their ways and modes of deception are no doubt familiar to you all and need not be related here. Yet to see how such views are accepted by intelligent people is beyond comprehension. In a case of this kind, or in any case for that matter, it ought to be considered criminal for them to interfere, and it seems the duty of the medical profession, and especially of the State societies, to see that laws are enacted that would exterminate them as a class from inflicting their nonsense upon the human race.

## CHRONIC ULCERS OF THE LEG.

By A. F. E. KROG, M.D.

If there be any part of the human body that seems to have any more inclination or a greater predisposition to any form of chronic ulceration than another it is undoubtedly the leg. In consequence of its anatomical relation, being farthest distant from the heart, its circulation of blood is slower and less forcible. The weight and quantity of venous blood to be propelled and returned to the heart are in themselves quite an impediment to be overcome; the erect and vertical posture, the activity of muscles in walking, and the close adherence of the skin to the tibia, add to its retardation. Consequently, all the conditions for a venous hyperæmia of the leg are given. Slight causes result in swelling and œdema, and more especially in a varicose condition of the vessels. Thus it is not difficult to understand that such slight accidents or injuries as the opening of an eczematous pustule or furuncle, or the scratching and rubbing of the itching surface of the eczematous or hyperæmic and œdematosus skin, should result in a chronic ulcer of the leg. Very frequently it is caused by spontaneous inflammation of a varicose vein, a phlebitis in consequence of a thrombus, maceration of the skin as the result of perspiration, or irritations due to improper stockings, boots, shoes, or garters.

Whatever the causes, we shall find that the epidermis forms a crust and the surrounding tissue is tense. Taking off this necrotic tissue, we find underneath a circumscribed deficiency—the ulcer. Its form may be either

round or elliptic, but almost always it becomes irregularly circular. Its borders are generally devoid of all reaction and sensation, but sometimes very hyperæsthetic; they are flat or undermined, deep, rounded, as if rolled upon themselves. The callosity is specially peculiar to the chronic ulcer of the leg. The floor of the ulcer is filled with its necrotic contents, with a smoky mass of a white, yellow, or dirty-gray appearance, sometimes with fungous granulations, which have a tendency to bleed easily. The secretion is confined to very little pus. The surroundings of the ulcer are, as a rule, hard, callous, indurated, and œdematos; the immediate vicinity is red, varicose, and at times pigmented. The chronic ulcer of the leg has no tendency to heal of itself, but, on the contrary, has a tendency to spread irregularly. It may be of the size of a silver dollar or a hand, or even take in the entire circumference of the leg. The skin, the underlying muscles, and the periosteum are changed into a thick and hard mass. New bone is formed; periostitis and ossification between the tibia and fibula take place; thickening and ossification of the capsules of the ankles, and hence ankylosis. Furthermore, hypertrophy of the papillæ takes place, the skin becomes œdematos, the epidermis horny, hard, dry, and devoid of all natural secretions, and consequently the leg takes on the appearance of "elephantiasis."

The continuance of such ulcer not alone gives rise to erysipelas, lymphangitis, or septic poisoning, but also acts detrimentally by giving rise to hectic fevers, amyloid degeneration, marasmus, and carcinoma (Broca, Meissner, H. Fischer, Eulenburg). It is for these reasons that all the care possible should be bestowed upon them, in order to effect a prompt and speedy cure.

In the treatment of these ulcers it is pre-eminently necessary to obviate and relieve the lower extremity of its venous congestion; therefore the leg is to be placed in a horizontal or, better, in an elevated position, to allow of perfect freedom and better return of its circulation; this latter can also be assisted by means of bandages, preferably elastic. The callosity is removed with warm and moist applications, or baths containing soda, in order to obtain a healthy appearance of the ulcer. The wound itself is dressed with iodoform, absorbent cotton, and an elastic bandage. If the ulcer has no tendency to heal, I have applied—after cleansing—tinctor of iodine with very good result, also chloride of zinc 1 : 1, and nitrate of silver.

Fowler, of Brooklyn ("Medical Record," July 2, 1887), recommends a solution of hydrarg. biniod., 1 to 4,000, for disinfection, and a paste of zinc. oxid. and hot water in order to remove the callosity. Antonio Grossich ("Gazzetta med. italiana lombard.," No. 44) recommends an application of a ten-per-cent. solution of acid. phosphor. as having an excellent effect toward healing these ulcers.

In case, though, the callosity is so great that the acids or other applications applied would have no effect or might produce destruction of the neighboring parts, it will be found necessary to cut the margins of the ulcer by means of knife or scissors, and then to destroy the granulations with the thermo-cautery or eurette. The resulting wound is dressed as has already been mentioned.

Through whatever means we may have succeeded in bringing about a clean wound with healthy granulations, our next object must be to produce a covering, for the skin has as little tendency as possible toward cicatrization. To this end transplantation is best resorted to.

Jacques Reverdin was the first to attempt this, in 1869, at the Hôpital Necker in Paris. The skin to be used for the purpose can be taken either from the same individual or another, or from an amputated extremity, even six hours after it has been severed from the body. By means of Cooper's scissors minute pieces of skin are cut off, containing nothing but the rete Malpighii and papillæ. The success depends entirely on taking no subcutaneous tissue and on the avoidance of bleeding. These particles are then placed upon the ulcer. The plastic lymph and secretion are sufficient to "fix" and keep them in position. The whole is then dressed as mentioned above. These little islands of skin form the center of new skin formation; thus hundreds may be implanted. The cicatrix thus formed is smooth, strong, and permanent. By means of this method contractions are warded off, which otherwise would hinder and impede the functions of the leg.

Amputation of the diseased limb, as the *ultimum refugium*, will be necessary in case of long continuous discharge, marasmus, immobility, pain, nephritis, amyloid degeneration, and the like.

## Correspondence.

### LETTER FROM LONDON.

*The Medical Session.—The British Medical Association.—The New Lunacy Act.—Work at the Medical Societies.*

LONDON, October 12, 1889.

THE commencement of another medical session has come and gone with its usual accompaniment of introductory addresses and annual dinners of old students. The latter form of entertainment is very naturally highly popular, but I can not say as much for the former. The addresses themselves seem to have been singularly unproductive, and I look forward to the, I hope not far distant, time when they as well as systematic lectures will be swept away with the advance of civilization. One of the lecturers, Mr. Godlee, at University College did not hesitate to say that he thought they might be given up with advantage, and one circumstance which will, I think, materially contribute to bring about this result is the increasing tendency of students to begin work in the summer. It is a practice which has been openly encouraged by the school authorities only within the last year or two, and it seems by no means impossible that in another ten years May will have taken the place of October as the birthtime of the medical student. It is too early yet to have official information as to the entries this year, but I have heard privately that at St. Bartholomew's, Guy's, St. George's, and Charing Cross the numbers are considered very good; of the other schools at present I know nothing.

There has been singularly little doing in the world of medical polities. August and September are always very slack months; the leaders are away and the small fry are too busy in their absence trying to pick up the crumbs they may have left behind. The annual meeting of the British Medical Association generally supplies some material for gossip. This year the

meeting took place at Leeds, when it was expected that something of the nature of a row would take place, as it was known that a memorial objecting to the conduct of the "British Medical Journal" in one respect had been signed by about a thousand prominent members in London. The Council of the association treated the memorialists with a very high hand, and when the subject was brought up at the general meeting in the report of the Council none of the party in opposition were present to fight their cause, the result being an almost unanimous vote in support of the action taken by the Council. The memorialists are now, according to their own statement, bound to secede from the association, but I have not heard yet that they have done so. This little disturbance has had one unfortunate effect, viz.: it has prevented the next meeting from being held in London, as was at one time contemplated, and up to the present time no decision has been arrived at as to where next year's meeting shall be held.

The Lunacy Laws have received important modifications in the Act passed last session, which will come into force next May. The most important of the changes is perhaps the requiring that in the case of a private, i.e., a non-pauper, lunatic, the order for his reception must be signed by a magistrate, such magistrate being specially appointed for the district, so that it will not do to rush off for the nearest magistrate, but the particular officer appointed must be found and his sanction obtained. There is no proposal, however, as was, I believe, at one time contemplated, that he should see the patient. In case of emergency the patient may be placed under control on one medical certificate as heretofore, but the detention order must be obtained from the magistrate subsequently. A most inconvenient proviso has been added giving the patient the right of insisting upon being seen by some other magistrate or judge after his admission. A report must be made by the asylum superintendent within a month of the patient's admission, and the reception order only remains in force for a year, but at the end of that time may be renewed for two years and after that for three years, and subsequently it must be renewed every five years, and as each time for renewing the certificate comes round the superintendent of the asylum must make out a special report as to the mental and bodily condition of the patient and send it in to the Commissioners, so that the amount of additional work placed on the superintendent of a large asylum will be very great. Another novelty is that a person may voluntarily enter a lunatic asylum as a boarder, and may leave the asylum at any time by giving twenty-four hours' notice. Henceforth, therefore, it will not be necessary for the enterprising young men who represent a certain class of periodical literature to feign madness to get within the sacred precincts of an asylum, so as to be able subsequently to describe to a gullible public the imaginary horrors they have become acquainted with.

The work of our chief societies will be somewhat delayed this session, for the new premises of the Medico-chirurgical Society are very far from ready, while the old ones have been given up, so that at present the four leading societies are without a meeting room. The Ophthalmological Society will get to work next week under the guidance of a new president, Dr. Hingshings Jackson, who is the first physician to hold the office, but he has been closely identified with the society since its foundation, nine years ago, and it was therefore only natural that he should be invited to become its chief officer.

---

"*Typhoid fever*," says the "Medical and Surgical Reporter," "is epidemic at Aurora, W. Va., and it is said the country for miles around is infected. It is said that there is scarcely a family without one or more of its members prostrated with the disease, and in some localities there are scarcely enough well persons to nurse the sick."

THE  
NEW YORK MEDICAL JOURNAL,  
*A Weekly Review of Medicine.*

Published by  
D. APPLETON & CO.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, OCTOBER 26, 1889.

**THE PREVENTION OF RABIES BY PASTEUR'S TREATMENT**

In order to secure a discussion on the advantage of recommending persons bitten by rabid animals to submit to Pasteur's inoculations of rabietic virus, the chairman of the Section in Medicine, at the recent meeting of the British Medical Association, requested M. Pasteur to designate some one to present his views. Dr. A. Ruffer, being selected, read a paper on the subject in which he reviewed the genesis of Pasteur's discovery, referring to the existence of twenty antirabietic institutes in various parts of the world as attesting their value. Dr. Ruffer believed that the virus was probably a micro-organism, propagated by inoculation, easily destroyed by sunlight, heat, or drying—a temperature of 50° to 60° C. for an hour, of 45° C. for twenty-four hours, or of 62° C. for four minutes, completely destroying its virulent properties, while low temperatures (30° C.) did not affect it. Inoculations of virus from the central nervous system of an animal dead of rabies, under the dura mater of an animal, was the only absolutely certain means of reproducing it, though it had been produced by inoculations of blood, of urine, of the liver, of the kidneys, of the spleen, and of the salivary glands. The recorded incubation period in man varied from thirteen days to eighteen months after the inoculation, the average being within two months.

After injecting an emulsion of the medulla oblongata of rabid animals under the dura mater of rabbits, symptoms of rabies appear in from nine to fifteen days. Successive inoculations from one rabbit to another reduce the incubation period to six or seven days, the animal invariably dying of rabies on the tenth day. If the spinal cord of a rabbit that has died of rabies is suspended in a sterilized bottle, the air of which is dried by a piece of caustic potash in the bottom, and the bottle is kept at a temperature of 25° C., inoculations of a healthy rabbit with an emulsion of the cord after one day's drying will cause rabies, but the animal dies one or two days later than when fresh virus is employed. Each day that the cord is kept in the sterilized bottle decreases its virulence; careful and extensive experiments by Dr. G. B. Uffreduzzi show that eleven days' drying postpones death until from the twentieth to the twenty-fifth day, and after twelve days' drying the cord is harmless.

Dr. Ruffer calls attention to the fact that injections of the emulsion of the spinal cord of rabid animals introduce not only the micro-organism of rabies, but the ptomaine produced by it. If an emulsion of the spinal cord of a rabid rabbit, after fourteen and thirteen days' drying, is injected under a man's skin, there is probably introduced a large quantity of ptomaine in proportion to the small number of micro-organisms.

If on the second day an inoculation is made of an emulsion of a cord dried for thirteen days, and on the third day one of an emulsion of a cord dried for twelve days, each succeeding day a cord dried for a shorter period being inoculated, there will be introduced on successive days a decreasing amount of ptomaine and an increasing number of micro-organisms. This is the method adopted by Pasteur in treating men bitten by rabid animals, except that in bites on the face, on account of their greater severity, an intenser form of inoculation is employed—on the first day matter from cords dried for fourteen, thirteen, twelve, and eleven days is injected; on the second day, from cords dried for ten, nine, eight, and seven days; on the third day, from a cord dried for six days; on the fourth and fifth days, from a cord dried for five days; on the sixth, from a cord dried for four days; on the seventh, from a cord dried for three days; and on the succeeding days, matter from cords dried for longer periods is again employed. Each injection consists of about half a cubic centimetre of spinal cord crushed in two cubic centimetres of sterilized beef-tea. The cord is tested for the bacteria of putrefaction by placing a piece in sterilized beef-broth for twenty-four hours, at a temperature of 38° C. No bad results follow the injection of this fluid under the skin of healthy men.

The author believes that the mortality from bites of rabid animals is probably placed too high by the statistics (twenty to fifty per cent.), the cases of many who recover without treatment not being included; fifteen per cent. is a fair average. In wolf bites, however, the mortality varies from sixty to sixty-four per cent. At the Pasteur Institute careful inquiries are made as to whether the animal was rabid or not; whenever it is possible, the animal's head is obtained and inoculations are made from an emulsion of the brain. Where this is not possible, a certificate from a veterinary surgeon that has seen the animal is obtained, and inquiries are made as to whether other persons were bitten or not. The patients are divided into three classes: those known to have been bitten by rabid animals, as demonstrated by inoculation experiments; those bitten by animals certified as rabid by a veterinary surgeon; and those bitten by animals suspected to be rabid. If these statistics are compared with those obtained by preventive inoculation, a telling argument will be found in favor of the latter.

Bujwid, at Warsaw, inoculated 370 persons bitten by animals undoubtedly rabid, and not a death occurred in the series. Up to July 29th of this year he had inoculated 146 bitten persons, and only one death from rabies had occurred among them. At St. Petersburg 484 persons bitten by rabid animals were inoculated from July, 1886, to September, 1888, and the mortality from the disease was only 2·68 per cent. At Odessa, in 1888, in 364 persons inoculated the mortality was only 0·64 per cent. At Moscow, in 1888, in 431 inoculated persons the mortality was only 3·46 per cent. At Turin the mortality was 1·88 per cent. in 531 inoculated persons. At Lisbon the mortality was 0·59 per cent. in 355 persons. At Palermo 343 persons were inoculated, with a mortality of 1·37 per cent. At Naples 347 persons were inoculated, with a mortality of 1·72

per cent. At Constantinople no deaths occurred among 34 inoculated persons. At Havana the mortality was 0·60 per cent. in 170 inoculated persons. During the past year the mortality in M. Pasteur's Institute was 1·16 per cent. As the inoculations have never caused death, it seems but justice to a person bitten by a rabid animal that the attending physician should employ, or recommend the employment of, Pasteur's system of inoculation. This opinion was expressed by those participating in the discussion.

#### THE CLIMATOLOGY OF CANCER.

THE "Lancet" for September 14th contains an article on "The Infrequency of Cancer among Females in the English Lake District," by Mr. Alfred Haviland. The article is supplementary to some remarks published last year by the same author, and is an important addition to the literature of medical climatology. Mr. Haviland has been engaged upon investigations into the geographical distribution of disease for a number of years. The conclusions he first drew were that those low-lying districts which were traversed by, or contiguous to, fully formed rivers that periodically flooded the country through which they flowed were characterized by the highest mortality from cancer. On the other hand, those districts which showed the lowest mortality had a high average level with free access of the prevailing wind, and were situated on or near the water-partings, where rivers derived their sources and where the rock base under them consisted of the older geological formations.

Subsequent investigation showed remarkable exceptions to the foregoing conclusions. It was found that in certain frequently flooded river valleys death from cancer in women was comparatively rare. The author found in these locations, coincident with low mortality, that limestone or chalk formed the rock base of the surface soil. Underlying the gravel and alluvium of the high-mortality riparial districts there were the different varieties of clay, all retentive strata, calculated to intensify the evils of floods and their sequels—dead vegetation and vegetable decomposition—and resulting in the formation of numerous gases and acids. This not only rendered the soil sour, but injuriously affected the atmosphere above it, and therefore the local climate where floods occurred. Grasses and other vegetation covering the soil overlying chalk or limestone, even when covered to a considerable depth by sand and gravel, remained sweet. The vegetable acids, the result of decomposition, were neutralized by the chalk.

The author's deductions were that the physiological configuration and the geological structure of a district greatly influenced the local climate, and that the chemical properties of the soil were answerable for a larger percentage of the mortality from cancer than had been generally supposed. In the English lake districts conditions of soil and local climate had been found to exist least conducive to the growth of cancer, and most favorable to the lowest mortality from the disease. Mr. Haviland found that the distribution of phthisis throughout Great Britain was decidedly the reverse of that of cancer.

The highest mortality districts in one map were, as a rule, represented by low mortality in the other, and where low mortalities from these two causes of death were coincident the districts were found to be the most salubrious, as indicated by their death-rates from "all causes."

#### MINOR PARAGRAPHS.

##### THE ANTISEPTIC METHOD AMONG THE ANCIENTS.

ACCORDING to the "Wiener klinische Wochenschrift," Dr. A. Agnastakis, of Athens, has recently published a brochure on this subject that is a valuable contribution to the history of surgery. He furnishes indisputable proof that antisepsis was, for more than two thousand years, the common practice of surgeons. It was practiced with all the forms and rigor of a perfected method, and Hippocrates was its originator. The work is divided into several sections, containing the Hippocratic precepts that have full force to-day: 1. Cleanliness in treating wounds is a precept that Hippocrates can not often enough repeat; again and again he emphasizes the necessity of the cleanliness of dressings, of the hands, etc. The ancient surgeons employed warm sterilized water (boiled rain-water) for dressing wounds. 2. The antisepsis of the ancients was founded on theoretical principles. Hippocrates taught that suppuration came from putrefaction. For example, he said: "A wound must be made clean and dry, so that it does not remain moist too long, or it will swell and become spongy; this, it is to be feared, causes putrefaction." "In a word, where the moist wound surface threatens to putrefy, suppuration is prevented by drying substances." Among the surgical appliances of the ancients were the exsiccative substances; all drying media were those that had long been used in embalming cadavers and preserving breadstuffs. 3. Alcohol, in the form of wine, was given for its direct effect in catarrhs. Sea salt in solution and powder was esteemed an excellent local remedy for the bite of a mad dog. Fine powdered salt was strewn on a serious wound during an operation. For the ligature of vessels, aseptic prepared silk and fine catgut were employed. Wounds were covered with poplar-tar. As we use corrosive sublimate to-day, so the ancients employed sulphate of copper; the copper compounds were almost exclusively employed in the treatment of wounds. 4. The antiseptic treatment of wounds by the ancients had the explicit aim of preventing putrefaction by hindering suppuration. To stop haemorrhage, the wound was covered with warm wine or salt solution, and then cleansed with linen: the surface was then treated with a copper solution or a preparation of tar, and the wound finally closed with sutures. Over the surface antiseptic substances (copper compounds, rosin, etc.) were sprinkled; then a tar plaster or a compress saturated with wine or asphalt was applied. The vicinity was made air-proof by spreading cerate over it; finally, a compress wet with wine was applied, and thus a clean dressing was secured.

##### CONGENITAL SEXUAL PERVERSION CURED BY HYPNOTISM.

PROFESSOR VON KRAFFT-EBING has recently added another to his important studies in hypnotism. The article is published in the "Internationales Centralblatt für die Physiologie und Pathologie der Harn- und Sexual-Organe," and we find an abstract of it in the "Deutsche Medizinal-Zeitung." A young man of thirty-four years, a doctor of philosophy, of unusually high education, with a special love for the fine arts, and physically the peer of any man, made application to von Krafft-Ebing for treatment by hypnotic suggestion. He hoped in this way to be

relieved of a perverted sexual impulse toward his own sex. Women had no attraction for him, and, although he was engaged to be married, he feared he should never be potent in his connubial relations. There was some hereditary taint in his family. While, however, erections were easily excited by the presence of members of his own sex, he never had the desire to have carnal relations with them. It was an impulse only, but without the imperative idea of acting upon it. He was hypnotized according to the Bernheim method and repeated the following suggestion after the operator: "I feel that from now on I am sexually indifferent to men, that men are to me sexually no more than women." Five days later he reappeared, joyously stating that he had been freed from his disorder and felt a new desire for life. For a week following he was hypnotized daily, and made to repeat the same formula. He was then pronounced well. No attempt was made to inculcate the normal desire for the opposite sex into his mind. Doubtless the professor thought he would be better off without it.

#### A DEALER IN FRAUDULENT DIPLOMAS.

THE arrest of "Dr." Henry Freeland, the alleged head of seven bogus medical colleges, took place in Maine on the 2d inst. He is to be tried at Portsmouth, N. H. It is not known how long this diploma-mill had been working before its exposure was published in one of the Boston papers, but one of the fraudulent diplomas is known to have been issued early in 1888. The buyers of diplomas were charged from fifty to three hundred dollars. It is a partial compensation to note that these frauds are brought to book more speedily than was formerly the case; but even now the punishment that will be visited upon this dealer in diplomas—if he is punished—will be only that for an illegal use of the mail, rather than for a crime against his clients or the public at large. In other words, the General Government must be invited to intervene and prosecute the accused for an act which is not, or might not be, essential to the carrying on of an extensive business in fraudulent credentials. The truth is that comparatively few States have any laws that are competent to the punishment of this kind of iniquity; and this shrewd indirection about the "illegal use of the mail" is a decidedly fortunate circumstance for some of them.

#### VIRCHOW AND THE DARWINIAN THEORY.

ACCORDING to the Vienna correspondent of the "British Medical Journal," in Professor Virchow's presidential address at the recent meeting of the Anthropological Congress, the Darwinian theory was referred to, and he said that the intermediate link that should bring man and the ape into connection—the proper "prosanthropos"—had been sought for in vain. It was impossible even to determine the descent of single races from others; and it could be asserted that among the ancient races there was none that stood in any nearer relationship to the ape than ourselves. There was no tribe of people in the world that we were unacquainted with; and not one of the known tribes could justly be considered ape-like, appearances common to apes—such as prominences of the skull—being insufficient evidence of relationship. There was evidence that in the course of 5,000 years no remarkable changes of type had taken place. This adds to the evidence of the impassability of the chasm between the highest type of anthropoid ape and the lowest type of man.

#### A MEDICAL CANDIDATE FOR OFFICE.

WE are glad to learn that Dr. Paul H. Kretzschmar, of Brooklyn, has been nominated by one of the political parties for the

office of supervisor at large for the County of Kings. It is too seldom that members of the medical profession are willing to accept that particular duty of citizenship that is involved in the tenure of public office. Dr. Kretzschmar has already served on the Brooklyn Civil Service Commission.

#### A DEATH BY HYDROPHOBIA.

AT Astoria, Long Island, the second death by hydrophobia, after the lapse of a generation, has recently been reported. The victim was bitten by a random, ownerless Spitz dog, five months ago. The cur was killed, but whether it was rabid or not at the time of the biting is not known. The patient's symptoms had once or twice pointed toward an infection by rabies, but they were dispelled by treatment and other agencies until about a week ago, when the marked indications of hydrophobia became unmistakable and advanced, during a period of four days, until death by asthenia occurred.

#### PROFESSOR STRUTHERS, OF ABERDEEN.

THE professorship of anatomy at Aberdeen University is vacant by reason of the resignation of Professor John Struthers. Dr. Struthers had been at Aberdeen since 1863, but had been a teacher of anatomy at the Edinburgh University from the time of his graduation, in 1845; so that forty-four years has been the tenure of his instructorship in the two great schools. In 1866 he published an excellent history of the Edinburgh Anatomical School.

#### ANTIPYRINE IN UTERINE CANCER.

A LETTER to the "Lancet" calls attention to the use of antipyrine in cancer of the cervix uteri. Severe lancinating pains, worse at night, occurring in an advanced stage of this disease, disturbed sleep, intense fetor of the discharge, and many other discomforts rendered the case particularly harrowing. Ten grains of antipyrine subdued the pain at once, though the beneficial effect of the drug was of short duration. This treatment was repeated as often as necessary, without the occurrence of any unpleasant symptoms attributable to antipyrine.

#### THE NECROSCOPISTS IN THE BISHOP CASE.

THE board of trustees of the Society of Medical Jurisprudence and State Medicine has taken action that has resulted in the passage of a resolution by the society expressive of sympathy with the medical men under indictment for the part taken by them in the post-mortem examination of the late Mr. Bishop. We are sure that they have the sympathy of the entire profession also. Their action was at most only a technical offense, and the trouble that has already come upon them in consequence of it undoubtedly constitutes as much punishment as any fair-minded citizen would wish to see inflicted on them. We think, therefore, that their further prosecution might be stopped without any disadvantage to the public welfare.

#### THE PHYSICIANS' MUTUAL AID ASSOCIATION.

A FRESH manifestation of the growing appreciation on the part of the local profession of the usefulness of the New York Physicians' Mutual Aid Association is afforded by the fact that its members are now so numerous as to have recently warranted the board of trustees in voting to pay six hundred dollars, instead of five hundred and fifty, to the beneficiaries of deceased members. A decided additional increase of its membership is to be expected.

## THE LATE DR. PHILIPPE RICORD.

THE death of M. Ricord, at the age of ninety, is announced as having taken place on Tuesday of this week. As all the world knows, he was for many years the most noted of venereal specialists, and our knowledge of venereal diseases is largely the outgrowth of his investigations. In spite of his great age, he was, almost to the last, seen and heard from in Parisian medical circles. He was born in Baltimore, of French parents.

## ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 22, 1889:

DISEASES.	Week ending Oct. 15.		Week ending Oct. 22.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	77	13	58	13
Scarlet fever.....	40	3	32	4
Cerebro-spinal meningitis.....	1	0	0	0
Measles.....	12	1	27	1
Diphtheria.....	64	20	79	26

**The New York Polyclinic.**—Dr. Carl Koller, formerly of Vienna, to whom we owe our knowledge of the anaesthetic power of cocaine, has been appointed instructor in ophthalmology at the Polyclinic.

**The Medical Society of the State of New York.**—Last week we published the address of the chairman of the business committee. Experience shows that many of the members choose to address the president. That they may be able to do so, we will state that the address of the president, Dr. Daniel Lewis, is No. 62 Park Avenue, New York.

**The Philadelphia Polyclinic and College for Graduates in Medicine.**—The board of trustees have recognized the distinguished services rendered the institution, as former professors, by the following four eminent physicians: Richard J. Levis, M. D., who has been elected emeritus professor of surgery; J. Solis-Cohen, M. D., who has been elected emeritus professor of diseases of the throat and chest; Charles H. Burnett, M. D., who has been elected emeritus professor of otology; and Charles B. Nancrede, M. D., who was recently called to the chair of surgery at the University of Michigan, has been elected emeritus professor of general and orthopaedic surgery. An additional chair of orthopaedic surgery has been created, and Dr. Thomas G. Morton has been elected professor. A new department of dentistry has been created and the faculty has been authorized to place a competent person in charge until the next meeting of the trustees. A new department of experimental therapeutics and physiology has been created, and Thomas J. Mays, M. D., has been elected professor. The chair of clinical surgery has been filled by the election of Thomas S. K. Morton, M. D. C. L. Bower, M. D., has been elected adjunct professor of clinical and operative surgery, and J. Abbott Cantrell, M. D., adjunct professor of diseases of the skin. The chair of pathology is left vacant until the next meeting. The report of the building committee states that contracts have been signed for preliminary work to the amount of \$23,150. About \$30,000 will be required to finish the building, and it has been decided to push the work to completion as fast as donations for the purpose can be obtained. The overcrowded condition of the present building makes it necessary to use every exertion to move into the new building early in the spring, even if it is unfinished.

**The late Dr. Alexander B. Mott.**—At a meeting of the New York County Medical Association, held October 21, 1889, the following minute was unanimously adopted:

"In the death of Alexander B. Mott the well-maintained heritage of a name illustrious in the annals of surgery is transmitted to posterity with added memories of good work faithfully done. Self-reliant, ingenious in device, and exceptionally skillful in execution, his career exemplified the best attainment of his chosen art, and his departure leaves a vacancy long to be deplored. Sharing the grief of the whole profession which he adorned, this association desires to record its special regret for the loss of a valued member and its sympathy with those who mourn, not alone for the distinguished surgeon, but for the beloved relative or dear friend."

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 13 to October 19, 1889:*

BRADLEY, ALFRED E., First Lieutenant and Assistant Surgeon. Relieved from duty at David's Island, New York Harbor, and ordered to Fort Omaha, Neb. Par. 2, S. O. 241, A. G. O., October 16, 1889.

EVERTS, EDWARD, Captain and Assistant Surgeon. Relieved from duty at Fort Apache, Arizona, and ordered to David's Island, New York Harbor. Par. 2, S. O. 241, A. G. O., October 16, 1889.

BRECHEMIN, LOUIS, Captain and Assistant Surgeon. Relieved from duty at Fort Laramie, Wyoming Territory, and ordered to Fort Apache, Arizona Territory. Par. 2, S. O. 241, A. G. O., October 16, 1889.

HARRIS, H. S. T., First Lieutenant and Assistant Surgeon. Relieved from duty at San Antonio, Texas, and ordered to Fort Keogh, Montana. Par. 2, S. O. 241, A. G. O., October 16, 1889.

O'REILLY, ROBERT M., Major and Surgeon. Granted leave of absence for six months, with permission to leave the United States. Par. 3, S. O. 241, A. G. O., October 16, 1889.

HEGER, ANTHONY, Lieutenant-Colonel and Surgeon. Relieved from duty in Division of the Atlantic and ordered for duty as Attending Surgeon, Washington, D. C. Par. 2, S. O. 241, A. G. O., October 16, 1889.

LORING, L. Y., Major and Surgeon. Sick leave extended two months on surgeon's certificate of disability. Par. 16, S. O. 241, A. G. O., October 16, 1889.

ADAIR, GEORGE W., Captain and Assistant Surgeon. Leave of absence extended for fifteen days. Par. 15, S. O. 238, A. G. O., October 12, 1889.

BRECHEMIN, LOUIS, Captain and Assistant Surgeon. Granted leave of absence for one month. Par. 1, S. O. 98, Headquarters Department of the Platte, October 12, 1889.

HAVARD, VALERY, Captain and Assistant Surgeon. Leave of absence extended one month. Par. 3, S. O. 240, A. G. O., October 15, 1889.

GIBSON, JOSEPH R., Surgeon. Relieved from duty at Fort Sheridan, Ill., and ordered to Governor's Island, New York Harbor. Par. 10, S. O. 242, A. G. O., October 17, 1889.

MAUS, LOUIS M., Assistant Surgeon. Relieved from duty at Fort Porter, N. Y., and ordered to Fort Stanton, New Mexico. Par. 10, S. O. 242, A. G. O., October 17, 1889.

GARDNER, EDWIN F., Assistant Surgeon. Relieved from duty at Fort Lewis, Colorado, and ordered to Fort Porter, N. Y. Par. 10, S. O. 242, A. G. O., October 17, 1889.

EWEN, CLARENCE, Surgeon. Relieved from duty at Madison Barracks, N. Y., and ordered to Willet's Point, N. Y. Par. 10, S. O. 242, A. G. O., October 17, 1889.

GIRARD, ALFRED C., Surgeon. Relieved from duty at Boise Barracks, Idaho, and ordered to Fort Niagara, N. Y. Par. 10, S. O. 242, A. G. O., October 17, 1889.

HALL, JOHN D., Assistant Surgeon. Relieved from duty at Fort Niagara, N. Y., and ordered to Madison Barracks, N. Y. Par. 10, S. O. 242, A. G. O., October 17, 1889.

TAYLOR, MARCUS E., Assistant Surgeon. Relieved from duty at Fort Stanton, New Mexico, and ordered to Boise Barracks, Idaho. Par. 10, S. O. 242, A. G. O., October 17, 1889.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending October 19, 1889:*

BERTOLETTE, D. W., Surgeon. Detached from the Franklin and ordered to duty at Naval Hospital, Philadelphia.

RUSH, N. H., Passed Assistant Surgeon. Detached from Naval Hospital, Philadelphia, and ordered to the Saratoga.

HIBBETT, C. T., Passed Assistant Surgeon. Ordered to the Franklin.

**Marine-Hospital Service.**—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the six weeks ending October 19, 1889:*

VANSANT, JOHN, Surgeon. Granted leave of absence for fifteen days. October 16, 1889.

GOLDSBOROUGH, C. B., Surgeon. Leave of absence extended thirty days on surgeon's certificate of disability. October 18, 1889.

PERRY, T. B., Assistant Surgeon. Ordered to temporary duty at San Francisco, Cal. October 15, 1889.

VAUGHAN, G. T., Assistant Surgeon. When relieved, to proceed to Evansville, Ind., for temporary duty. October 9, 1889.

#### Society Meetings for the Coming Week:

MONDAY, October 28th: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

TUESDAY, October 29th: Medical Societies of the Counties of Queens (semi-annual—Garden City) and Rockland (semi-annual), N. Y.; Boston Society of Medical Sciences (private).

WEDNESDAY, October 30th: Auburn, N. Y., City Medical Association; Berkshire, Mass., District Medical Society (Pittsfield); Middlesex, Mass., North District Medical Society (Lowell); Gloucester, N. J., County Medical Society (quarterly).

THURSDAY, October 31st: Cumberland, Me., County Medical Society (Portland); Massachusetts Medical Benevolent Society (annual).

FRIDAY, November 1st: Practitioners' Society of New York (private); Baltimore Clinical Society.

SATURDAY, November 2d: Clinical Society of the New York Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

**Listerine.**—“Offensive odor of the breath, due to bad teeth or other causes, may be overcome, or at the least greatly abated,” says the “Sanitarian,” “by the habitual use of listerine. Add a teaspoonful to a tumblerful of water for a mouth-wash and gargle, and if a little is swallowed, so much the better. Indeed, a bad breath is not infrequently caused by the gaseous eructations of indigestion, and for this also listerine is an excellent remedy, in doses of twenty to thirty drops in a little water.”

#### Proceedings of Societies.

##### NEW YORK STATE MEDICAL ASSOCIATION.

*Sixth Annual Meeting, held in New York, September 25, 26, and 27, 1889.*

The President, Dr. W. T. LUSK, of New York, in the Chair.

(Continued from page 444.)

**The Treatment of Hernia.**—Dr. J. D. BRYANT, of New York, read a paper which formed the basis for a discussion on this subject. He reviewed briefly the surgical history of hernia from the fourteenth century to the present day, describing the various forms of trusses from time to time in vogue. At the present day he said medical men were, for the most part, ignorant alike of the truss armamentarium and how to fit a truss, and this necessitated patients being sent to the instrument-makers for that purpose. Though cures from the use of trusses did undoubtedly result, unfortunately the number was small. It had been his custom to recommend these appliances, and at this time patients of his were still using trusses by his advice which they had already worn for a long time. They came to him for permission to lay them aside, with the statement that “it never came down now,” but he recommended the continuance of the truss as an element of safety. In cases of reducible inguinal herniae children might expect a cure. He usually advised his hernia patients to provide themselves with three forms of truss—one for comfort, strong and durable, to be worn during the day; another specially adapted for use in the bath; and one for ease and security during the hours of rest. The advantages of this advice were obvious, and it was equally obvious that care should be taken to assume the recumbent position when the interchange was made. How cures were accomplished by the use of the truss was still a matter of conjecture. It had been urged that the result was brought about by the irritation establishing adhesive inflammation between the surfaces of the sac, or by keeping the intestine for a long period in the normal position, or that both these were active factors. In his judgment, cures were rare where each of these influences played an important part. It was not his view that adhesive processes were often caused by truss appliances, but rather that the result was due to contracture of the stricture dependent upon the normal resiliency of the parts. If the obliteration were due to inflammatory adhesion, there would be local symptoms pointing to this change as a means of cure. His experience had led him to the following conclusions: 1. That no form of mechanical appliance yet constructed could be relied upon to effect the cure of simple reducible inguinal hernia. 2. That the cure of hernia could not be effected with certainty by any mechanical means. 3. That these mechanical appliances would in many cases afford relief and enable the wearer to pursue ordinary vocations. 4. That the so-called cures were dependent upon the restriction of the abdominal contents, with subsequent contraction due to resiliency of the part and not to the inflammation of serous surfaces. 5. A hard, slightly convex pad, with steel spring attachments, was the best appliance. As to the method of treatment by injection, there were many around him who had tried the procedure thoroughly, and it was for them to state their conclusions. For his own part he had no experience in this direction. He then went on to describe the details of radical cure by means of the open method, giving the approximate results of nineteen of his own cases so treated, and then described, by means of diagrams, his recent modification of the open method. After freeing the hernial sac and ligating its neck, he then quilted the sac between the pillars of the ring, thus affording an animal mem-

brane to give additional strength to the parts. He had operated three times by this method, and the results were, so far, such as would encourage him to further adopt it. He considered the open method the most simple and rational yet devised for the radical cure of hernia. The additional time required was time well employed, because the cure effected promised greater immunity from relapse. The interweaving of the sac with the pillars of the ring might be followed by either the open or closed method, and offered at least equal, and, from his point of view, even greater security than other processes. In cases of strangulated hernia he believed that moderate and well-directed taxis would suffice to return the intestine under ordinary circumstances, but, when this had been conscientiously tried without success, operation should be resorted to at once. If properly conducted, the attempt should not last over a quarter of an hour; if improperly conducted, this was too long. He did not wish to disparage the use, but the abuse of taxis. Surgeons, when called upon to operate for strangulated hernia, should consider it a part of their duty to make the operation for radical cure an addendum to that of the kelotomy. In conclusion, he detailed the various forms of intestinal gangrene likely to come under the surgeon's notice when performing heriotomy, laying down as general principles that: 1. If gangrene of the intestine had already taken place, and the patient's condition were such as to warrant the procedure, the intestine should be repaired and returned to the cavity. 2. If the gangrene involved the upper two thirds of the intestine, then, though the result might be doubtful, repair and return should be practiced. 3. When gangrene existed and the patient's condition contra-indicated interference, a temporary artificial anus should be made. 4. It was better to form an artificial anus, when the necessary surgical assistance was not at hand, for the more formidable operation. 5. Division of the sac was not always called for, and was often unwise when the formation of an artificial anus was anticipated.

Dr. MILLIGAN described the mechanical construction, technique of application, and respective merits of the various forms of truss appliances which experience had demonstrated to be most effective in the treatment of hernia patients at the New York Hospital for the Ruptured and Crippled.

Dr. R. PARK said that he gathered, from what had been said, that the final cure of hernia was a very rare occurrence, and he began to believe that this was the case. Still, he believed thoroughly in the endeavor to effect a cure by radical operation. He thought that even though this effort failed, the patient was in a far better condition than before the attempt. In a certain percentage of cases a radical cure was certainly achieved. He thought the Czerny operation met all the requirements. It could readily be combined with kelotomy in cases of strangulation, and with a minimum of risk to the patient. He certainly preferred the open method. In the closed method the cicatrix was necessarily so much wider, and if this cicatricial tissue was going to stretch, a large one would be a disadvantage. He approved of the suggestion of Dr. Bryant, and should proceed to make use of the plan. By interweaving the sac, as had been described, the inguinal canal was practically closed by animal membrane, which, better than anything else, should act as an additional protection and at a point where it was most needed. He had operated sixty times for radical cure, but had not been able to watch all his cases. In only three of these, however, had any evidence of relapse come under his notice.

Dr. W. T. BULL related the result of his experience with seventy-two cases, and gave his reasons for preferring the closed method.

Dr. DETMOLD said that, though the fact was not exactly pertinent to the subject of discussion, he thought it would be interest-

ing to mention the fact that life insurance companies required all those who were suffering or had at any time suffered from hernia to wear a truss. He thought, too, he might venture to give them a little history of a circumstance which happened over fifty-two years ago. A young woman had come to his office and asked him whether hernia could be operated upon. He had said "Yes," but had not paid much attention to the question. The woman had, however, persisted in her importunity that he should operate, saying that if he did not she should commit suicide. Upon making further inquiries into the case, he had learned that she had recently been married, and that when her husband came to survey his new territory and found evidence of a prominence not laid down in his chart, he had ascribed it to syphilis, and had put on his trousers and left the house. The speaker sent for the man and expostulated with him to no purpose, and so consented to operate. At that time there were no libraries, no journals, and he did not know whether anybody had ever done the operation. The leading medical men around him refused their aid, so with what assistance he could command he went to work. The case was one of simple femoral hernia. He made an incision large enough to enable him to tie the sac, and when he had done this he laid the crural canal bare and filled it thoroughly with lint, and kept this up for several weeks. So far as he knew, the recovery was complete. The husband, hearing what the woman had undergone, came and nursed her, and they "lived happily ever after."

**Lantern Views of Bacteria.**—Dr. E. K. DUNHAM entertained the members of the association at the evening session of the second day's proceedings by a most interesting account of the details of germ culture in the laboratory. His lecture was effectively illustrated by means of lantern views.

**The Cure of Hæmorrhoids by Excision and Closure with the Buried Animal Suture.**—In his paper on this subject Dr. H. O. MAROY, of Boston, said that the recent discussion of the surgical treatment of hæmorrhoids, published in the "New York Medical Journal," evoked by a late paper of Mr. Whitehead's, of Manchester, England, had been both timely and interesting. The medication of wounds, and treatment based upon aseptic measures, marked the present as an era of surgical evolution, to which surgery of the rectum should be no exception. Few of the minor surgical diseases caused so much suffering and gave to the general practitioner such constant repetition of complaints as those of the rectum, and, in return for services rendered, no class of patients were more appreciative and grateful. The teachings of the text-books, with few exceptions, offered very little improvement upon the methods of the past in the treatment of the diseases of the rectum. The advocates of the ligature perhaps equaled those who claimed superior advantages to be derived from the use of the clamp and the cautery. Although a practical cure was often obtained from the use of either, he could not but believe that both were surgically defective and should be relegated to history. While it might be conceded that the general practitioner was in a large majority of cases familiar with the pathological conditions pertaining to the hæmorrhoidal diseases, still it might be well to be reminded that the blood was carried with the arterial impulse directly to the part through short branching vessels, and in turn received from the capillaries into an extraordinary network of veins, which emptied through the inferior mesenteric into the portal system. These veins were entirely without valves. Boerhaave and Morgagni had pointed out these anatomical peculiarities, and remarked upon the horizontal position in the lower animals, which thereby took off the superincumbent weight of the blood column. They adduced this as a reason why quadrupeds were not subject to diseases of this nature. He took pleasure in calling attention to a most interesting and

learned article on this subject by Dr. Bodenhamer ("N. Y. Med. Jour.", Jan. 12, 1889, p. 39). It seemed, however, a just criticism that the weight of the venous column alone acted only in a very subordinate degree as a predisposing cause, although manifestly an important factor after the blood-current becomes gradually retarded in the oftentimes enormously dilated haemorrhoidal veins.

Were the cause to be found in this peculiar distribution of the portal circulation, the upright position of man would make this condition the rule instead of the exception, and it would be extraordinary to find the varicosities limited to the haemorrhoidal plexuses and lying almost entirely external to the sphincter muscle. Oftentimes, however, after the pathological conditions became well established, the current through the ectasic vessels was so greatly retarded by the weight of the blood-column in the erect position that most patients learned to seek relief by change of posture. Anatomists emphasized the fact that in the normal condition many of the haemorrhoidal veins were of comparatively large size. In relation to the surrounding pelvic organs these veins occupied a dependent position, and their only support was derived from a loose network of connective tissue. It would be apparent, then, that the anatomy of these thin-walled vessels, their relation to the surrounding parts, and their physiological function, furnished, as it were, a predisposing cause of disease. To this, however, probably might be added a certain condition of weak circulation so often found in persons with thin-walled veins of the lower extremities. It had long been recognized that the varicosities of the haemorrhoidal vessels, which were probably wanting in the lower animals and were comparatively rare in the savage races, became a more and more constant factor in the sedentary occupations of modern civilization. A great variety of pelvic diseases in the female and the genito-urinary diseases in the male, complicated with constriction, were active causes of rectal disease. The rectum might be regarded as a convenient cess-pool for the reception of the waste and *débris* of the alimentary canal, which poured into it in a more or less fluid state. The curves of the lower bowel, from the sigmoid flexure downward, were an evident design, in part at least, to vary the support of the weight of the column and admirably adapted to equalize the pressure. When the rectal contents remained sufficiently soft to produce equable pressure, the circulation was comparatively little disturbed, and defecation was accomplished with very little muscular strain. If, however, there should be retention of the contents, with absorption of the fluid portion going on until the molding process became difficult, the reverse would be true. The overloaded rectum produced pressure upon the venous return current, causing a train of reflex nervous symptoms, and the hyperesthetic state followed. Although the pathological condition above described produced by far the larger part of the suffering ascribed to so-called "piles," we must not forget that there were other diseased conditions which might be confounded therewith. Small fleshy masses about the folds of the anus, sometimes called condylomata, were very easy to distinguish. These had nothing to do with the haemorrhoidal veins or mucous membrane, and might be the result of friction or erosion arising from a variety of causes. The so-called villous tumor of the rectum was, however, of sufficient frequency to be taken into consideration. It was not unlike the villous growths of the bladder or other mucous surfaces. This extra vascularit only revealed its presence because of the haemorrhage, and was apt to be diagnosticated as a bleeding pile. The soft mucous polypus of the rectum was an adenomatous structure of close relationship to the villous growth, and was sufficiently often the cause of suffering to be borne in mind.

Mr. Whitehead, of Manchester, had emphasized the pathologi-

cal conditions upon which the author had touched, and insisted that the extraordinary dilatation which the veins often underwent could only be learned by dissection upon the living subject. The author's own attention had been called to the condition many years ago when he found how very commonly the veins of the rectum became enormously dilated in a female who had suffered laceration of the perineum. It was probable that the changes incident upon retention of the rectal contents and other causes acted to bring about dilatation of the vessels rather than the superincumbent weight of the portal column of blood. When the venous plexus of haemorrhoidal vessels had become pronouncedly varicosed, they had as a covering the lax submucous tissue of the rectum close to the anus, and when put on tension were protruded as a ring of transverse rugae around the anal aperture. Certain of the rugae were developed into rounded protuberances, and sometimes even into fungoid tumors of considerable size. The veins sometimes ruptured into the connective tissue and changes followed which resulted in tumors of various sizes, color, and density, called "external piles." The strain in defecation or gentle pressure by the finger from above downward would frequently cause soft, fleshy, exquisitely sensitive grape-like masses to protrude—"internal piles." The mucous membrane covering these would frequently be found congested and abraded so that more or less continuous hemorrhage ensued.

The method for the cure of haemorrhoids by the use of the ligature applied with slight modifications of detail had been considered the safest, surest, and most manageable procedure. The projecting tumors, having been well drawn down, were usually transfixated with a curved needle, armed with a double ligature; this being tied firmly, a portion of the constricted mass was excised. In this way all the haemorrhoidal tumors were ligated and the mass was then returned within the sphincter. This was the favorite operation of the late Dr. Van Buren and his followers, and had at present in Mr. Allingham, the famous English surgeon, its most distinguished advocate. The use of the ligature, applied to cause necrosis of tissue and then allowed to remain in the wound, was open to the same general objections which had caused its abandonment. When applied in this manner to the constriction of the large vessels, sloughing necessarily supervened, which meant an infected wound, exposing the patient to the same dangers, although, perhaps, of less degree, as infection in any other part of the body.

That this was not hypothetical criticism the writer thought there was abundant proof. The stoutest advocates of the ligature admitted that abscesses, general septic poisoning, and other dangers, as secondary haemorrhage, were not wanting in the experience of the most careful and practical surgeons. The use of the clamp and cautery came into vogue and had been specially popularized by the distinguished surgeon, Mr. H. Smith, of London. This procedure the author had early adopted in his own work. It had advantages over the ligature in that the primary wound was aseptic. Then, by the time the slough was ready for separation, the subjacent tissues would be fairly well protected by the abundant proliferation of granulation tissue. In his own experience, the suffering caused by the burning was objectionable, while all wounds caused by burning were invariably slow of repair. He was of the opinion that the results obtained from the use of the cautery were generally of a more satisfactory character than from the ligature. Secondary haemorrhages were reported to have occurred, and it was claimed that contraction was not uncommon after cauterization. It might be accepted as a fact that the use of the cautery, except in certain conditions in uterine cancer, had been relegated to the past. Even here it found fewer advocates than formerly. Certainly bleeding was to be controlled without its use, and it

might be questioned whether deep burning was safer than deep cutting in any disease. Then various crushing instruments had been devised, to be used, however, with or without the ligature, for the purpose of producing more rapid necrosis of the tissue involved. The advantage alleged for the operation of crushing was an avoidance of haemorrhage, but, on the other hand, some operators reported that haemorrhage had followed crushing. Theoretically this method seemed to offer little, if any, advantage over the ligature, therefore he had discarded it without trial. There remained something to be said of the cure of haemorrhoids by the chemical action of certain medicaments injected into the parts. Few of the modern methods had received more speedy attention than this, the so-called "carbolic-acid treatment of piles." It had much to warrant its acceptance. Carbolic acid of itself was at that time believed to be the chief of antiseptics, rapidly coagulating the blood and the albuminoids. It had been variously combined with morphine, cocaine, etc., and little pain had followed its use, and patients and physicians had been alike enthusiastic. At present, however, it appeared that the consensus of surgical opinion was that the result was in a large degree disappointing. When a considerable proportion of acid was used, causing necrosis of tissue, no matter how carefully injected, the tissues not infrequently which it was desirable to remove failed to be acted on, while those which should have been retained were destroyed by sloughing. The explanation was that the fluid introduced into the loose margin of the connective tissue escaped to the extraneous parts. When weaker proportions were used, even after many repetitions of the injections, the haemorrhoidal vessels remained comparatively unchanged. The method of cure by injection was also sometimes objectionable and even dangerous. The writer had seen a young and healthy man made seriously ill, with considerable fever and general septic poisoning supervening upon the injection of haemorrhoids at the hands of one of our most capable men. The connective tissue around the anus remained for some days oedematous, reddened, and painful. There now remained for discussion the operation of Mr. Whitehead, of cure by excision. This the author of the paper did not hesitate to accept as a step in advance of all surgical procedures previously discussed. It had been demonstrated that the vessels were frequently so deformed as to fail entirely in the original purpose for which they were designed, and the end sought to be obtained by all previous methods had been their destruction and removal. The real objection to destruction had been the fear of haemorrhage, and, as a means to obviate this, the ligature and clamp and the cautery were devised. Mr. Whitehead had clearly shown that his method of dissection was safe, that the haemorrhage was not excessive, and that a rapid cure resulted. The method was certainly scientific. By a clean dissection the parts which it was desirable to eliminate were removed. The free edges of the divided tissues were then stitched together, primary union generally resulting. Mr. Whitehead's method was best given in his own words:

"By the use of scissors and dissecting forceps the mucous membrane is divided at its junction with the skin around the entire circumference of the bowel, every irregularity of the skin being carefully followed. The vessels are then exposed by a rapid dissection of the mucous membrane, and the attached haemorrhoids, thus separated from the submucous bed on which they rest, are pulled bodily down. Each individual point is brought below the margin of the skin. The mucous membrane below the haemorrhoids is now divided transversely in successive stages, and the free margin and the severed margin above are stitched, as soon as divided, to the free margin of the skin below by a suitable number of sutures. The complete ring of pile-bearing mucous membrane is thus removed." Mr. White-

head very wisely emphasized thoroughly paralyzing the sphincters by digital stretching. The bleeding vessels, which were small and easily seized, were immediately twisted upon division. The sutures were interrupted and of braided silk. Mr. Whitehead's operation had been, of course, variously criticised, but, as that gentleman could refer to a record of some three hundred cases in which the operation had been, "to the best of his knowledge and belief," a perfect and permanent cure, there was enough upon which to base a conclusion. Some ten years ago Dr. Marey said he had operated in two cases of prolapse of the rectum by first, before resection, entirely encircling the prolapsed part upon a row of continuous double sutures. From the excellent result following these operations he had been led to apply the same method to the base of a ring of haemorrhoidal vessels before resection. For some years this method of suturing had entirely superseded all others in his practice, and had been repeatedly demonstrated to members of the profession. He now offered his method for consideration on account of its great safety and excellent result, as presenting advantages in the treatment of a troublesome affection. Care should be taken previous to the operation to have the large intestines thoroughly emptied, usually by an active cathartic, supplemented by a copious injection given a few hours before the operation. The patient was to be placed in the lithotomy position, the limbs suitably supported, and the parts to be thoroughly cleansed by a sublimate solution as usual. The digital dilatation of the sphincter was carefully made until the muscle was paralyzed. The rectum was then washed with sublimate solution, care being taken that none of it was allowed to remain. A pledget of wool, into which iodoform was to be freely dusted, was passed into the rectum, and the subsequent stages of the operation were carried out under irrigation with sublimate solution. Along the line of the junction of the mucous membrane with the skin, either with a knife or scissors, division was made from a central line, posteriorly, from below upward on both sides to the median line above. With a little care this division could be made without injury to the plexus of vessels. The loose connective-tissue fascia was usually separated by the finger or a blunt instrument, cutting any connective-tissue bands which might appear. The mucous membrane above the plexus should be then divided transversely in a somewhat similar manner. The deformed haemorrhoidal plexus was then separated from its surroundings except at its base. The needle, with eye at point, threaded with tendon, was carried posteriorly behind the mass, unthreaded, and rethreaded with the opposite end and withdrawn, the stitch resembling that taken by the shoemaker, drawing the waxed end of his thread in opposite directions through the hole made with the awl. In this way the entire base was encircled by a line of deep double continuous sutures. This was the stitch the author had for many years used in the coaptation of deep parts by the buried suture—as, for example, in rupture of the perineum and constricting pedicles of abdominal tumors. In this way it was impossible for any tissue to escape. The stitches were not to be drawn too tight, since they were intended merely to control haemorrhage and not to produce necrosis of the parts they inclosed. Then with scissors the haemorrhoidal plexus, just above the line of sutures, was to be dissected away; the mucous membrane to be then stitched by continuous suture to the line of division, either with an over-and-over stitch or with a running blind stitch taken from side to side from within outward. The paper concluded with a description of the usual dressings and after-treatment. If the operation was properly done, it was generally followed by primary union. The patient was remarkably free from pain, and the process went on without trouble. The patient need not keep his bed. The bowels should be moved the third or

fourth day. By the method above described the author constricted the blood-vessels before division, insuring a much more accurate readjustment and closure of the parts, while the buried animal sutures manifestly presented advantages over interrupted silk sutures, which latter must be thrown off by suppuration.

The author then exhibited specimens of prepared animal tendons which he advocated as in every way to be preferred in all cases where deep or buried sutures were indicated. He had given *carte-blanche* to a friend in Australia for kangaroo tendon

**Extraction of Cataract without Iridectomy.**—Dr. CHARLES STEDMAN BULL, of New York, read a paper with this title (to be published).

(To be concluded.)

#### AMERICAN DERMATOLOGICAL ASSOCIATION.

*Thirteenth Annual Meeting, held at Boston, on Tuesday, Wednesday, and Thursday, September 17, 18, and 19, 1889.*

The President, Dr. I. E. GRAHAM, of Toronto, in the Chair.

(Continued from page 441.)

#### Microscopical Studies of Malignant Tumors of the Skin.

—Dr. C. HEITZMAN, of New York, read a paper on this subject. The pathology of the skin was intelligible only upon the recognition of the fact that the basis substance of the fibrous connective tissue of the derma was living and capable of proliferation in the same manner in which the protoplasm of this tissue, the so-called "cells," were viable. The reader had first announced this fact in 1873, and since 1880 Stricker, of Vienna, had adopted the same view. In inflammation of the derma there was first noticed an increase in the amount of living tissue in the interstices, and at the same time the basis substance bordering such an inflammatory area returned to its protoplasmic condition, and split up into inflammatory corpuscles, just as the protoplasm between the bundles of connective tissue did. From this inflammatory structure bundles of fibrous tissue might again form, giving us the hyperplasia of Virchow. A breaking asunder of the inflammatory corpuscles led to the formation of pus corpuscles, the sum total of which we termed an abscess.

In the formation of tumors the tissue of the derma invariably returned into its protoplasmic or embryonal condition with the production of new-formed medullary or indifferent corpuscles, and either a tissue kindred to the normal tissue originated from it—as in myxoma, fibroma, etc.—or it remained in an embryonal condition—as in sarcoma, which the author preferred to call myeloma. In cancer a new formation of epithelium took place, with a new formation of myxomatous or fibrous connective tissue. The author would divide all myelomatous—*i. e.*, sarcomatous—tumors into two main divisions: the globo-myeloma, corresponding to the round-cell sarcoma, and the spindle-myeloma, or spindle-cell sarcoma. All other varieties he would consider embraced by these. Globo-myeloma was made up exclusively or prevailingly of globular corpuscles of different sizes; sometimes the smallest was not larger than a lympho-corpuscle, and in that case we had the lympho-sarcoma, which the author thought identical with the outgrowths of the mycosis fungoidea of Kaposi. There were two main sources for these cells—viz., the protoplasm between the bundles, and the basis substance of the bundles themselves. First were observed globular bodies between the bundles; these had unquestionably sprung from the protoplasm by an augmentation of its living matter or by a proliferation of its cells. The newly formed elements were first small, homogeneous, and highly refractive, representing, therefore, solid lumps of living matter. These increased in size and became vacuolated, and a solid or reticulated

nucleus appeared in the center of each corpuscle. At the same time there was a transmutation of bundles of fibrous tissue into either reticulated masses of protoplasm or single pieces, being separated from one another by a little cement substance. Later on these square pieces were further split up into myeloid corpuscles.

When the lymphoma appeared in the derma there was a gradual thinning of the epithelial covering and loss of the hairs, with final disappearance of all epithelial structures. According to the idea of the author, the epithelia were transformed into giant cells, which in turn split up into myeloma corpuscles. In the case of the spindle-myeloma the same course held true as with the formation of the globo-myeloma. In the case of carcinoma the normal epithelium was not transformed directly into cancer cells; there was a stage of indifferent corpuscles of protoplasm, the production of multinuclear masses, which split up into cancer epithelia by the appearance of a new cement substance.

What Waldeyer considered an inflammatory new formation in the surrounding connective tissue was considered by the author to be only the preliminary stage of cancer. The medullary corpuscles which had been formed were transformed into cancer cells. In the epidermal cancer this change was seen along the border of the epithelial pegs. Here the indifferent corpuscles changed into multinuclear bodies in which boundaries of cement substance appeared. In this case, too, the medullary corpuscles within the connective tissue arose from the basis substance as well as from the cells. That the connective tissue participated in the growth of the cancerous tumor, and that its so-called small-cell infiltration was a mere preliminary stage of cancer, was clinically of the utmost importance. Whenever a cancer was removed with the knife, and we found at the cut surface of the extirpated mass small shining medullary corpuscles, we could positively foretell a recurrence, however small the number of such corpuscles found in the fibrous connective tissue of the derma or in the myxomatous network of the fat globules of the subcutaneous tissue.

Dr. ROBINSON did not wish to express positive opinions in regard to the views advanced by the author of the paper until he had studied the matter thoroughly. He would agree entirely with Dr. Heitzman in regard to the histology and growth of connective tissue. He would not, however, classify sarcomata with tumors proper, but considered them the manifestation of an infectious process. They were the result of a dermatitis, and were not a new growth. In the case of an epithelioma we had to do with a specialized structure, and it seemed to him that it would be at least very difficult to prove that epithelial tissue could spring from an ordinary connective tissue. The necessity of the previously existing epitheliomatous tissue was shown by the character of the secondary tumors and the hereditary tendencies of the disease. If epithelial tissue could arise from the embryonal tissue coming from connective tissue, it might be expected that sometimes epitheliomatous growths would form in tissues which were more or less embryonal naturally, such as the lymph glands.

Dr. HEITZMAN remarked that he had just such a specimen.

Dr. ROBINSON thought that no one else had ever seen such a case. As regarded the change from epithelial structures into indifferent corpuscles and then into cancer cells, in his experience he had never seen such a case. He would summarize his position as follows: That an irritation, if not too severe, in which case it would be destructive, might produce a formative growth; that sarcomatous formation might take place from connective tissue without requiring the presence of elements from foetal life; that in the case of the epitheliomata there must be the presence of a previously existing epithelium; that

epithelial elements could not change into medullary corpuscles and then into elements; and no more could connective-tissue elements pass into epithelium.

Dr. HEITZMAN said he was ready to admit that when the myeloma was just starting in the dermal tissues it was impossible to distinguish it from simple inflammatory action. We must depend upon clinical observation, since the origin was identical in the two cases.

Dr. ROBINSON, referring to his belief in the infectious nature of the sarcomata, mentioned Dr. Sherwell's case of round-cell sarcoma of the skin. It had been noticed that some of the tumors disappeared while new ones arose. If they were a new growth they ought to continue to grow indefinitely. It was known that in cases of mycosis fungoidea the tumors would come and go constantly.

Dr. SHERWELL mentioned a quite similar case observed in Burlington, Vt., where many of the tumors had disappeared under treatment, their place being taken by a distinct depression in the skin.

**The Diagnosis of Leprosy, especially the Division of the Anæsthetic Form from Syringomyelia.**—Dr. P. A. MORROW, of New York, read a paper with this title. Little was said in the text-books about the diagnosis of this disease, perhaps because few writers had been personally familiar with it. In the later stages the diagnosis was not difficult, but in its inception it was often doubtful. In the examination of the suspects at Honolulu a large number were remanded for further developments, and it should be borne in mind that this was not owing to any lack of skill on the part of the physicians. Many of the initial symptoms were quite indeterminate, and might be referred either to leprosy or to other diseases. The affection was most likely to be confounded with erythematous diseases, with lupus, and with certain affections of the nervous system, while many parasitic diseases had lesions similar to those met with in this disease. Two main forms of leprosy were recognized—the tubercular and the anæsthetic. In one there was a determination of the process to the integumentary tissues and in the other to the nervous system. In tubercular leprosy the prodromal symptoms had little value, and the same might be present in syphilis and other diseases. In this form the presence or absence of anæsthesia was of no diagnostic value whatever. The eruption was not at all pathognomonic. The macules which first appeared were round, oval, or irregular, of a bright or sometimes dark-red color, fading on pressure. As a rule, they were not infiltrated, and might disappear without a trace, or they might leave a yellowish spot. Sometimes they might present a picture similar to that of erythema multiforme. After a time these macules became persistent, and then there was a tendency to the formation of tubercles; but the latter might develop in isolated spots, quite apart from the large erythematous areas. In its origin the disease resembled syphilis in the long period of incubation and the successive crops of the eruption. The syphilitic roseola corresponded to the leprous erythema; the mucous membranes were affected in each, although the throat was not affected in leprosy. There was more infiltration of the skin, especially in the face, in leprosy, and leontiasis was more often seen, as well as the breaking down of the osseous framework of the nose. Sometimes the tubercles of this disease resembled very much those of lupus. Sarcoma had been confounded with the disease, but when the fungoid state was reached and the tumor suppurated the distinction was easily made. The disease had also been mistaken for acne, sycosis, lichen planus, erythema nodosum, molluscum fibrosum, and dermatitis medicamentosa. The *Bacillus lepræ* was invariably found in the tissues and stamped the disease when such examination could be made.

The anæsthetic form of the disease presented a greater variety and complexity of symptoms. While the demonstration of the bacillus was rarely practicable, yet the invariable presence of anæsthesia had almost a pathognomonic value. The macular lesions which were seen were pigmented, and tended to clear up in the center while they spread peripherally. On their first appearance the macules were hyperæsthetic, but this condition was followed by anæsthesia in the center as the affected surface widened. The author showed colored drawings representing a case that had existed five years, where the lesions had been well marked upon the feet and lower part of the leg. Here the central portion had presented a bluish or grayish appearance distinct from the reddish outline of the edges. There had been anæsthesia in the center, with normal sensation just outside the margin. In general it was found that there were many irregularities in the course of the anæsthetic symptoms. It was distinguished from chromophytosis by the absence of scaliness and the absence of the parasite of that disease. It was to be distinguished also from vitiligo and morphea. The hairs of the affected surface often fell out. An interesting point was the plantar ulcer which very frequently formed, owing, the author thought, to the custom of going with bare feet. This lesion resembled the malum perforans.

The nerves most frequently affected were the ulnar, the peroneal, and the third and seventh pairs. There might be wrist-drop and a peculiar claw-like contraction of the fingers. Since the pathological lesion was a multiple neuritis, it was not surprising that there were many diseases of the central nervous system which resembled leprosy. The atrophy and degenerative changes might be limited to the muscles of the hand and forearm, and might present a perfect picture of the lesions of progressive muscular atrophy. They were distinguished by the presence or absence of sensory disorders. The disease most difficult to distinguish from it was syringomyelia. This disease had formerly been considered to be very rare, and to be met with only post mortem, but of late a number of cases had been reported. Its main symptoms were sensory disorders and trophic changes. The atrophy was localized in the muscles of the hand and forearm. There was a flattening of the thenar and hypothenar eminences, with absolute loss of pain and temperature sense, with retention of tactile and muscular sense. The reaction of degeneration was sometimes present. After a time the disease might remain stationary.

The author related the case of a person living in this country, but who had been born in the Sandwich Islands—a young man of twenty years. When eight years old he fractured the right clavicle. Within from one to three years afterward, the history not being definite, a numbness of the hand was felt. It was supposed to be of spinal origin, and the actual cautery was applied. Contraction of the fingers came on and had remained since, but the numbness had crept up the forearm. The right arm measured an inch and a quarter less than the left. There was also atrophy of the muscles of the right leg. A superficial sore appeared on the index-finger, and would not heal. Electric excitability of the hand was lost. After a time two or three brownish spots appeared upon the forearm. This case presented many of the symptoms of syringomyelia, but might be distinguished by the sensory loss. The child had been to the Sandwich Islands when nine years of age, and that fact was of weight in making the diagnosis. The fact that the present good health of the patient was not conducive to the spread of the disease might explain the asymmetrical character of the lesions and the non-progressive type of the disease. There were many abortive causes, and no doubt the removal of this boy to a different climate had increased his capacity for resisting the disease.

Dr. HARDAWAY said that, in his experience, most of the cases in this country were mixed cases. He presumed it was admitted that tropical cases were mostly anaesthetic, while in temperate climates the cases were mixed.

Dr. MORROW did not think so. In India it was comparatively a minimized form of the disease. In the Sandwich Islands there had been noticed a progressive increase in the number of anaesthetic cases, the anaesthetic representing the milder type. About one half were tubercular, one third anaesthetic, and the remainder mixed.

Dr. BRONSON spoke of the great resemblance shown by some of the photographs which the author had presented to syphilitic lesions, and Dr. GREENOUGH called special attention to the same point.

Dr. BULKLEY asked if the lesion on the sole of the foot was sufficient alone to establish a diagnosis.

Dr. MORROW replied that the photograph of this lesion that he had shown had been taken several years before, and that since that time other lesions had appeared, and the patient had afterward been sent to the leper settlement. He did not think that lesion would be present as an early symptom, except in places where the people went barefoot.

The PRESIDENT cited the case of a woman, seventy-two years old, who had the anaesthetic form of leprosy, who suffered with an ulcer on the sole of the foot, though she had not gone barefoot.

**Dermatological Bibliography.**—Dr. G. T. JACKSON, of New York, presented to the association a very complete list of dermatological published material.

The PRESIDENT returned to Dr. Jackson the thanks of the association.

**The Occurrence of Prurigo in America.**—Dr. ZEISLER read a paper on this subject. His inquiry was intended to throw light upon the subject question of whether true prurigo occurred in America, and, if there was a difference in the proportionate amount, to what it might be due. In France, up to ten years ago, the disease had been almost unknown. In 1876 Dr. James C. White said that it was not seen in this country. It was now generally believed that true prurigo did exist here, but that the severe form was quite uncommon. The mild form of the disease did certainly occur. Out of 1,370 cases of skin diseases the author had seen twelve cases of prurigo—five of them severe and the rest mild. Out of 1,108 cases in private practice nine had been cases of prurigo, of which three had been severe and six mild. Out of the whole number, the percentage would be 0·875, which was a larger proportion than was generally supposed. According to the reports of this association, a year ago the percentage was 0·027, and last year it was 0·033. In Prague, in 1874, it had been 0·566, and in 1875, in the same city, it had been 0·714. In Christiania there had been reported an occurrence of a little over three per cent., while in Vienna it formed from two to three per cent. of all skin diseases. In the five severe cases there could be no doubt about the diagnosis. Of the twelve patients, only one of whom had been born of native parents, seven might be classed as being in poor circumstances, and four of these seven had been affected with the severe form of the disease. Of the five who had been in moderate circumstances, only one had had the severe form. Five of the seven with mild cases had been cured, and the other two were improving. The five severe cases, which had been watched for a long time, seemed at times to improve a little, and then relapse when neglected. Frequent bathing was one of the best remedies for the disease, and the reader thought that the greater habits of cleanliness in this country would explain the greater rarity of the affection.

The following conclusions were drawn: 1. Prurigo did cer-

tainly exist in America. 2. The severe form, while occurring in perfectly typical examples in patients born or reared here, was comparatively rare. 3. Prurigo initis was not uncommon here.

Dr. R. W. TAYLOR, of New York, had seen two cases of what seemed commencing prurigo in children who had had chronic urticaria, and one case of true prurigo in the adult.

Dr. FOX had seen two cases in adults where there could have been no question about the diagnosis. Several cases had been presented before the New York Dermatological Society, and some of the members had questioned the diagnosis. Their objections had been based on the cases shown in Vienna in the clinic, where only the marked cases were presented. It seemed to the speaker that there had been a great diffidence in making the diagnosis, on the ground that the cases did not present these marked characteristics. In its mild form the speaker did not believe it to be a very rare disease, although, of course, it was not a common one.

Dr. ROBINSON had never seen a case in this country that he would be willing to diagnosticate as such, although he had seen them in Hebra's clinic.

Dr. GREENOUGH had seen many cases in Vienna, but he had never seen at the Boston Dispensary any cases of what Dr. Zeisler would call the severe prurigo. He had seen several cases about which there was a question. He would not deny that they might have existed, and thought it possible that some of the cases that he and his colleagues had entered as pruritus had been mild cases of prurigo.

Dr. E. WIGGLESWORTH, of Boston, said that the first case reported in this country had been reported by him. He had at present a case under observation—that of a boy who would be presented to the association on the last day of the meeting.

Dr. BRONSON thought something of a bugbear had been made of the subject. If we accepted the view that the disease was essentially a neurosis which primarily affected the sensory and motor nerves, and that the trophic changes were secondary and the result of irritation, we were justified in recognizing it as of common occurrence, even here. It had been his experience that pruritis most affected those portions of the skin which were most affected by prurigo. He believed that the neurosis was identical in the two cases. From certain causes this neurosis was much aggravated in Vienna and some other foreign places, but it was sometimes seen here in the severe form. The speaker had never seen a case of the persistent form as it occurred in Vienna.

Dr. JACKSON, Dr. BULKLEY, Dr. SHEPHERD, Dr. SHERWELL, Dr. HOWE, Dr. KLORZ, and Dr. HEITZMAN participated in the discussion, each having seen from one to three cases.

Dr. ZEISLER said it was no objection to the diagnosis that the patients were cured. Mild cases were perfectly curable, especially since the use of naphthol. In severe cases the patients could be rendered very comfortable, at any rate.

**Eczema Mercuriale.**—Dr. J. F. SHEPHERD, of Montreal, reported the histories of two cases of this affection. These cases had followed the use of Scott's dressing, which was made of one part of mercury to four parts of ammoniac plaster. He had used the dressing in the treatment of chronic synovitis. Both cases reported had occurred in young men. In the first case the dressing had been kept on three weeks without renewal. At the end of that time the knee had regained its normal shape. A year later a similar attack had come on and the same application was made, but this time on a surface that had recently been blistered. At the end of a week the skin about the knee was found inflamed, red, and brawny. The next day the face was red, hot, and swollen, and covered with fine vesicles, the

eruption extending down as far as the clavicle. At the same time the eczema about the knee had extended as far as the groin. Recovery was complete in two weeks. In the second case the dressing was removed after three weeks, and an exanthematous rash found on the surface which had been covered.

Three days later there was a marked swelling of the eyelids, and in two days the whole face had become reddened. At the same time a papular eczema appeared on the leg and forearm, and the genitals were acutely inflamed. Desquamation occurred in two weeks, but the rash did not disappear for six weeks. A third case had been reported to him as occurring in the practice of a colleague, the history being very like those mentioned.

Dr. MORROW referred to the fact that in certain cases the eruption caused by drugs would persist for a long time, although the general rule was for a speedy disappearance when the irritating cause was removed.

Dr. GREENOUGH had seen one patient who had seemed to have a peculiar idiosyncrasy. He had used the ointment and it had been followed by a severe dermatitis which had taken on a diffuse phlegmonous form, and he was confined to his bed for six months.

**Clinical Observations on Injections of Insoluble Mercurial Salts in Syphilis.**—Dr. H. G. KLOTZ, of New York, read a paper with this title. These injections seemed not to have been used much in this country, and little had been written on the subject. It had been generally considered that the method should be resorted to only in cases of emergency. Fumigations were not always well borne, and there was some danger of injury to the air-passages by inhalation of the fumes. The author had used the cyanide, as a soluble form of the mercurial, but it was expensive, and caused a good deal of pain. In private practice he had given twelve injections to twenty-three patients. It was better to have the patient lying on the face at full length, to avoid sudden motions. The point selected for the injection was preferably about an inch outside the gluteal fold; this point was such that the patient could sit afterward without much discomfort. The needle should be stouter and longer than that used for ordinary purposes. It should be inserted with one thrust, and then should be held quiet for a quarter or half minute, until the quivering of the muscle had ceased. The barrel was emptied slowly, and a fold of the skin pinched up as it was withdrawn. No massage was to be used, and the patient should be enjoined from muscular exertion for several hours.

At the very beginning of the practice, in the hands of the author, one or two abscesses had followed the injections, but for the past two years he had not seen an abscess; when they did occur they were not very troublesome. Sometimes there was a more or less painful swelling after the treatment, not followed by suppuration. The trouble had followed the use of calomel in five cases, and after the yellow oxide it had occurred but twice. Of the fifteen accidents, twelve had been experienced after the use of calomel in water. It was noticeable that the use of calomel in oil never caused local trouble. Salivation seemed less frequent than after injection. A slight diarrhoea had been present in one case. One patient had had a chill after the treatment, and this had been followed by loss of appetite and a temperature of 103° F., with pain in the chest and difficulty of breathing, accompanied by a few rhonchi. The next day he was better, after profuse perspiration. There had been, probably, an embolism of oil from the injected fluid. In one other patient there had been pain in the chest, but nothing was found on physical examination, and he was soon better.

All affections of the skin disappeared rapidly after two or three injections, as a rule. The pigmented spots went rapidly, generally, but there was not so much effect upon the pustular lesions. In the tubercular syphilitides there was a good effect at

first, but it was not lasting, and the iodides had to be given. Mucous-membrane affections were benefited. Persistent primary induration had disappeared in one case after it had lasted a year. In two cases of tertiary syphilis the result had been very satisfactory.

Dr. TAYLOR thought that this subject of mercurial injections was a good illustration of the fact that there were fads and fashions in medicine. Such a method would rarely have to be resorted to as an emergency treatment. He had seen it carried out in Charity Hospital, and it had added much to the discomfort of the patients. Taking into consideration the dangers of embolism, the occurrence of abscesses, the painful nodules that formed, and the pseudo-paralytic condition of the legs, it seemed to him there would be considerable objection to the employment of this method of medication.

Dr. MORROW had had an excellent opportunity to watch the effect of these injections in a large hospital, and he would only reiterate his conclusions, which had been given before the New York Academy of Medicine—viz., that it was a reserve treatment to be followed in cases where the usual and better plan of administration by the stomach could not be followed. He could not see how any drug introduced into the tissues was transformed, by any strange chemistry of nature, into something more potent than if taken by the stomach. He remembered to have seen post-mortem examinations of persons that had died of some intercurrent disease, and the tissues about the point of injection had been in such a necrobiotic condition that he had concluded it to be bad surgery to duplicate these results on a large scale. He had used the treatment in two cases in the last two years, and he did not believe the results had been any better than they would have been by other methods. A strong argument against the treatment was the fact that there were so many dermatologists who had immense numbers of patients passing through their hands, and who rejected this treatment altogether.

Dr. ZEISLER thought that, while the injections might be practicable in hospitals, they should not be used in private practice to any extent. He had never had the courage to treat a patient with the method, which seemed in many respects doubtful. He had always been satisfied with the old methods.

Dr. BRONSON thought we should not condemn the method till we had learned all that was to be obtained from it. It seemed to him to represent a very scientific line of treatment. For frictions, the speaker preferred the mercurial soap to the ointment.

Dr. HEITZMAN said his son had given the injection in the most antiseptic manner possible. In the first case an extremely painful inflammation had been the result, but it had not formed an abscess. Two weeks afterward a second injection had been made, and an abscess had formed. He had been discouraged from making another trial. He did not consider the objection to fumigation, that it injured the respiratory tract, a serious one, for he had never seen such results.

Dr. KLOTZ raised the point that private patients were the very ones on whom this treatment should be tried. He had always explained to patients what the discomforts of the method were, and he had never had any difficulty with them. Some of the patients whom he had treated liked the injections so much that they had insisted upon having them afterward. The objection to the use of injection was the fact that the patients could not do it thoroughly enough. Many bad results in the way of salivation, bone diseases, and eczemas had been caused by the reckless use of injections. In regard to the post-mortem appearances, he had seen cases where no bad results could be discerned at all. His total experience with the method had not been such that he felt that he could not go on.

(To be concluded.)

## New Inventions, etc.

### PRESENTATION OF INSTRUMENTS

AT THE ELEVENTH MEETING OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION.

DR. JOHN O. ROE, of Rochester, N. Y., exhibited three instruments and said:

"At the meeting of this association last year I reported a case of internal oesophagotomy, and also described a new oesophageal bougie. I should now like to present, not only an improved form of the bougie then described, but also certain other instruments I have devised and have found exceedingly useful."

"*A New Oesophageal Bougie.*—The bougie which I described last year was made by attaching the tip of a conical gum-elastic bougie about three inches in length to the end of a hard-rubber bougie by

FIG. 1.

means of a plug and screw. Since that time I have made this improved oesophageal bougie, which I now show you (Fig. 1). This is made all in one piece by simply governing the vulcanizing process so that one end of the bougie is vulcanized as hard rubber while the other is vulcanized as soft rubber.

"It is well known that caoutchouc when mixed with 25 per cent. of sulphur and vulcanized at about 250° F. becomes soft rubber, whereas if the caoutchouc is mixed with 50 per cent. of sulphur and vulcanized at about 300° F. it becomes hard rubber. By carefully considering these principles in the manufacture, the bougie is made with one end of hard rubber and the other end of soft rubber, as is represented by c and d, Fig. 1.

"These bougies are made in a series of six or more of different sizes. I have each one of mine attached firmly to a whalebone stem, although the bougie can be so made that one stem can answer for the set by attaching it to them with a screw. The advantage of this form of bougie over both the long gum-elastic bougie and the bulbous hard-rubber bougie is that it combines the advantages of both and overcomes the objectionable features that both possess. The flexible soft-rubber tip facilitates the passage of the bougie through the throat and readily directs it into the stricture, and is thereby more easily introduced than is the hard-rubber bulbous bougie; and the slender, flexible whalebone stem causes much less irritation of the throat and gagging, and does not fill up the throat as does the long gum-elastic bougie.

"The advantage of combining the hard and soft rubber instead of making the instrument entirely of soft rubber is that the hard-rubber portion is unyielding and far better for the purpose of dilating oesophageal strictures than it would be if the instrument were made entirely of soft rubber.

"*An Improved Powder-blower.*—The next instrument is an improved powder-blower. Nearly every powder-blower has its objectionable features. Some have to be recharged each time they are used. Some are used with a bottle as a reservoir for the powder, and are necessarily bulky and clumsy and easily broken, or the powder is liable to spill out in handling or to find its way back into the rubber bulb that is used for blowing. I think you will agree with me that nearly all these objectionable features are overcome in this powder-blower, which I now show you (Fig. 2). The stem of the instrument passes through the bottom of the reservoir. A hole is made in the bottom of the reservoir to correspond with a hole that is made in one side of the stem of the instrument. It will therefore be seen that if the hole in the side of the stem, b, is turned upward so as to be directly under the hole in the bottom of the reservoir

voir, a, the powder will fall into the stem or barrel of the instrument; and by giving it a half turn the powder in the reservoir is completely

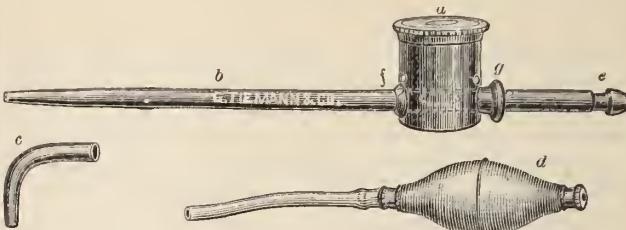

FIG. 2.—Powder-blower.

cut off. The position of the hole in the stem is indicated by an ivory guide, f, placed on the stem. When the stem is charged, only the powder that has fallen into it can be blown out. The stem is secured in the reservoir by the binding nut, g, which can be removed and the stem taken out for cleansing. The instrument can be used for throwing the powder not only straight, but also in any direction that is desired,

by attaching, in the latter case, the curved tip, c, to the point of the stem. A flexible rubber tube can be attached to the stem at e, by which the powder can be blown out by the operator's breath, or by the rubber bulb, d, as shown in the cut. The different parts of the instrument are so nicely adjusted as entirely to prevent the escape of any powder from the reservoir, and it is thus admirable for the use of iodoform.

"The only objectionable feature is that this instrument is not so well adapted to the use of a variety of powders as an instrument made without the reservoir; but the surgeon can readily provide himself with several of the powder-blowers, as their cost is not great, and keep them filled with the powders which he most frequently uses. The facility with which this instrument is used and the saving of time otherwise required for charging the plain powder-blower can at once be appreciated by those who do a large amount of office work.\*

"*A Nasal Bow-saw.*—I have one other instrument to show you which I have recently devised, and that is a new form of nasal hand-saw. At

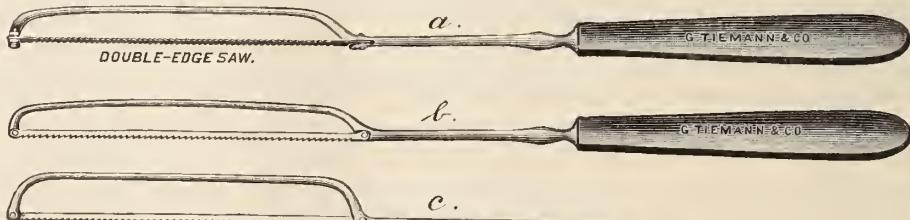

FIG. 3.

the meeting of this society last year I showed you my latest improved electric nasal saw, but as an instrument of this kind is not always at hand, the most simple and most nearly perfect hand-saw is therefore a desideratum.

"This form of saw, as you see (Fig. 3), consists of a blade of a jeweler's saw held by a bow similar to a bow-saw, but made very light and delicate.

"The saw devised by Dr. Bosworth is a very excellent instrument. The only disadvantage the operator finds in using that saw is the flexibility of the blade, so that in attempting to saw off a very hard and rounded exostosis it is often with difficulty that the blade can be

\* Since I described and exhibited this instrument before the Laryngological Association on May 28th last, the idea has been appropriated by a certain instrument-maker, who has published a similar cut of the instrument without giving any credit to the originator of the idea.

started in at exactly the spot the operator desires; and even in making a slight lateral pressure to hold the blade up to the point desired, the saw is very apt to make a curved cut. With this little bow-saw these objections are entirely done away with. A very much thinner and finer blade can be used in these saws than in the case where the blade must be sufficiently thick to carry itself. By using the same thin and highly tempered blades that jewelers use for sawing metal, an exostosis of any degree of hardness can be very easily and quickly cut through. These saws I have had made for me in various sizes and shapes. The only disadvantage attached to the saw is that the blade can only be made to cut as deep as the distance of the saw from the back. This objection is obviated by having a saw with the blade placed at right angles to the bow, and with the bow sufficiently high to allow it to pass over the obstruction. In other cases where the bow may interfere with the completion of the operation, the first incision may be made with this saw at exactly the spot desired and the operation completed with the Bosworth saw. The latter saw will then have the perfectly straight groove to run in which has been made with the bow-saw. One of the special advantages of this little bow-saw with the blade set at right angles is in sawing out exostoses in the floor of the nostrils. The very narrow blade will permit the sawing to be done on the exact curve of the floor of the nostril. The saw is also admirably adapted to remove small angular projections and irregularities of the septum. The very fine teeth of this little saw also give it an advantage over saws with coarser teeth, in that they leave a very smooth surface over which the soft parts more quickly spread, and the wound more readily heals.

"Some of these saws I have had made with the handle straight, on the line with the blade of the saw, while in others I have had the handle placed at about the same angle as in the Bosworth saw (see *a*, *b*, and *c*, Fig. 3). In many instances the little straight handle is much more conveniently used than the bent handle, especially when in sawing it is desired to deviate from a straight line.

"The saw with the plane of the blade placed at right angles to the back is represented by *a*, Fig. 3. The blade of this saw is made with teeth on both edges, so as to saw in either direction. In order to prevent the blade from cutting under, when sawing close to the septum, the blade should be placed entirely on the side of the bow, as shown by *b*, Fig. 3. The blade can be put on either side of the bow for sawing upon either side of the septum.

"All these instruments have been made for me in the most admirable manner, by Messrs. Tiemann & Co., 107 Park Row, New York."

*A Pharyngeal Douche* was shown by Dr. SAMUEL JOHNSTON, of Baltimore, who said: This simple apparatus consists of an ordinary soda-water siphon charged in the usual way, with a soft-rubber tube twelve inches long attached to the nozzle.

FIG. 4.

The method of using it is as follows:

A bib of water-proof cloth or oiled silk large enough to protect the clothing is first fastened around the neck of the patient, the free end of

the bib resting in a basin to receive the return current. The tube is then inserted into the mouth to a convenient distance, and the pressure turned on by the attendant; the contents of the bottle will then flow with force into the mouth and out again, varying, of course, with the amount of pressure exerted on the stop-cock.

The quantity of tenacious mucus expelled by this means in some cases is enormous, and the relief afforded can only be appreciated by those who have had experience with this process of cleansing the oral cavity.

We have all, doubtless, used the syringe with a flexible rubber tube attached to the tip for washing out the mouth and nasal passages in cases of acute amygdalitis, diphtheria, scarlatina, etc., but I believe we have in this simple apparatus an agent which will give greater ease to those suffering with the class of affections before mentioned than any other local treatment yet employed.

Thus far I have only used soda water; the contents of the siphon can, however, be carbolized or otherwise medicated to suit special cases. A lady, recently under my care with quinsy, for several days used six to eight siphons daily in this way, greatly to her comfort and relief, and it is to her that I am indebted for the suggestion of this novel application of the soda-water siphon.

*A Modification of Voltolini's Palate Retractor* was shown by the president, Dr. MORGAN, which was intended to draw the velum forcibly forward while operating on the bursa pharyngea. The handle was so

FIG. 5.

bent as to allow the hand of the assistant, who retracted the velum, to be entirely out of the line of vision of the operator. Truax & Co., of Chicago, had made the instrument.

## Miscellany.

The Southern Surgical and Gynaecological Association will hold a meeting in Nashville, Tenn., on the 12th, 13th, and 14th of November, under the presidency of Dr. Hunter McGuire, of Richmond, Va. The preliminary programme includes the following: The President's Annual Address; "A Report of Gynaecological Work, with especial Reference to Methods," by Dr. R. B. Maury, of Memphis, Tenn.; "Direct Kelotomy, with Cases," by Dr. W. O. Roberts, of Louisville, Ky.; "Open Abdominal Treatment," by Dr. B. E. Hadra, of Galveston, Texas; "The Abortive Treatment of Acute Pelvic Inflammation," by Dr. Virgil O. Hardon, of Atlanta, Ga.; "The Importance of Early Treatment of Inflammatory Affections of the Uterus," by Dr. W. C. Dabney, of University of Virginia; "The Relation of the Nerve System to Reparative Surgery," by Dr. T. O. Summers, of Jacksonville, Fla.; "Concerning the Causes of Frequent Failure of Relief of Reflex Symptoms after Trachelorrhaphy," by Dr. W. F. Hyer, of Meridian, Miss.; "Cranial Surgery," by Dr. De Saussure Ford, of Augusta, Ga.; "The Treatment of Ectopic Pregnancy," by Dr. W. H. Wathen, of Louisville, Ky.; "Laparotomy in Extra-uterine Pregnancy," by Dr. Waldo Briggs, of St. Louis, Mo.; "Epithelioma of the Penis, with the Report of a Case," by Dr. D. W. Yandell, of Louisville, Ky.; "Laparotomy in Intestinal Obstruction," by Dr. C. Kollock, of Cheraw, S. C.; "An Experimental Study of Intestinal Anastomosis," by Dr. J. D. S. Davis, of Birmingham, Ala.; "Operative Interference in Ascites," by Dr. Hugh M. Taylor, of Richmond, Va.; "Observations pertaining to Pregnancy and Parturition," by Dr. W. Duncan, of Savannah, Ga.; "Puerperal Convulsions," by Dr. J. Herbert Claiborne, of Petersburg, Va.; "Some Remarks upon Aneurysms, relating more especially to their Surgical Treatment," by Dr. F. T. Meriwether, of Asheville, N. C.; "Coccygodynia and its Treatment," by Dr. Hunter P. Cooper, of Atlanta, Ga.; "The

Improved Caesarean Section *versus* Craniotomy," by Dr. W. D. Haggard, of Nashville, Tenn.; "Conservative Surgery in Injuries of the Foot," by Dr. J. T. Wilson, of Sherman, Texas; "Gunshot Fractures of the Femur," by Dr. J. Brownrigg, of Columbus, Miss.; "Tropho-neuroses as a Factor in the Phenomena of Syphilis," by Dr. G. Frank Lydston, of Chicago, Ill.; "Trophic Changes following Nerve Injury in Fractures, with a Report of Two Cases," by Dr. W. Perrin Nicolson, of Atlanta, Ga.; "The Treatment of Malignant Diseases of the Rectum," by Dr. W. T. Briggs, of Nashville, Tenn.; "Gynaecology in its Relations to Obstetrics," by Dr. W. L. Robinson, of Danville, Va.; "Observations based upon an Experience of Seventy-five Abdominal Operations," by Dr. J. Taber Johnson, of Washington, D. C.; "Twenty Consecutive Cases of Abdominal Section," by Dr. L. S. McMurry, of Danville, Ky.; "Triple Amputations," by Dr. J. B. Luckie, of Birmingham, Ala.; "The Treatment of Contracted Bladder by Hot-water Dilatation," by Dr. I. S. Stone, of Lincoln, Va.; "Complications occurring in the Clinical History of Ovarian Tumors," by Dr. Richard Douglas, of Nashville, Tenn.; "What Kind of Instruments does Modern Antiseptic Surgery demand?" by Dr. J. W. Long, of Randleman, N. C.; "Intestinal Anastomotic Operations with Segmented Rubber Rings, with Some Practical Suggestions as to their Use in other Surgical Procedures," by Dr. A. V. L. Brokaw, of St. Louis, Mo.; "Leucocythaemic Tumors as a Neoplastic Exponent of Rheumatism, and their Similarity to Malignancy—with a Case," by Dr. W. Locke Chew, of Birmingham, Ala.; "What Civilization is doing for the Human Female," by Dr. A. Lapthorn Smith, of Montreal, Canada; "The Achievements of Modern Surgery," by Dr. J. Ewing Mears, of Philadelphia; "The Treatment of the Pedicle in Suprapubic Hysterectomy," by Dr. W. M. Polk, of New York; "Pus in the Pelvis and how to deal with it," by Dr. Joseph Price, of Philadelphia.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the abstract of sanitary reports received by him during the week ending October 18th:

CITIES.	Week ending—	Estimated popu- lation.	Total deaths from all causes.	DEATHS FROM—								
				Cholera.	Yellow fever.	Small-pox.	Varioloid.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Mesenteric.
New York, N. Y.	Oct. 12.	1,584,771	573	...	...	...	...	8	4	19	1	7

**Billroth on the Dangers of Carbolic Acid.**—“The following letter of Dr. Th. Billroth, of Vienna, has been published: ‘I have lately seen four cases in which fingers, which had suffered a most insignificant injury, became gangrenous through the uncalled-for application of car-

bolic acid. Carbolic acid is now much less used in surgery than formerly; we have only gradually become acquainted with its dangers. The acid may not only cause inflammation and gangrene, but also blood-poisoning, and so may even prove fatal. It is useful only in the hands of a skillful surgeon, and ought never to be used without his advice. The best lotion for recent injuries is the ordinary lead lotion, which can be bought at any chemist’s. The best antidote in carbolic-acid poisoning is soap, which should be taken immediately and repeatedly until all symptoms of poisoning have disappeared.’”—*Lancet*.

**Torticollis in Inflammation of the Middle Ear.**—“Torticollis, when it occurs in the course of acute otitis media, has generally been looked upon as a very serious complication due to periostitis of the mastoid process, and the formation of an abscess, with myositis of the sternomastoid. That this is not always the explanation of the complication is shown by Dr. Radshik in an article in the ‘Meditinskoe Obozrenie,’ in which he gives an account of a case of inflammation of the middle ear following measles, which on the third day became complicated by torticollis, this being due to periadenitis of the neck, and Dr. Radshik suggests that in these cases enlarged and inflamed glands in the neck may frequently be the cause of wryneck.”—*Lancet*.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of “original contributions” are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters’ hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer’s name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author’s name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies’ regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

## Original Communications.

### EXTRACTION OF CATARACT WITHOUT IRIDECTOMY.

REPORT OF ONE HUNDRED CASES, WITH REMARKS.\*

By CHARLES STEDMAN BULL, M. D.,

PROFESSOR OF OPHTHALMOLOGY IN THE UNIVERSITY OF THE CITY OF NEW YORK; SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY; CONSULTING OPHTHALMIC SURGEON TO ST. LUKE'S HOSPITAL.

WITHIN the last three years the old method of the extraction of cataract without iridectomy, which was formerly devised and practiced by the French surgeon David, and called by him "simple extraction," has been revived by Panas, Wecker, and others, and has been in many quarters hailed with all the *éclat* of a new operation. Most of the modern French authors report very enthusiastically in its favor, but none of them have as yet given us any detailed or conclusive statistics in regard to the results obtained, nor any comparative statements as to the advantages of the "simple operation" over those of the so-called "linear extraction with iridectomy" devised by von Graefe, and practiced almost universally with great success for the last twenty-five or thirty years.

The ideal operation for the extraction of cataract is undoubtedly the removal of the lens in its capsule through a corneal section, and without wound or excision of the iris; and the restoration of sight in this manner, with the preservation of a round and movable pupil, is certainly to be regarded as one of the greatest of operative achievements.

Sufficient time has now elapsed since the revival of the old "simple operation" to enable us to draw some conclusions as to the merits of this method of operating and the results obtained, in so far as the ultimate vision is concerned; and the writer now presents to the association for their consideration his own experience in one hundred cases of extraction of cataract by the simple method without iridectomy.

As a firm believer in the value of antiseptics in ophthalmic surgery, the reporter deems it wise to give in detail all the steps which he considers necessary in the operation, from the preparation of the patient for the operation to the final testing of the vision and the discharge of the case from observation.

*Preparation of the Patient.*—If the patient be a hospital case, he should have a bath of the entire body the day before the operation, special attention being paid to the cleansing of the hair and beard with soap and water. This is not considered necessary in the case of a private patient. On the day of operation the patient's face should be carefully washed with soap and water, and just before the operation the face should be laved with Panas's solution of the biniodide of mercury, or with a solution of mercuric bichloride (1 to 5,000), or with a saturated solution of boric acid, and the latter solution should be used for irrigation of the conjunctival *cul-de-sac*. The patient should be placed in the bed which he is to occupy throughout the entire course of

treatment, so as to avoid all unnecessary moving about. This precaution reduces to a minimum the dangers which may arise from prolapsed iris, opening of the wound, loss of vitreous, haemorrhage, etc.

After the necessary local anaesthesia has been produced by a few drops of a five-per-cent. solution of cocaine hydrochloride, the conjunctival *cul-de-sac* is again thoroughly irrigated with the boric-acid solution, and the patient is then ready for the operation.

The instruments have previously been cleansed and sterilized in boiled water, and have been placed in a bath of absolute alcohol. From this bath they are taken wet as they are wanted for the operation. The hands of the operator and of the assistant, if he has any, are carefully cleansed with soap and water, and then washed with a solution of sublimate (1 to 2,000). Some operators prefer Panas's solution for purposes of cleansing and irrigation; this consists of mercuric biniodide, 0.05 gramme; alcohol, 20 grammes; and distilled water, 1,000 grammes.

The surgeon should sit behind his patient, and should operate on the right eye with the right hand and on the left eye with the left hand. In this way he is never in his own light. If he is not naturally ambidextrous, he should strive to make himself so. A speculum is then introduced to hold the lids open, and the eyeball is firmly grasped with a fixation forceps, the latter being made to seize the conjunctiva and subconjunctival tissue over the insertion of one of the straight muscles of the eye.

A straight, narrow knife, somewhat more slender than the cataract knife of von Graefe, is then introduced on the temporal side in clear cornea, near the limbus, and is passed quickly across the anterior chamber, horizontally in front of the iris, and is brought out at a corresponding point in clear cornea on the nasal side, and the incision is then completed, if necessary, by a to-and-fro movement. The length of the incision should involve about two fifths of the circumference of the cornea.

Some operators, in completing the corneal incision, make a small conjunctival flap as a protection against secondary infection from the conjunctival *cul-de-sac*. I never make such a flap if it can be avoided, as I regard it as a useless complication unless the patient has a chronic conjunctivitis or dacryocystitis; and it undoubtedly increases the danger from primary infection by enlarging the wound. In making the corneal section, care should be taken to pass the knife quickly across the anterior chamber and thus complete the section as rapidly as possible. This prevents almost entirely the escape of aqueous humor, and there is but little danger that the iris will fall over the edge of the knife and be divided.

If the iris prolapse outside of the wound as soon as the section is completed, it is better to restore it to its place in the anterior chamber before opening the capsule. The capsulotome or angular cutting needle is then introduced and carried well behind the inferior margin of the sphincter of the iris, and the capsule is then lacerated by a T-shaped incision or, better, by a quadrilateral one, care being taken to avoid wounding the iris.

\* Read before the New York State Medical Association, September 27, 1889.

The extraction of the lens now follows. This is effected by pressure on the eye above the wound and counter-pressure on the lower portion of the cornea with a spatula or rubber spoon. This causes a gaping of the wound and a revolution of the lens upon its horizontal axis, the upper margin of the lens coming forward and presenting in the wound. A brief continuance of this pressure and counter-pressure causes the extrusion of the lens and a more or less extensive prolapse of the iris. It is perhaps safer to remove the speculum before this manœuvre is attempted, so as to avoid as far as possible the danger of prolapse of the vitreous. This should always be done in cases of complicated cataract, especially when the suspensory ligament is defective and the vitreous disorganized, or the lens partially dislocated.

The next step—a very important one—is the removal of the remnants of soft lens matter or cortex, if there are any, from the anterior chamber. This is best done by pressure with the fingers upon the eyeball through the closed lids; or by curette, or spoon, or spatula, by repeated slow movements of the instrument over the cornea from below upward toward the wound; or by repeated and continuous rotary massage of the lids upon the eyeball. These manœuvres should be accompanied by frequent irrigation of the conjunctival *cul-de-sac*, and even of the anterior chamber, by a warmed saturated solution of boric acid or by Panas's fluid. It is very rarely necessary to introduce any instruments into the anterior chamber.

The next step is the replacing of the prolapsed iris. If the iris has not spontaneously reduced itself during the manipulations employed for removing the lens fragments from the anterior chamber, it may be readily replaced or reduced by a gentle stroking with a smooth probe or spatula. If on reduction of the prolapsed iris the pupil is neither central nor round, some surgeons consider it advisable to do an iridectomy at once, so as to avoid the necessity of doing it later. But it is much better to so choose your cases for simple extraction as to exclude all such cases as may possibly necessitate an iridectomy.

For irrigation of the anterior chamber any small lacrimal syringe may be used, but it should always be sterilized and kept exclusively for the purpose. The nozzle should be introduced between the lips of the wound, and the fluid used should be injected very slowly and gently and in small quantities.

The final steps in the operation before the application of the bandage are a careful irrigation of the lids and conjunctival *cul-de-sac* with the boric-acid solution and the instillation of a few drops of a solution of eserine sulphate (half a grain to the ounce) into the *cul-de-sac*, or the application of an ointment of eserine of the same strength. This causes a contraction of the pupil, and thus aids in preventing a secondary prolapse of the iris.

The lids of both eyes are then closed, carefully and smoothly covered with a wad of antiseptic cotton, and a double roller flannel bandage applied over both eyes.

The after-treatment varies somewhat with the nature of the case and the temperament of the patient. The patient is to be kept in bed on an average for three or four days. He is allowed to sit up while eating and to rise from bed

to satisfy the calls of nature. The room need not be darkened. It is my custom usually to remove the bandage and dressing on the next day, but without opening the eyes. The edges of the lids are to be gently cleansed with a saturated solution of boric acid or a solution of mercuric bichloride (1 to 5,000), and a drop of a solution of eserine sulphate is to be introduced. If there is much mucous secretion or any swelling of the lids, the lids are opened, the eyeball and conjunctival *cul-de-sac* are carefully irrigated with the boric-acid solution warmed, and then the eye is carefully inspected. If, on the contrary, the lids look well, the eye is not inspected until the fourth or fifth day, but the dressings are renewed and the lids cleansed daily. If on the fourth or fifth day the pupil is round and central, the eye is carefully cleansed, and, if the wound has closed throughout, the bandage is discontinued except at night, and then is used only on the operated eye. The eye not operated upon is usually left uncovered after the second or third day. If the pupil is round and central and the wound closed, but circumcorneal injection or pain is present, a weak solution of atropia should be used at once several times a day until both these symptoms have subsided.

A few words now in regard to the accidents which may occur in the course of the operation:

1. The iris may fall upon the edge of the knife in its passage across the anterior chamber, and may be wounded or excised as the corneal section is completed. This accident may happen to any surgeon. The rapid passage of the knife across the anterior chamber to its point of exit in the cornea on the opposite side, and the avoiding of any undue pressure on the eyeball by the fixation forceps, will go far toward preventing the occurrence of this accident. The rapid completion of the corneal section also aids in this endeavor. Should the iris be cut or excised in this first step of the operation, an iridectomy must be done at once, and the artificial pupil thus made clean and smooth.

2. *Prolapse of the Vitreous.*—This may occur at any period during the operation, and is always a misfortune. In the hands of a careful operator it is usually slight, and need not interfere with the usual careful manipulations for causing the extrusion of the lens. Any portion of vitreous that remains in the wound after the lens has been removed must be cut off, and great care must then be exercised in any manœuvres undertaken for extracting the remains of cortex from the anterior chamber. It is well, also, in such cases, to avoid all irrigation of the anterior chamber, as it will be very apt to increase the loss of vitreous. Should the vitreous prove to be fluid and the prolapse extensive, the lens should be removed at once, either with the blunt hook or spoon, and the eyelids at once closed temporarily for a few minutes. Then the iris should be replaced, eserine instilled, and both eyes closed with the usual antiseptic dressings and bandage.

3. *More or Less Extensive Haemorrhage into the Anterior Chamber.*—This may be in great part prevented by avoiding the conjunctival flap. If the haemorrhage comes from a wounded iris, the latter is to be smoothly excised, and then the further steps of the operation are to be interrupted until the haemorrhage has been controlled and the blood, as

far as possible, removed from the anterior chamber, as its presence interferes with the proper opening of the capsule and the removal of the lens.

**COMPLICATIONS OR ANOMALIES OF THE HEALING PROCESS.**—There are several of these complications, which will be considered in the order of the frequency of their occurrence:

1. *Posterior synechiae* or adhesions of the posterior surface of the iris to the remains of the anterior capsule of the lens. These are very common, and are in many case filiform or thread-like in character. They rarely obstruct the pupillary area. They are caused by the edges of the lacerated anterior capsule coming in contact with the pupillary margin of the iris, which has already been bruised in the passage of the lens through the pupil. These adhesions occur independently of any actual iritis.

2. *Iritis*, usually of the mild, plastic type, and very often involving only a segment of the circumference of the iris. This is best combated by a weak solution of atropine and warm applications.

3. *More or Less Complete Obstruction of the Field of the Pupil by the Opaque or Thickened Posterior Capsule of the Lens.*—This is a very common complication of the healing process, and usually requires some operative interference—such as discussion or some more serious surgical procedure, to be described later.

4. *A more or less irregular pupil*, usually oval, caused by a puckering of the iris in the upper part of the angle of the anterior chamber, without there being any actual adhesion or incarceration of the iris tissue in the lips of the corneal wound. For this there seems to be no remedy of any actual value.

5. *Incarceration of the iris* in the corneal wound, or else merely anterior synechia, a more or less marked adhesion of the iris to the inner lips of the wound. The use, once or twice a day, of a drop or two of a half-grain solution of eserine sulphate sometimes succeeds in breaking these adhesions, though more frequently it does not succeed; and it may prove disadvantageous by causing irritation of the iris, and thus increase the chances of posterior synechia.

6. *Secondary Prolapse of the Iris.*—If this occurs early and it can not be reduced, it should be cut off as neatly as possible, and the edges gently stroked into place in the anterior chamber. If the wound has already partially closed and the prolapse of the iris is a late occurrence, it is better to leave it undisturbed by any manipulation. This secondary prolapse of the iris is almost always of traumatic origin, from some sudden jar or displacement of the bandage on the part of the patient, and its prevention depends largely on careful nursing. Great care in operating and the rigid exclusion of all unsuitable cases—such as rigidity of the iris, prolapse of the vitreous, dislocation of the lens, or unmanageable patients—will all undoubtedly aid in reducing the cases of secondary prolapse of the iris to a minimum.

7. *Capsulitis, or Inflammation of the Capsule of the Lens.*—This is almost always of the mildly plastic character, and is usually associated with the mild form of iritis. Should it prove to be of the suppurative type, it is almost invariably accompanied by a purulent inflammation of the

iris and infiltration of the tissue of the cornea in the vicinity of the wound, and is always the result of secondary infection from without.

8. *Suppuration of the Lips of the Wound in the Cornea.*—This is always the result of secondary infection, and, if not combated at once, may end in total loss of the eye from suppurative panophthalmitis. Its cause is usually some chronic inflammation of the palpebral conjunctiva or lacrimal sac, and it should be treated at once by a removal of the dressings and bandage, frequent irrigation of the wound, eyeball, and *eul-de-sac* with a hot solution of mercuric bichloride (1 to 5,000), and prompt cauterization of the entire length of the wound by the galvano-cautery. This may be repeated daily, if the surgeon deem it necessary, as long as it seems to influence the course of the suppurative process. If the latter increases in extent, in spite of hot applications and the cautery, the latter does no good, and should be discontinued.

**SECONDARY OR AFTER-OPERATIONS.**—An important factor in the restoration of good visual acuity in cases of cataract extraction is the performance of what are called secondary or after operations. These are usually of two kinds: 1. Discussion or laceration of the posterior capsule. 2. Excision of a piece of thickened capsule or of a piece of membranous tissue, composed of thickened capsule and the products of inflammatory exudation. The gain in sight from a secondary operation is often very great.

1. *Discussion or laceration of the posterior capsule* is very often, perhaps in the majority of cases, necessary, but sometimes is dangerous. It is a delicate operation, requiring great nicety in manipulation, good judgment and perfect sight on the part of the surgeon, a sharp knife-needle, and a good light. It is sometimes necessary to employ the electric light in this delicate operation. The capsule may be lacerated by a simple stop-needle with a double cutting edge, but by far the best instrument is a slender, sharp, curved knife-needle, with a sharp point and a curved cutting edge, shaped something like a sickle. This is plunged through the cornea on either side, near the limbus, and the capsule is then lacerated by a single vertical or transverse stroke of the blade, or, if necessary, a crucial incision is made through the capsule. Under cocaine, this may be done by a good operator without the employment of fixation forceps, and this is an advantage, as all undue pressure upon the eyeball is thus avoided. The danger of the operation is proportionate to the density and duration of the pupillary capsular membrane. A capsule which is not thickened by the products of inflammation can be lacerated easily and without danger; but pseudo-membranous opacities resulting from iritis or iridocyclitis must be approached with caution. This leads to a brief consideration of the second variety of after-operation.

2. *Excision of a Piece of Thickened Capsule or of a Pseudo-membrane, and its Removal from the Field of the Pupil and the Interior of the Eye.*—This may be done by making an incision in the cornea near the limbus, and employing the narrow cataract knife or Beer's triangular knife to cut out a triangular piece of the opaque membrane, and its removal by Tyrrell's blunt hook, or by the introduction

of Wecker's knife-scissors through the corneal wound, and the excision and removal of a triangular piece of membrane. This is an extremely delicate, somewhat difficult, and dangerous operation, as the operation may set up a fresh attack of iritis or iridocyclitis, with possibly subsequent closure of the gap made by the knife, or somewhat rapid phthisis bulbi or atrophy of the globe.

Some variations in the general technique of the operation of extraction of cataract without iridectomy have been proposed by different surgeons. Panas always employs an alcoholic solution of the biniodide of mercury as an anti-septic fluid for the irrigation of the anterior chamber. Some writers have used a solution of mercuric bichloride (1 to 10,000) for the same purpose. Knapp found that when small quantities of the latter were employed there was no reaction, but that the injection into the anterior chamber of moderate quantities was followed by more or less transient opacity, appearing in patches on the posterior surface of the cornea. He has therefore abandoned its use in favor of Panas's fluid or a saturated solution of boric acid.

Most surgeons make the incision in the cornea in its upper section, and this is undoubtedly wise, as the chances of secondary prolapse of the iris or loss of vitreous are much diminished, and because the corneal scar, if there be any, is partially concealed by the normal position of the upper lid.

Another modification of the technique of the operation as described in this paper is in the manner of opening the capsule, which consists in lacerating the capsule with the point of the cataract knife while making the corneal incision. This is the revival of a method practiced many years ago by Wenzel and other German surgeons, the capsule being split horizontally in the upper portion of the pupillary space. It was thought that it simplified the operation of extraction, and it certainly demands one instrument the less. It is a difficult manœuvre to perform, and may cause the corneal wound to be irregular and even ragged, and thus protract the healing process. If the capsule were thick, the knife would probably fail to penetrate it, and there would be some danger of causing rupture of the zonule and dislocation of the lens. It would be a very difficult manœuvre if the pupil were narrow and the anterior chamber shallow, and the iris would probably be wounded in such a case. In the opinion of the writer, this method of opening the capsule should be abandoned.

*Comparison of the Two Methods of extracting Cataract, with and without Iridectomy.*—The advantages of simple extraction without iridectomy are as follows:

1. It preserves the natural appearance of the eye, a central, circular, and movable pupil.
2. The acuteness of vision, other things being equal, is greater than after the old operation.
3. Eccentric vision and orientation are much better than by the old operation.
4. Small particles of capsule are not so likely to be incarcerated in the wound, and thus act as foreign bodies and excite irritation.
5. The necessity of after-operations is probably not so great as after the old operation.

The disadvantages of simple extraction are as follows:

1. The technique of the operation is decidedly more difficult. The corneal section must be larger in order that the extrusion of the lens may be facilitated, as the presence of the iris acts as an obturator or obstacle to its passage. The corneal section must be performed rapidly so as to avoid the danger of the iris falling on the knife and being excised. The cleansing of the pupillary space and the posterior chamber is much more difficult than after the old operation.

2. Posterior synechiae, secondary prolapse, and incarceration of the iris are more frequent than after the old operation.

3. The operation is not applicable to all cases. This objection, however, applies to all operations.

*Indications for performing Iridectomy.*—The indications for performing an iridectomy in cases of cataract extraction may be formulated as follows:

1. When the vitreous is fluid or the zonula is ruptured, causing non-presentation of the lens and prolapse of the vitreous.

2. Insufficient length of the corneal section with prolapse of the iris.

3. Bruising of the iris during the operation.

4. A stiff, unyielding sphincter iridis.

5. Irreducible prolapse of the iris after the completion of the operation.

A few words in regard to the wisdom of the employment of general antiseptic rules.

1. The removal and exclusion, as far as is possible, of all bacteria by the employment of unirritating, aseptic fluids for all purposes of cleansing and irrigation, the best of these being boiled water or boiled boric-acid solution.

2. The employment, whenever necessary, of some really valuable antiseptic solution, such as chlorine-water, mercuric bichloride, or silver nitrate, the indications for their use being the appearance of the slightest muco-purulent secretion from the conjunctiva, or cloudiness of the lips of the wound.

3. The fearless employment of the galvano-cautery to the whole length of the corneal wound, if the lips of the wound show any signs of infiltration.

4. The performance of the operation with the most extreme neatness and accuracy, and with the minimum of traumatism.

5. Endeavor to obtain primary union of the wound by careful removal from between the lips of the wound of all foreign substances, and by perfect coaptation of the edges, and the maintenance of the most complete immobility of the organ possible until the wound is firmly closed.

Of the one hundred eyes on which this operation of the "simple extraction" of cataract was performed, useful vision was regained in all save one. This case was that of a patient whose eye had been rendered entirely blind by frequent attacks of irido-chorioiditis, and the lens was removed simply to allay the severe pain, and possibly to aid in quieting the inflammatory process. Not a single eye was lost from suppuration.

Fifty-two of the patients were males and forty-eight were females. The youngest patient was thirteen years old and the oldest was eighty-seven. The complications exist-

ing were as follows: Corneal macula or opacity in nine cases, broad arcus senilis in nine cases, old chorio-retinitis in six cases, chronic Bright's disease in five cases, chronic bronchitis and asthma in four cases, diabetes mellitus in two cases, dilated and immovable iris from a contused wound in two cases, conjunctivitis and marginal blepharitis in two cases, irido-chorioiditis and blindness in one case, posterior synechiaæ from old iritis in one case, pulmonary phthisis in one case, and hypertrophy and valvular disease of the heart in one case.

The reduction of the prolapsed iris after the extraction of the lens occurred spontaneously in fifty-six cases, and the iris was replaced by the spatula in forty-four cases. In eighty-three cases there was neither incarceration nor secondary prolapse of the iris. In fifty-three cases there were no posterior synechiaæ or adhesions of the iris to the lacerated capsule. In forty-seven cases these adhesions were present, and in ten of these they were due to plastic iritis.

The healing process was normal in eighty-six cases, though in some the process was very slow, especially in the closure of the external lips of the wound.

Iritis of the mild plastic type occurred in ten cases, and retraction of the iris toward the ciliary processes in three cases. There was loss of corneal epithelium in two cases,

and "striped" keratitis in one case. The wound became infiltrated in three cases, necessitating the use of the galvano-cautery. Chorioiditis and hyalitis occurred in two cases, and irido-chorioiditis with occlusion of the pupil also in two cases. Capsulitis followed in one case.

The accidents which occurred during the operation were as follows: 1, loss of vitreous in thirteen cases; 2, haemorrhage into the anterior chamber in two cases; 3, complete collapse of the cornea in two cases; 4, dislocation of the lens in three cases; 5, the lens was removed with the blunt hook in five cases.

The duration of the treatment varied from eleven days, the shortest period, to forty-seven days, the longest period.

Secondary or after operations were done in fifty-three cases—discission or laceration of the capsule in fifty cases, and excision of a piece of capsule or pseudo-membrane in three cases.

The resultant degree of vision in the one hundred cases was as follows: In six cases,  $\frac{2}{0}$ ; in thirteen cases,  $\frac{2}{0}$ ; in twenty-four cases,  $\frac{2}{0}$ ; in twenty-two cases,  $\frac{2}{0}$ ; in twenty-one cases,  $\frac{2}{0}$ ; in ten cases,  $\frac{2}{0}$ ; in two cases,  $\frac{2}{0}$ ; counting fingers at several feet in one case. No perception of light in one case, eye previously blind for many years.

No.	Sex.	Age.	Nature of cataract.	Complications.	Operation.	Reduction of iris.	Healing process.	Second'ry prolapse or incarceration of iris.	Posterior synechia.	Duration of treatment.	Primary vision.	Secondary operation.	Ultimate vision.

## ON GUNSHOT WOUNDS OF THE ABDOMEN, WITH ESPECIAL REFERENCE TO WOUNDS OF THE INTESTINES.

BY LEWIS A. STIMSON, M. D.,

SURGEON TO THE NEW YORK, CHAMBERS STREET, AND BELLEVUE HOSPITALS;  
PROFESSOR OF SURGERY IN THE UNIVERSITY OF THE CITY OF NEW YORK.

(Concluded from page 455.)

In the cases which recovered without operation the diagnosis of penetration was made by Dr. Sands, Dr. Markoe, and Dr. Bull, and the recorded symptoms seem fully to justify it. If to them should be added the cases treated at the Roosevelt Hospital, the records of which are also apparently complete—six cases without operation, two deaths; and three treated by laparotomy, all fatal—we have these totals:

Without operation, 23 cases, 15 deaths. Mortality, 65 per cent.

With operation, 16 cases, 13 deaths. Mortality, 81·2 per cent.

Most of the Roosevelt cases treated without operation were under the care of Dr. Sands.

It is not a brilliant showing for either method of treatment, and we must still look beyond percentages of results to details and principles—*observationes perpendenda non numeranda sunt*. Time will not permit me to give even an abstract of the histories of the cases; I can only refer to some of the more important features.

In the first place, in some of the cases the injuries were such that death, in the light of our present knowledge, must be deemed to have been inevitable under any method of treatment. Of the thirteen cases treated by laparotomy at the Chambers Street and New York Hospitals, four were of this character; of the seventeen not operated upon, three were of this character, and possibly two others in which death followed promptly and there was no autopsy.

Of the remaining eight that died without operation, two survived one day, and one each two, three, four, five, twenty-three, and twenty-eight days. Of the four cases that re-

covered, in one (Sands's) the wound was "in the left hypochondrium, five inches and a half from the median line"; in another (Markoe's) in the "right hypochondrium, on a line with the free border of the liver" (.32-caliber ball); in another (Bull's), two inches to the right of and half an inch above the umbilicus, "a probe passed four inches"; in another (Bull's) the ball (.22 caliber) entered the right eighth intercostal space one inch posterior to the mammary line; a probe passed three inches downward and forward; there was considerable shock and some tympanites at first.

The patient that survived twenty-eight days died of pyæmia; the bullet entered above the right sacro-iliac synchondrosis and lodged under the skin six inches above the right anterior superior spine of the ilium; at the autopsy no wound of the intestine was found, and no peritonitis; it can hardly be doubted that his chances of recovery would have been increased by enlargement and drainage of the parietal wounds. Possibly the bullet did not fully enter the peritoneal cavity, but opened it, if at all, by a slit along the side of its track in the lateral abdominal wall.

Of the remaining cases, it can only be said that the injuries were such as have been successfully treated in other instances by laparotomy.

Of the ten cases of death after operation, the histories of four (including the two reported in this paper) have been published. In four, as I have said, the injuries seem to have been necessarily fatal; in two of the remaining five there is perhaps some ground for thinking that the chances of recovery might have been better if the operation had not been undertaken; in one of them a small bullet (.22 caliber) had lodged in the liver without wounding any other organ; it was removed, and the patient died of peritonitis; in the other the bullet had traversed the abdomen from the left eleventh intercostal space, three inches from the spinal column, and lodged under the skin below the free border of the ribs in the left mammary line; it was removed and the cavity explored with the finger through the wound of exit without finding evidence of intestinal injury; three days later the wound of exit was enlarged to three inches and a half and the finger again introduced; this was followed by a gush of faeces that had escaped from a ragged opening in the transverse colon, and had collected in a space that was apparently shut off from the general cavity by recent adhesions; the incision was further enlarged by a transverse addition extending four inches to the left, the cavity cleaned, the edge of the wound in the colon stitched to that of the parietal incision, and the cavity lightly packed with gauze. The patient died six hours later. Possibly, if the interference had been limited to providing free escape for the faeces, the patient might have recovered with a stercoral fistula, as so many others have done; but his condition previous to the operation was very unpromising.

Of the remaining four fatal cases, in one the operation was done three hours and a half after the receipt of the injury; five wounds were found in the small intestine and were closed; the patient survived forty-three hours, and at the autopsy an additional wound was found in the transverse colon, from which faeces had escaped into the cavity. In another the operation was done four hours after injury,

and five wounds of the intestine were sutured; the patient survived twenty-four hours, and the autopsy showed general peritonitis. In the third (Dr. Wilkin's case, reported above) there was an interval of seven hours between the injury and the operation; there were six wounds of the intestine, and faecal extravasation had already taken place and excited peritonitis. Of the fourth the hospital record gives no details.

The thirteen cases may be fairly summarized, I think, as follows: Three recovered; the injuries were multiple (six, two, and four perforations of the intestine, and in two free haemorrhage from the wounded mesentery), and would probably have caused death if not repaired by the operation. In four the injuries were necessarily fatal within a short time, and at the most the operation hastened an inevitable death. In three in which the injuries were multiple (six, six, and five perforations), but limited to the intestine, it failed to save; and in these the probability of recovery without operation turns entirely upon the trustworthiness of the diagnosis in other cases which appear thus to have recovered. In one (wound of the liver alone by a small ball) the chance of recovery without operation was good; and in another the chance would probably have been better if the first exploration had been carried far enough to detect the wound of the bowels, and if the second had been limited to providing a free escape for the extravasated faeces. Of the nature of the injuries in the remaining case nothing is known.

Against the three recoveries is to be offset, then, one death, probably due to the operation, and the question remains whether or not the percentage of recovery under non-operative treatment justifies the belief that it would have furnished two recoveries from among the remaining twelve. My conviction is that at least seven of the twelve would certainly have died.

Corroborative evidence of a better prognosis under non-operative treatment has been recently supplied by Reclus,\* in the recovery of three patients treated with opium and compression of the abdomen, and by a military surgeon, Dr. Nimier,† who has reported the results in 63 cases of penetrating wounds received by French soldiers in Tonquin, with only 53 deaths, a mortality of 78 per cent. His analysis has been criticised by Chauvel, who maintains that in 4 of the 15 cases recovery is not proved, and that in 27 of the fatal cases the survival was sufficiently long to justify the opinion that they might have been saved by operation.

Turning now from these details to general considerations, the facts relating to the pathology of these injuries can be briefly stated. When a bullet penetrates the abdominal cavity it usually causes multiple lesions of the viscera, the principal exception being when it is a small one and first encounters the liver, in which case it may lodge within that organ. It has long been a subject of dispute whether or not a bullet can traverse the cavity without wounding the viscera, but the possibility must now be conceded on the strength of a very few cases in which an

autopsy has proved both the fact of penetration and the absence of injury to the viscera.\*

In several cases a ball has perforated the abdominal wall obliquely, cutting the parietal peritoneum for a greater or less distance between its orifices of entrance and exit, but not opening the intestine, and it seems probable that most of the cases of alleged complete perforation without visceral injury or of circuitous passage within the substance of the wall between two points separated by a considerable interval have been of this character, the apparent deflection being due to a change in the attitude of the patient, or to the comparatively slow motion of the ball, which permits the fasciae to be pushed aside instead of being perforated. Certain it is that, even if it is possible for a bullet to traverse the cavity without wounding the intestines encountered in its passage, the occurrence is far too rare to have any weight in prognosis or treatment, and we may safely assume that any ball that has fairly entered the abdominal cavity has also wounded some of the viscera; while, on the other hand, the more oblique the track of the ball, the greater the probability of the escape of the viscera from injury, even if the peritoneal cavity has been opened. It sometimes happens that the intestine, if not perforated, is so bruised by the bullet that the contused part sloughs and an opening is formed, if the patient survives for a sufficient length of time.

The number of openings made in the stomach and intestines by a single ball has varied from 1 to 28 in observed cases, the average lying between 2·63 (Colonel Otis) and 5 (Reclus, in experiments upon animals). The size of the openings, while corresponding in a measure with that of the bullet, is yet so seriously affected by other circumstances that no favorable prognostic influence can be safely drawn from the small size of the ball. Thus, in Koehler's case, a ·22-caliber ball made an opening in the stomach one centimetre and a half in diameter, the increase in size being probably due to retraction of the divided muscular fibers; in others a small ball, by entering obliquely or by cutting along the convexity of a loop of intestine, has made an opening an inch or more in length. Sometimes the openings are even smaller than the ball that made them, the tissues being pressed apart instead of being punched out by it in its passage. In all except the smaller openings there is a marked tendency to eversion of the mucosa, and this may so fill the opening as greatly to hinder the escape of the contents of the bowel into the peritoneal cavity, although, on the other hand, it carries with it the possibility of direct infection by its own soiled surface. The escape of faeces into the peritoneal cavity appears generally to be slow to occur, except when the opening is large and the bowel is distended; and the same is true, so far as known, of the intestinal gases, the presence of which in the cavity has been rarely recognized except in connection with faeces.

The direct observation has been made that some fresh small openings are impervious to gas even under considerable pressure. If an opening is made at a point uncovered by peritoneum, as on the posterior aspect of the duodenum or ascending or descending colon, the gas may escape into the connective tissue and be recognized under the skin.

The bullet may lodge in the abdominal parietes or in one of the solid viscera and become encysted there without having provoked any reaction, or it may come to rest within the stomach or intestines, to be subsequently passed with the faeces; or even in the bladder, and be voided with the urine through the urethra (case of Sands, "Roosevelt Hospital, New York, Reports," vol. xv, p. 32).

The mesentery or mesocolon is frequently perforated by the bullet, and dangerous haemorrhage may ensue.

Of the solid viscera, the liver is the one most frequently wounded; wounds inflicted by small bullets, even when they lodge within it and are left there, are capable of spontaneous cure, and, I think, are not to be deemed very dangerous; but large or lacerated ones add greatly to the gravity of the prognosis, because of the free bleeding and of the irritating effects of the bile upon the peritoneum. Associated wounds of the pancreas, spleen, and kidney occasionally occur, and are very dangerous. Wounds of various large vessels have been reported—the common iliac and renal arteries, the common iliac, portal, splenic, and renal veins.

The position of the wound on the surface of the abdominal wall bears little or no fixed relation to that of the visceral injuries, but if the direction taken by the bullet can be ascertained, some inferences, more or less important, may be drawn. A bullet entering at right angles to the surface in the epigastrium or the left hypochondrium probably wounds the stomach or the transverse colon. The sigmoid flexure may be encountered at any point to the left of and below the umbilicus. The liver will be wounded by a ball entering at any point within the hepatic area, and if the ball is small there is considerable probability that it may lodge in this organ without wounding any other. Bullets entering the back between the twelfth rib and the ilium are likely to wound the kidney or colon, but small bullets entering at this point, within three inches of the spinous processes, are likely to lodge in the wall. As the position of the loops of intestine appears not to change much within a few hours after the receipt of an injury, the search for lesions may be safely restricted to the neighborhood of the line marking the course of the ball.

So far as I know, there has been no demonstration of the details of the process by which spontaneous closure of a wound of the intestine without stercoral fistula takes place. That healing can take place, and without the aid of art, is shown by Dr. Lange's case ("Med. News," 1887, p. 630). He closed several perforations with sutures and left one untouched, because it was small and seemed to be impervious. The patient recovered. We do know, however, that the irritation of an injury excites an adhesive peritonitis in the neighborhood by which an opposing serous surface may be fixed against the opening so as to close it against the escape of faeces, and thus effectually to protect the general cavity

\* I can add to the cases already reported one recently received in the German Hospital, New York, in which laparotomy was done by Dr. W. Meyer. The ball entered below the apex of the heart, traversed the pleural and abdominal cavities, and lodged under the skin of the back at the left of the spine, grazing the lesser curvature of the stomach, but not opening it or wounding any other viscera.

while a permanent cicatrix is forming in the wound. And we know, also, that, even where faeces escape into the peritoneal cavity, the contamination may be prevented from becoming general by the agglutination of adjoining loops of intestine; and a channel may form between the wound in the intestine and that in the abdominal wall along which the extravasated faeces will pass to the exterior, and that this channel may be permanent or temporary.

The *symptoms* may be conveniently grouped in three classes—those common to all serious injuries, those indicative of special visceral injuries, and those later ones belonging to the pathological processes excited by the injuries.

Among the first are the symptoms of shock and haemorrhage, often so closely associated that they can not with certainty be distinguished from each other. Shock, often extreme shock, is present in a large proportion of cases, but it is also sometimes very slight or even entirely absent. It is at times unquestionably the direct result of the physical injury inflicted upon the organism, and varies directly with it; but, on the other hand, it is sometimes slight when the injury is great, and great when the injury is slight. I am convinced that it is often as much affected by extraneous conditions, notably the circumstances under which the wound has been inflicted, as it is by the extent and severity of the injuries; that it is as much emotional as physical. Thus, in injuries inflicted by accident it is usually much less than in those inflicted with homicidal intent, and it is noticeably augmented by the patient's fear that the injury is a mortal one. Some severely wounded patients have walked to the hospital almost unaided, and have shown no pallor, no quickening of the pulse, no lowering of the temperature, while in others the prostration has been extreme where the injury has been slight, or even where no injury at all has been received. A few weeks ago a man who had just been shot in a quarrel, and presented all the symptoms of marked shock, was brought to my hospital; on examination, the bullet was found to have stopped at his undershirt, not even to have broken the skin; in another, stabbed in the abdomen, the pallor, almost imperceptible pulse, and semi-unconsciousness pointed to extreme shock or overwhelming haemorrhage; yet the weapon had not even penetrated to the abdominal cavity, and, although it had divided the circumflex ilii artery, the bleeding had not been profuse.

External haemorrhage is habitually slight, that from the track of the bullet soon ceasing, unless the deep epigastric vessels are wounded, and in this latter case the blood flows into the cavity much more freely than to the outside. Free haemorrhage into the cavity is slow to manifest itself externally, unless the parietal wound is large. The constitutional signs of haemorrhage are the common ones, and, as a rule, appear as the prolongation and intensification of those of the pre-existing shock. Blood in the urine indicates a wound of the kidney or bladder; blood voided at stool, if present in any considerable amount, is evidence of a wound of the intestines, but the symptom has rarely been noted, and only as a late one; vomited blood may come from the wounded stomach or upper part of the intestine, but such vomiting may occur when there has been no perforation of either stomach or intestine.

Vomiting immediately after the accident is common, and is evidence only of the moral or physical shock; but its persistence or return indicates the beginning of a peritoneal reaction, either peritonitis or that form of septicaemia described by Verchère, and to which he gave the name *septicémie intestino péritonéale*—an affection distinguishable from peritonitis by its slight elevation of temperature and slight abdominal tenderness and meteorism, and later by the clouding of the intelligence and the facies of a profound intoxication.

The signs of perforation of the stomach or the intestine are of the utmost importance in the diagnosis and the prognosis, but, unfortunately, they are rare and inconstant. One has been already mentioned—blood in the stools or in the vomit. Another is the escape of the liquid or gaseous contents of the bowel, and their recognition at the parietal wound or within the abdominal cavity, if the exploration is carried so far. This escape into the cavity is infrequent in the early stages, and is practically limited to those cases in which the intestinal wound is large, and in which the bowel is distended at the time of the accident; and its recognition at the cutaneous wound is very rare, being restricted to those cases in which the parietes are thin and the opening in them large. Occasionally the intestinal gases escape into the abdominal cavity in sufficient amount for their presence to be shown by the resultant loss of the area of hepatic dullness; but the cases in which this evidence can be obtained are extremely infrequent. On the other hand, resonant distension of the abdomen is common after the lapse of a few hours, and has long been deemed evidence of a probable perforation. Although authors are not agreed upon its explanation, it certainly is commonly due, not to free gas in the abdominal cavity, but, on the contrary, to distension by gas of the intestinal loops, and the explanation of this rapidly occurring distension is yet to be found. In one of my cases it was noted that the intestines, which were contracted when the abdomen was opened in the course of the operation, promptly became largely distended during the search for and the suturing of the wounds—a change which I attributed to the irritation of the handling and exposure. If this explanation is correct, it suggests a similar cause for the distension which follows injury. In two or three reported cases in which the bowel had been wounded at a point where it was uncovered by peritoneum, the intestinal gas escaped into the connective tissue, and was recognized by emphysematous crackling under the skin in the loins. Erichsen noted this symptom about twenty years ago, but, so far as I know, it has since been observed in only one additional case. Attention has been called to the possible existence of similar emphysematous crackling about the parietal wound, produced by the infiltration of intestinal gas after its escape into the peritoneal cavity, but the symptom does not appear to have been clinically noted in more than a single case; and, in view of the fact that it may possibly be produced by the entrance of the external air through the cutaneous opening, its presence can not, I think, be accepted as proof of the existence of a wound of the intestine.

In a few cases a thin liquid has escaped freely through

the parietal wound, sometimes with a faecal odor or a slight recognizable admixture of feces, and sometimes with a color suggesting the admixture of bile; it appears to be mainly a peritoneal liquid, having its origin either in a pre-existing dropsy or in a peritonitis excited by the traumatism.

The course and the prognosis of the injury have been indicated in what has preceded; they may be briefly summarized as follows: In the great majority of cases the course is toward a fatal termination by shock, haemorrhage, peritonitis, and septicæmia. Death by shock and haemorrhage follows promptly—usually within a few hours. As between peritonitis and septicæmia, death by the latter seems much the more common, although there may be some limited peritonitis associated with it. It has long been recognized that intestinal lesions, with or without recognizable escape of the contents of the bowel into the peritoneal cavity, lead to death with a train of symptoms which are not those of a frank suppurative peritonitis, and have been described under various names, such as peritonism, latent peritonitis, or the asthenic form of acute peritonitis. It has been described in detail quite recently by Verchère,\* under the name of *intestino-peritoneal septicæmia*, and seems to deserve a place in our nosological schedule as a pathological entity with distinctive characteristics and requiring special treatment. Its origin is attributed to the infection of the peritoneal cavity by intestinal gases or microbes that have escaped either through an opening or by transudation through the unbroken intestinal wall, and by this is set up a fermentation which produces ptomaines, whose absorption is the immediate cause of the poisoning. Attempts to isolate these ptomaines have not yet been successful. At the autopsy there is found but a slight redness of the peritoneum, or possibly at one or more points a distinct inflammation, and sometimes a brown foetid effusion; the intestines are distended, and decomposition advances rapidly. The clinical features are a prompt and marked meteorism; painlessness of the abdomen, both spontaneous and on pressure, except for that which is due to the wound of the parietes when present; a normal, subnormal, or but slightly elevated temperature until shortly before death, when it rises rapidly; a small, rapid pulse; anorexia, thirst, nausea, and even vomiting of faecal-like matter; and a marked alteration of the expression. Its course may be marked during the first three or four days only by constipation, anorexia, and meteorism; then the severer symptoms appear, and death follows in from five to twelve days from the beginning. A well-marked case came under my observation at the New York Hospital in December, 1888—a stab-wound of the abdomen, which I treated by laparotomy and suture of four wounds of the intestine; the patient survived for a week, and until the last twenty-four hours I was hopeful of his recovery; at the autopsy the intestinal wounds were found completely healed, and there was slight peritonitis at only two points. I believe the best treatment is to be found in drainage of the peritoneal cavity, or possibly in free purgation if that can be effected.

In some of the patients that survive, a stereoral fistula is

established and persists for a longer or shorter time, perhaps indefinitely or until closed by operation; in others, after a day or two of anxiety, because of the threatening of peritonitis, the symptoms subside and the patient goes on to a complete recovery. Occasionally this progress toward recovery is abruptly interrupted by the intercurrence of an acute peritonitis, due apparently to the tardy escape of faeces through a wound of the bowel, or through the opening created by the sloughing of a contused portion, or to the leakage into the peritoneal cavity of pus that has formed in the track of the bullet through the abdominal wall.

It is not surprising, in view of the facts above stated concerning the mortality and the character of the lesions, that the opinion should be widely held that a resort to laparotomy is imperatively demanded in any case of penetrating gunshot wound of the abdomen. Not only has it been generally taught and believed that recovery under non-operative treatment is so rare that the fact of recovery is almost to be deemed a proof that the intestine has not been wounded, but also the very existence of a communication between the interior of the intestine and the peritoneal cavity creates a condition of probable infection which we have learned to recognize as a grave danger, and to the prevention of which all our efforts are now directed. While the statistics which I have collected indicate, to my mind, that the mortality under non-operative treatment has been considerably overestimated, yet few, I think, who were cognizant of the facts would be willing to take their chances under it if they believed that laparotomy held out even an equal prospect of success. Unfortunately, the chances of error in the statistics at present at command are so great that the question can not be thus determined, and it seems unlikely that the doubt cast upon the diagnosis in almost all cases of recovery without operation will ever be entirely removed; we must therefore still be guided by general considerations.

The first question in every case—one upon the affirmative answer to which all other questions turn—is whether or not the bullet has entered the peritoneal cavity. As has been above shown, the cases in which the bullet has entered the cavity without wounding the alimentary canal are so few that the possibility of its escape from injury in any given case of penetration may properly be disregarded. From this I would except only those cases in which a small bullet has entered at such a point and in such a direction that its course must lie for a considerable distance in the substance of the liver, and those in which the ball has traversed the abdominal wall very obliquely. In view of the fact that this opinion is almost universally held, it seems somewhat singular that so much attention should have been paid to the means of recognizing a wound of the intestines. It is sufficient as a first step to prove the fact of penetration; and this can be readily done by a measure which not only involves no additional risk, but may even be properly deemed salutary. I refer to a free incision along the track of the bullet. It has occasionally happened that the surgeon has not been able thus to follow the course of the ball, but I am convinced that in the great majority of cases it can be successfully done if the incision is deepened carefully and a close watch is kept for the slit-like opening which the bul-

\* Verchère, "Revue de chirurgie," 1888, p. 559.

let usually makes in a strong fascia. If the search fails, I see no great objection to a small incision near the wound, preferably in the median line, for the purpose either of recognizing the presence of blood in the abdominal cavity, or of introducing the finger to feel for the opening made by the bullet in the parietal peritoneum. I have employed this measure several times in stab-wounds, and never with an ill result. Such a free incision along the track of the bullet is not only valuable as a means of diagnosis, but is also an important aid in the proper treatment of the parietal wound, for it favors the removal of foreign bodies that may have lodged in the track, and, by securing efficient drainage, protects the peritoneal cavity from infection by pus that may form in the parietal wound.

I hold the opinion strongly that this exploration should be made in every case of doubtful penetration, even if no further operative treatment is to be undertaken, for it is only by having first clearly established the fact of penetration that the non-operative treatment can gain the credit of its successes and perhaps show its superiority.

As soon as the wound in the parietal peritoneum has been thus demonstrated and exposed, the escape through it of blood, intestinal gas, or faeces may at once prove the existence of an important internal haemorrhage or of a wound of the bowel; and if there should be no such escape, the introduction of a sponge upon a holder may furnish the evidence. In the absence of positive proof of the existence of a wound of the stomach or intestine, the surgeon who proposes to close such a wound, if present, has his choice of several procedures. He may seek for the wound by direct examination of the viscera, either through his first incision, after having enlarged it, or through another made in the median line for the purpose; or he may seek to demonstrate its existence and to be guided to its position by injecting gas into the bowel through the anus, as proposed by Senn.

This insufflation of hydrogen gas or of atmospheric air under moderate pressure has been studied experimentally, and has been actually employed in practice in some eight or ten reported cases. It is asserted that its action is prompt, efficient, and free from danger, and that by its aid, in at least one case, a perforation was found which would certainly have been otherwise overlooked. Two main objections at once suggest themselves: first, that the resultant distension of the bowel may prove a serious obstacle to the closing of the parietal incision; and, second, that the escaping gas may force out the liquid or gaseous contents of the intestine into the peritoneal cavity, and thus cause a dangerous infection. It is maintained that the first objection does not arise in practice, and that the gas or air is rapidly absorbed by the intestinal mucosa; but in a recent report of two cases by Dr. H. C. Dalton, of St. Louis ("Weekly Medical Review," Sept. 28, 1889), the distension is said to have constituted a very serious trouble, leading to the tearing out of the intestinal sutures in one case, and greatly interfering with respiration in the other, in which laparotomy was not done. Dr. Dalton further states that Dr. Senn told him he had himself experienced the same difficulty, but had been able to overcome it by elevating the hips (presumably

with a tube or cylindrical speculum in the anus) and making pressure upon the intestines with "a large funnel-shaped towel." In view of this evidence and of Dr. Senn's admission, it must be held, I think, that the objection is better founded than the statements heretofore published have led us to suppose.

As to the second objection—the danger of infection by the contents of the bowel forced out by the gas—it does not seem to be capable of direct proof or disproof; that is, if faeces were found in the peritoneal cavity after the insufflation, it could not be known that they had not previously escaped; and the possible causes of infection are so numerous that if it should ensue it could not be attributed with certainty to the insufflation. A comparison of the frequency of infection in a large number of cases in which the test had been employed with that in a similar number in which it had not been used might throw some light upon the question.\*

Another theoretical objection to the test—that the gas might fail to escape through an existing perforation, and that consequently its negative evidence was not trustworthy—has also been proved by experience to be well founded. In Dr. Dalton's second case the test gave no evidence of perforation, but the post-mortem disclosed two large openings in the stomach covered by semi-solid food; and in another case, above referred to, it was observed that intestinal gas could not be forced out by pressure through a visible perforation.

Finally, other lesions than perforation of the intestine are possible and equally in need of operative treatment, to which the test of insufflation gives no clew, notably haemorrhage, and here again its negative evidence would not justify abstention. In short, I believe the method, as a preliminary to operation and as a means of diagnosis, to be distinctly inferior to an exploratory incision in facility, efficiency, and security.

The penetration having been demonstrated and an operation determined upon, the surgeon has to choose between an incision in the median line and one passing through the bullet wound. The preference has usually been given to the former, but those who have employed the other do not appear to have found any unusual difficulty in completing the operation. In one case in which the incision was made along the outer border of the rectus, a second incision was carried transversely from the upper end of the first along the free border of the ribs, giving very free access to the abdominal cavity. The patient recovered; but so large an incision is to be deprecated. Two methods of searching for wounds of the small intestine have been employed; in one, the bowels are freely exposed or turned out through a relatively large incision; in the other, only a small portion is drawn out at a time through a small incision and immediately returned after examination. I think the former method is to be preferred for several reasons: the larger incision does not in itself add materially to the danger, less time is required, the exposure of the intestines, if they are properly

\* Insufflation has been done in nine reported cases with eight deaths. For brief details of seven cases, see a paper by Burrell in the "Boston Med. and Surg. Journal," July 25, 1889.

protected, is not much increased, and the search can be more readily extended to their fixed portions if desirable. Moreover, the manipulations needed for the repair of other injuries than those of the movable parts of the small intestine require a fairly large incision.

There seems to be no reason to doubt that the ball pursues a straight course through the abdominal cavity, and consequently it is not desirable to spend time or enlarge the incision in order to examine portions of the viscera or wall that lie well outside of that course; as the coils of the small intestine may shift their position, the examination should, however, cover the entire length of its movable portion in every case, and also the sigmoid flexure if the wound is on the left side, and the central part of the transverse colon if it is near the umbilicus.

Time will not permit discussion of the various methods of closing wounds of the intestine, and I shall therefore only add that experience has shown that a single row of Lambert sutures of fine silk is sufficient in all wounds of moderate size. If the wound is large and ragged, and especially if two or more such are near each other, it is better to excise the corresponding portion, and either reunite the divided ends or establish a lateral anastomosis. Since Dr. Senn reintroduced this method and so greatly improved it by his invention of absorbable bone plates, experience has shown its efficiency and ease and rapidity of execution. Possibly the independent and, perhaps, somewhat earlier suggestion of the French surgeons\* to use plates of cartilage or catgut rings to reunite the divided intestine end to end may prove equally practicable and safe, but at present lateral anastomosis is to be deemed preferable.

In consideration of the fact that death is so frequently caused by septicæmia, I think a drainage-tube should always be used, in order that the peritoneal effusion may escape as rapidly as possible, and that thus the chances of fatal absorption may be reduced.

It is greatly to be regretted that the anticipated improvement in results to be obtained by laparotomy under antiseptic protection should not yet have been realized, but, notwithstanding the unfavorable showing of the statistics at present, I believe that the operation will not only make a better record in the future by a closer selection of cases in which it shall be resorted to, but also that it will show an actual gain in the saving of life, as the result of an earlier and better performance. The tabulation of statistics, according to the length of the interval that has elapsed between the receipt of the injury and the performance of the operation, has unmistakably shown that the chances of success diminish almost to disappearance as this interval lengthens. The cause thereof seems very clear. The patient has to recover not only from his injury and his operation, but also usually from an already established peritonitis or septicæmia, and experience has clearly proved that the dangers of the laparotomy itself are vastly increased when it is undertaken in the presence of such a complication. The simple exposure of the congested and distended intestines creates a dangerous shock, and when to this are added the

greater difficulties and the necessary prolongation of the operation and the dangers arising from the already established infection, it is not surprising that the result should be so uniformly and so promptly fatal. These are the patients who die upon the table or shortly after their removal from it, and this is the side, I think, upon which we should first restrict the operation. Between the two parties—those who would operate in every case and those who would operate in none—stands a third: those who would operate only after symptoms indicative of dangerous processes have appeared; but I believe this course to be the worst of all, and that if it were generally followed it would lead to the entire abandonment of the operation. We know that an individual in fairly good general health can have his abdomen opened and explored without very great risk, and one who has just received an abdominal wound not necessarily fatal ought, at the moment and for a short time thereafter, to be able to bear such an exploration almost equally well. In such a case the risks of the operation, when performed under proper safeguards, are, I believe, less than those of the injury which the bullet has probably inflicted, and it is in such cases, notwithstanding the record, that I believe the operation is capable of furnishing valuable and superior results. If, on the other hand, several hours, perhaps a day, have passed and the patient is doing well, it may be better to accept the indication that the injury is not severe and is capable of spontaneous cure, and to abstain from interference. But when several hours have passed and the condition of the patient has changed greatly for the worse, and especially if the abdomen is largely distended and painful, then I believe we should abstain from an attempt to seek and close the perforations. It is urged against such abstention that the case is hopeless without it; it may be so, but I believe it is still more certainly hopeless with it, and to operate under such circumstances seems to me needlessly to compromise our art and to create a harmful prejudice against a resort to the operation under more favorable conditions. Must we then stand idly by and let the patient make his struggle for life unaided? Possibly, if the limitations of our art require it. But between non-interference and the full operation there may lie a middle course, by which the desperate chances of these unfortunates may be somewhat bettered. We have seen that a few such have survived without operation, the faeces and the peritoneal pus escaping through the parietal wound, and perhaps leading to the establishment of a stercoral fistula. Is it not possible that this way of escape may be made easier, that an enlargement of the bullet-wound and drainage of the peritoneal cavity may save some who could not survive a more formal operation? Slight as the chance may be, it seems to me to be the only one we can offer to such patients. In conclusion, I offer the following:

*Summary of the Points to which I have sought especially to call Attention.*—The (incomplete) hospital statistics of New York city show, for an average period of ten or twelve years previous to 1885, 17 cases of recovery under non-operative treatment after gunshot wound of the abdomen supposed to be perforating. The integral statistics of three hospitals—the New York, Chambers Street, and Roosevelt

\* Michaux, "Gaz. des hôpitaux," Aug. 13, 1887, p. 805.

—contain 23 cases, with 15 deaths—a mortality of 65 per cent.

The integral statistics of New York city since 1884 give 29 cases of laparotomy for gunshot wound of the abdomen, with 25 deaths—a mortality of 86·2 per cent.; and the statistics of the three hospitals above mentioned give 16 cases, with 13 deaths—a mortality of 81·2 per cent.

In view of the apparently greater mortality after operation, it is highly desirable that any doubt as to the correctness of the diagnosis in cases recovering without operation should in the future be avoided if possible, and that with this object the track of the bullet should be traced to the abdominal cavity.

Preliminary incision along the track of the bullet, or, in case of need, in the median line, is the best and safest means at our disposal to recognize the presence or absence of wounds of the viscera.

The relations between the number and severity of the visceral lesions and the size of the bullet, or the early symptoms, are not, in the majority of cases, sufficiently constant to guide us in the choice between operating and not operating.

An improvement in the results of operative treatment may be expected if the operations are undertaken earlier (before the intercurrence of peritonitis or septicæmia), and if their duration is shortened by rapidity of execution and by restriction of the search for lesions to the readily accessible portions of the intestine and to the probable course of the ball. While some may die through the overlooking of a perforation, fewer, I think, will be killed by the operation.

In cases in which considerable time has elapsed since the receipt of the injury and in which the symptoms of septicæmia or peritonitis are present, with marked distension of the abdomen, an attempt to discover and close the perforations of the intestine will almost certainly be fatal, and operative interference should be restricted to the establishment of free drainage of the abdominal cavity through the wound.

In cases seen at an earlier period and in which these grave symptoms have not been developed, the probable chances of success are sufficient to justify an operation to repair the injuries.

In the present state of our knowledge it can not be said that either interference or non-interference should be the rule of practice, and the surgeon may be guided by his own convictions and feelings, whether they lead him to seek to do as much good or only as little harm as possible.

**NOTE.**—Since the foregoing paper was read I have learned that I failed to recognize as a New York case a successful one reported by Dr. Manley in the "Medical News" for September 24, 1887. The addition raises the list to 30 cases with 25 deaths, a mortality of 83·33 per cent. Three days after the paper was read, on October 20th, I operated in another case which has progressed to the present time, the tenth day, without an unfavorable incident, so that the patient may fairly be deemed out of danger. He is a man, thirty-two years old, who was shot by a policeman with a revolver of .38 caliber, the ball entering four inches and a quarter below the umbilicus and one inch and a half to the right of the median line. The operation was done five hours after the receipt of the injury. There was some escape of faeces into

the abdominal cavity, with beginning peritonitis. Two large ragged openings, closely adjoining each other, in the lower part of the ileum were closed with a single row of Lambert sutures. It is interesting to note that the wounds were separated by a bridge of tissue only an eighth of an inch wide, and evidently had been made by the ball passing along the side of the intestine in the furrow of a sharp bend, on each side of which it cut out a piece without itself entering the lumen of the bowel. I purpose to report the case in full in due time. Accepting it as successful raises the New York city list to 31 cases with 25 deaths, a mortality of 80·64 per cent.

34 EAST THIRTY-THIRD STREET, October 29, 1889.

## GASTROSTOMY

### FOR NON-MALIGNANT ORGANIC STRICTURE OF THE ESOPHAGUS.

By J. C. CLARK, M. D.,  
OLEAN, N. Y.

STRICTURE of the œsophagus due to cicatricial contraction caused by swallowing of caustic alkali or acid is so rare that it is seldom a case is seen in the general hospitals of our largest cities, and when the patients do present themselves it is at a time that little can be done to relieve them.

A young woman recently entered the Olean Hospital suffering from the above-described condition, whose future, unless relieved, was slow starvation in the charitable institution of the county. She depended entirely upon her work for a living, and, being unable to take nourishment enough to keep up her strength, had finally to stop and depend upon friends to support her. After the operation of gastrostomy was decided upon the important question arose: how much of an invalid would she be if the operation proved successful?

My object in this article is, first, to report the case; second, to give more details of after-treatment; and finally, to answer the above-given question. Two important elements were favorable for recovery—first, the age of patient, and the fact that she was not in an extremely enfeebled and emaciated condition. Dr. Lewis A. Stimson, of New York, says ("Reference Hand-book of the Medical Sciences") : "In several of the successful cases, it is noted that the obstruction was not complete, and that the patient was nourished by the mouth up to the time of the operation. . . . If the operation is done at all, it should be done as early as is practicable."

**History.**—Nellie P., aged twenty, single, native of the United States, servant girl, admitted to Olean Hospital July 22, 1889. The patient gave the following history: In September, 1888, she took two swallows of strong washing fluid, producing severe inflammation of the mouth, pharynx, œsophagus, and stomach. Since that time for ten months she has not been able to swallow any solid food whatever, and when taking fluids can feel them stop and then trickle into the stomach. She has attacks daily, and sometimes several times during the day, of great difficulty in breathing, and is only relieved by vomiting whatever has last been taken and a large quantity ofropy saliva. She sustains life with milk, beef-tea, and whisky, taking half a pint of whisky daily. Does not drink her food, but sips it slowly from a teaspoon. Has lost strength rapidly during the past three months, and is considerably emaciated.

**Examination.**—Œsophageal bougies, of large, medium, and small caliber, being passed, all meet obstruction at eleven inches

and a half from the incisor teeth. They cause some irritation, but no blood is vomited. The heart and blood-vessels being found normal, a diagnosis of non-malignant organic stricture of the esophagus, four to five inches above the cardiac orifice of the stomach, with dilatation above the stricture, was made.

One week after admission the patient had several attacks of spasm of the glottis, and for twelve hours nothing would pass the stricture. From morning till night patient was to be seen with a tumbler of milk and a teaspoon continually feeding to satisfy her hunger.

*August 5th.*—Patient has lost ground during the last few days; has attacks of vomiting and spasm of the glottis every day. Rectal alimentation commenced to-day.

*10th.*—A moderate attack of amygdalitis during the week. All right again. Rectal feeding working perfectly; absorbs a pint and a half of peptonized milk and an ounce of Cibyl's beef-juice daily.

*14th, Operation.*—Antiseptic precautions used. The usual incision was made through the skin and muscles. When the peritonæum was opened, the greater curvature presented itself in the wound. The stomach was drawn downward and from the left and two long silk ligatures one inch apart, one above the other, were passed through to the mucous coat and used during the operation and for a month after as a guide to the wall of the stomach. Horse-hair drainage was used between the skin and peritonæum upon each side.

Iron-dyed silk was used to unite the stomach to the peritoneal surfaces. The upper and lower angles of the wound were closed loosely with silk, and the wound was dressed antiseptically. The operation was commenced with cocaine, but its use was found not practicable. Ether not acting well, chloroform was given.

*15th.*—No vomiting after operation. At 7 A. M., temperature  $100.5^{\circ}$  F., pulse 90. Tinct. opii deod., gtt. xx, every four hours by the rectum.

*16th.*—At 7 A. M., temperature normal, pulse 88. Rectal feeding working well; a quart of milk and six drachms of Cibyl's beef-juice daily. At 4 P. M., temperature  $101^{\circ}$  F., pulse 98. Complains of pain in the wound. Dressings removed. No pus. The opening into peritoneal cavity was found closed by adhesions between the opposing surfaces. The sutures between the skin and the peritonæum were partially removed because of great tension, giving immediate relief to the patient.

Having secured deep union at the upper and lower angles of the wound, and there being no reason for opening the stomach for some days, I determined to allow the skin and superficial part of the wound at these points to heal by granulation, so that the contraction of the scar would give a snug fit and grasp the proposed tube tightly. The sutures were removed at the angles, and the skin was allowed to separate.

At 9 P. M., temperature normal, pulse 88.

*18th.*—Temperature continues normal. The patient was given two cups of thin chicken-broth to-day by the mouth, with no unfavorable result.

Opium stopped.

*25th.*—The patient continues to improve. Nourishment pushed; takes a quart of milk by the mouth, and a quart by the rectum; swallows better than she did before the operation.

To-day, the eleventh after the operation, an incision was made into the stomach, between two silk ligatures, large enough to allow a glass tube of the size of a lead-pencil to be introduced, producing no symptoms.

*September 2d.*—The permanent tube, furnished by Messrs. Stohmann, Pfarre, & Co., was put into the stomach to-day, and the patient commenced eating solid food.

The tube is of silver, with a caliber of a third of an inch,

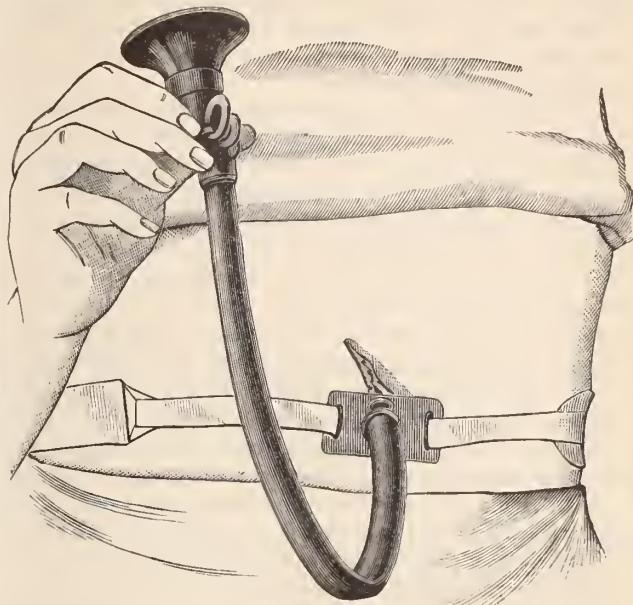

FIG. 1.

two inches long, with a flange half an inch from the outer end; straight except at the inner end, where it makes a slight curve. It was introduced by removing the glass tube and dilating the

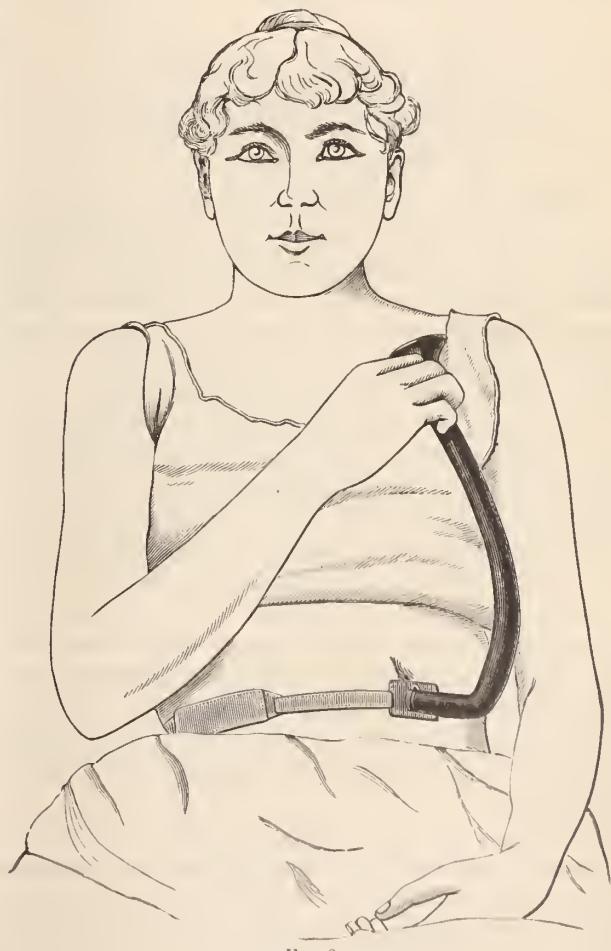

FIG. 2.

small opening into the stomach by means of a Hanks's uterine dilator. A soft, flexible rubber tube, with a caliber of half an inch, was connected to the silver tube, a hard-rubber mouth-piece being fitted to the outer end. The silver tube was first

kept in place by an ordinary piece of tape; but the patient would eat so heartily that the tape became uncomfortably tight after meals, and required to be let out.

On September 18th she went to bed, neglecting to tighten the tape, and awoke in the morning to find the tube entirely out of the stomach. It was necessary to use the dilator again before the tube could be reintroduced, and this complication was overcome by using elastic webbing with the tape, which allows of free distension of the stomach.

An attempt was made to pass a bougie from the stomach upward, but was not successful.

There is and has been no leakage at the side of the tube, and, after a few days' practice, there was no trouble from air entering the stomach while eating, or from swallowing solid particles of food while chewing them. There is no trouble whatever in the food passing into the stomach after mastication, there being no valves or complicated apparatus to get out of order. This method of feeding is simplicity itself. After eating, the rubber tube is doubled up, tied, and put into a pocket provided for that purpose upon the inside of the dress.

At night the patient removes the rubber tube, corking up the silver tube, and connects them again in the morning without assistance.

*30th.*—The patient left the hospital to-day, having gained twenty-five pounds in weight, and, instead of terminating a miserable existence in some charitable institution, returns to her usual duties in perfect health.

## THE BLUNT CURETTE IN UTERINE HÆMORRHAGE.

BY THOMAS W. KAY, M. D.,

SCRANTON, PA.,

EX-SURGEON TO THE JOHANNITER HOSPITAL AT BEYROUT, SYRIA.

In a paper read at Newport, June 27th, Dr. Georges Apostoli, of Paris, in lauding the use of electricity in uterine affections, remarked that the curette had fallen into desuetude in France, the place of its birth, and he intimated that the doctor of to-day who still stuck to its use had not kept pace with the advance of gynaecological science.

That electricity is an important agent in the treatment of uterine troubles no one denies, and we are chiefly indebted to the care, industry, and perseverance of Dr. Apostoli for our present knowledge of its therapeutic value; but it is not applicable in all cases where the curette can be used, and in some where its application is suitable it gives no better and not as rapid results. The use of the curette is best limited to those troubles arising from disease of the endometrium, while that of electricity should be limited to those affections arising from disease of the parenchyma or the appendages of the uterus. Each of these fields overlaps the other to some extent, and here either agent can be used indifferently.

The bleeding caused by fibroids of the uterus can be arrested by the curette, but we do not get the diminution in the size of the fibroid that is obtained by the use of electricity. Metrorrhagia, due to degeneration of the endometrium, may be cured by electricity, but it takes more time and the results are not more satisfactory than those given by the curette. But the curette is as inapplicable in salpingo-ovaritis as is electricity in uterine polypi. The field of each is pretty sharply defined, and the closer each

agent is confined to its own sphere, the better will be the results obtained.

The present tendency in America seems to be to ignore the blunt curette in all cases where the sharp curette can be used. This is bad practice, for denuding the uterins of all of its mucous membrane is no small matter, and with the sharp curette this can be done not only where the membrane is diseased, but also where it is healthy. With the blunt curette, however, it is only the diseased portion of the membrane that can be removed, while the uterine glands are emptied of their contents. Where we wish to remove a small piece of the endometrium for diagnostic purposes we find nothing to take the place of the sharp spoon; and in intra-uterine growths of long standing, where the bases are broad and firm, the sharp curette will be found to be indispensable. When, however, we have to deal with growths of recent formation, as in the case of retained placenta or placental polypi, or where we have a degenerated condition of the mucous membrane, all that is necessary can be removed by the blunt curette, after which a strong styptic should be applied to arrest the bleeding and produce a healthy action on the endometrium.

Practically speaking, all diseases of the endometrium in which the blunt curette is applicable have the one common manifestation of hæmorrhage. This may be constant or periodical, profuse or moderate, and from various causes, which can be best illustrated by giving the histories of a few typical cases. It will be best, however, to say first a few words about the use of antiseptics and the dilatation of the uterus. Bearing in mind the direct communication between the uterine and abdominal cavities, and how richly supplied the uterus is with absorbent vessels, the greatest care should be used in all operations on that organ to prevent infection. The vagina should be thoroughly cleansed before all operations on the endometrium, and both uterus and vagina after. This can be done by solutions of permanganate of potassium, carbolic acid, corrosive sublimate, or creolin. Of these, creolin is probably the best, though I have got excellent results from the solution of the permanganate, as I have also done from simple hot water. For all operations on the uterine cavity a dilatation of the cervical canal is necessary. Where intra-uterine growths exist, the canal, as a rule, will be found more or less patulous, and here rapid dilatation will be found most suitable. Any of the many ingenious uterine dilators can be used for this, but I find a set of steel urethral sounds among the best. Drawing the cervix well down with a volsella, these are passed singly from the smallest to the largest, when a return to the moderate-sized ones is made, and two or more passed together till sufficient room is obtained. If the cervical canal is normal in size, or nearly so, as is generally found in degeneration of the endometrium, rapid dilatation causes too much bruising and injury to the cervix; so here it is better to dilate gradually by means of tents—laminaria, sponge, slippery elm, or tupelo. Of these, the tupelo is much the best, though requiring more time than the sponge.

Anæsthetics can be used or not as is deemed best by the operator, but in most cases, where the patient is of a

nervous temperament, their administration will be found to ward off complications. In all cases absolute rest should be enjoined for some days after the operation, for it not only prevents accidents, but it favors the return of the uterus to its normal state.

Some of the following cases were operated upon quite a while ago, but they are selected as types, showing where the blunt curette can be used:

**CASE I. Endometritis with Subinvolution.**—In November, 1879, I was called to see Mrs. M. J., twenty-six years of age, who was a resident of Baltimore. Eight months previous to that time she had had her first child, since which time she had suffered more or less from haemorrhage. During the last month this had become so profuse that she was compelled to take her bed, and was then too feeble to be around. Examination revealed a retroverted uterus, much enlarged and tender. Sounding was exceedingly painful, and gave a depth of four inches. After the parts were thoroughly cleansed, a small sponge tent was inserted and allowed to remain for ten hours. On the removal of the first, a second tent was introduced and allowed to remain till the following morning, when it was removed, and the uterine cavity carefully examined with the finger, but nothing abnormal could be found except a softened and thickened condition of the endometrium. This was thoroughly curedtted with a blunt curette, after which liq. ferri subsulph. was applied to the whole cavity. From this time on the haemorrhage ceased, and in one month sounding gave a depth of three inches and a quarter. ■■■

This case illustrates well a common class, where the trouble dates back to childbirth, and is probably due to improper care and a too early return to household duties.

**CASE II. Fleshy Mole.**—Mrs. J. B., of Columbia, Pa., sent for me to see her in September, 1880. She was twenty-nine years of age, the mother of three children, and supposed herself again pregnant. The previous April her menses failed to make their appearance, but during July and August there was a slight show of blood. When called, she seemed to be suffering from labor-pains with considerable bleeding. On examination, the uterus was found as large as the fist; its cervix was rigid, but its canal was large enough to admit the tip of the finger with difficulty. A firm, fibrous mass could be felt presenting at the internal os, and as this in no way resembled the normal product of conception, the cervix was drawn down with a volsella while the uterus was dilated with the finger. The mass was nearly as large as a hen's egg and pear-shaped, being attached by its base to the posterior wall of the uterus near its fundus. This was removed with some difficulty by the blunt curette and a solution of permanganate of potassium used to irrigate the cavity. Recovery was rapid and complete, the woman having since borne children. Though the mass presented no placental structure, it was undoubtedly the product of a blighted ovum and had probably become attached to an inflamed endometrium, thus escaping expulsion.

**CASE III. Retained Placenta and Membranes.**—In June, 1881, I was called to see Mrs. F. H., of Columbia, Pa., a multipara, who had three days before been delivered by a midwife. The cord and only part of the membranes had come away, and, as the discharge had become very offensive and there was considerable fever, I had been sent for. Before examining, the vagina was irrigated with hot water, when the uterus was slowly dilated with the fingers and the placenta found firmly attached posteriorly and above. About half of this was removed with the hand, but some portions were so firmly attached

that the blunt curette had to be used. Finally, all was removed and the cavity presented a uniformly smooth surface, after which it was irrigated with a hot solution of potass. permang. Recovery was uninterrupted, and in ten days the woman was attending to her regular duties. Prompt interference here probably saved the life of the mother, as there were marked symptoms of blood poisoning when I was called.

**CASE IV. Degeneration of the Endometrium near the Menopause.**—In December of 1881 I was called in, by her attending physician, to see Mrs. M. A., of Columbia, Pa., an invalid mother of several children. She was forty-seven years of age, and had suffered irregularly for eighteen months from metrorrhagia. During the last month the haemorrhage had become very profuse, and, as it did not yield to internal remedies, operative interference was deemed expedient. The uterus was found to be slightly enlarged, tender to the touch, and very flaccid, but normal in all other respects. A tupelo tent was introduced, and the following day a larger one was substituted, which in twenty-four hours gave sufficient room for the finger. On examination, the endometrium was found to be thickened and soft, so that shreds of tissue could be easily removed with the finger, but no growth of any kind could be found. A teaspoonful or more of degenerated tissue was removed by the blunt curette, after which Monsel's solution was applied to the cavity. For some days there was a slight discharge of bloody water, but this ceased in a short time, and after a month the woman, though still feeble, suffered no more from haemorrhage and was much improved in health.

**CASE V. Incomplete Abortion at about the Third Month.**—Hannah, a multipara, thirty-two years of age, presented herself at the Johanniter Hospital, in Beyrouth, Syria, in November, 1887, to be treated for corneal ulceration and partial staphyloma. A solution of atropine was instilled into the eye and subsequently the portion of prolapsed iris removed. Three days later she was taken with pains and haemorrhage from the womb, when she informed me that she thought herself about three months pregnant. The womb was found as large as the fist, with the cervix sufficiently dilated to admit the finger to the internal os. This was found partly dilated, with the uterine contents presenting. As haemorrhage was profuse, the pains strong, and all hopes of preventing the catastrophe passed, the cervix was drawn down with a volsella, the canal rapidly dilated with the fingers, and the uterus emptied of its contents with a blunt curette. As the uterus was now well contracted, the vagina only was washed out with hot water and rest enjoined. Recovery was rapid and without complications. This is undoubtedly the best treatment to adopt in all cases of incomplete abortion, though strenuously opposed by some good authorities.

**CASE VI. Placental Polypi of Several Months' Standing.**—During March, 1889, I was called in consultation by a physician who was attending Mrs. C. P., of Baltimore. She was a multipara, some thirty-eight years of age, and had miscarried several months previous to the consultation, since which time she had suffered from bleeding, that became profuse on the least exertion, but almost ceased, to give place to leucorrhœa, when she was quiet. The uterus was several times its natural size, and the cervix was sufficiently dilated to admit the finger as far as the internal os. Rapid dilatation was undertaken and accomplished in a short time, with urethral sounds, and three polypi of moderate size were found attached to the posterior wall near the fundus. These were removed with ease by the blunt curette, the haemorrhage arrested with Monsel's solution, and the vagina irrigated with warm water. Several hours after the operation there was a severe chill with a sharp rise of temperature, but by the next morning all bad symptoms had passed and she made a rapid and complete recovery.

THE  
NEW YORK MEDICAL JOURNAL,  
*A Weekly Review of Medicine.*

Published by  
D. APPLETON & CO.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, NOVEMBER 2, 1889.

**"MARASmus" AND OTHER VAGUE CAUSES OF DEATH.**

AT the last day's session of the American Public Health Association meeting, at Brooklyn, Dr. Ashmun, of Cleveland, inveighed against the practice of some physicians who employ the term "marasmus" to cover a great variety of causes of death among infants. Statistics are of little value where even a few practitioners, in any given community, consent to this vague form of certification. "Marasmus" under those circumstances has no pathological relevance, and means little more than that the child ceased to breathe. The reports of institutions are, in too many cases, robbed of their utility to the student of the causes of infantile mortality by the evasion and omission of the true causes of death. The root of this evil may lie either in indifference, in carelessness, or in a desire to conceal; but, whatever the motive, the result is one and the same so far as concerns every scientific purpose and pursuit. It was alleged at the meeting above referred to that ignorance was another occasion for this and some other mischievous forms of certification. One speaker went so far as to say that there were professors in our medical colleges whose teachings tended to promote vague pathological ideas and a slip-shod use of terms. If the teacher himself has not advanced beyond the "marasmus" period in pathology, it is unreasonable to expect precision and definiteness of expression on the part of those who are taught by him. And so the evil maintains itself for years, and is spread. "The profession itself needs enlightenment" was the sentiment of more than one of the speakers on the occasion referred to; a keener intelligence on the part of the profession in these matters is a prerequisite to the profitable study of "the great American Plague"—namely, the loss of children under five years—by associations or by individuals, on the statistics of the Federal census or the annual reports of asylums or maternities.

In conformity to this sentiment, the newly appointed special committee on infant mortality in the Public Health Association was proposed to be one whose work should extend over a number of years and might not be reported upon under three years, and even then might take the form of a report of progress. One result may be expected from the initial work of the committee; that it will early show to the profession the indispensable need which exists, in regard to the profound study of this subject, that the certifying members of the profession shall truly, clearly, and fully designate the causes of death in infants as well as in adults. The Health Officer of the port of New York spoke in this discussion of the duty devolving on officers of registry, in boards of health, of refusing to accept certificates of physicians who habitually resorted to such vague ex-

pressions as marasmus, infantile asthenia, atrophy, debility, or cardiae syncope, which meant little more, to writer or to reader, than that death had taken place. This view puts upon the registry departments of our boards of health a responsibility which is altogether new to some of them, the opinion of some registrars seeming to limit them to a slavish adoption of whatever cause may be specified to them by the practitioners. We call to mind a singular instance of this where an official permitted "cholera infantum" to stand in his tables through the whole of the winter quarter, because one or more physicians had chosen to adopt that expression as synonymous with entero-colitis or infantile diarrhoea. The "throwing out" of certificates of death is not the pleasantest duty of the health officer, and, if performed without tact and judgment, may become exceedingly unpleasant, but it is nevertheless a duty that should not be shirked or overlooked.

**RAILWAY SHOCK.**

THE subject of railway shock has been brought very prominently before the profession and the public of late. It must be admitted that at first thought some of the results which have been rightly ascribed to it seem to be hardly traceable to this source. In an address before the Lehigh Valley Medical Association Dr. Dercum ("Therapeutic Gazette") treats of the subject in a practical way. The causation of railway shock, he says, differs from that of other forms of shock in that it is more composite. It presents, therefore, special features which distinguish it from surgical shock, common traumatic shock, and purely emotional shock. If shock may be classified under three heads—that which acts upon the corporeal organization, that which affects the psychical functions, and that which involves both of the preceding—railway shock may embrace any of these three forms. In railway accidents the trunk and head are specially subject to injury; the body as a whole may be thrown violently against surrounding objects, and the brain and spinal cord may be so shaken or bruised that degenerative processes, actual organic changes, may be set up in the nervous centers of these organs. But, even apart from serious physical injury, the purely psychic effects of a railway accident may be of the most serious nature. The incidents connected with such a disaster may, taken together, form one of the most terrible pictures that the mind can conceive of. The vastness of the destructive forces, the magnitude of the results, the imminent danger to the lives of numbers of human beings, and the hopelessness of escape from the danger give rise to emotions quite sufficient in themselves to produce shock or even death. Whether there is a temporary loss of consciousness or not, the sudden, excessive, exhausting expenditure of nervous energy in the excitement, the fright, the horror of the moment must certainly result in a general weakness more or less marked and more or less enduring.

Two cases in point are related: A powerful man is exposed in a very severe and destructive collision, but escapes with only a few bruises on the limbs and a fracture of the nasal

bones, not having been stunned. Recovering from the more immediate nervous excitement, which lasted some weeks, he remains for years afterward, perhaps for the rest of his life, haggard, depressed in mind, with occasional palpitations, with loss of sleep, bad dreams, and loss of energy and of self-control. In the second case, personally studied by Dr. Dercum, a lady of nervous temperament, but always in good health, witnessed at close quarters a shocking mutilation of her little daughter by a railroad-tie. She was standing on the platform, and the train was moving silently past her. The mother was not injured, but remained hysterical for three weeks, and then miscarried. A year afterward she was neurasthenic, depressed, melancholic, of sallow color, weak, irritable, and unable to attend to household duties. Her pulse was weak and rapid, her knee-reflexes were sluggish, her back was painful with tenderness over the lumbar region, and her grip was tremulous. Why is it that in railway accidents passengers who are dreadfully mutilated show transient or slight symptoms of shock, while others who sustain hardly any physical injury are profoundly shocked and may be rendered invalids for life? Perhaps the very depth and intensity of the bodily injury may blunt the nervous centers or preoccupy the mind, the bodily injury being generally received before the mind can fully realize what is going on.

A short space is devoted to the consideration of the so-called "erethistic" form of shock, which is to be regarded as either a preliminary or an incomplete stage of simple shock, or as a stage of imperfect reaction from simple shock. In this there is prostration with excitement. The patient tosses about, complains loudly, says he can not breathe, acts as though suffering intense agony, and has a sense of impending death. He pays no attention to his surroundings, being absorbed by his own agony. He has muscular tremor, rapid short breathing, with occasional deep inspirations, a rapid, soft pulse, a hot and dry skin, and a flushed face.

The methods of treatment mentioned by Dr. Dercum are well known to the profession. In simple shock it is better to do too little than too much. In the severer forms, dry heat to the body, lowering of the head, and the injection or ingestion of whisky or some preparation of ammonia may be required. Injections of ether are recommended, but in abdominal operations, where he has seen them applied, they have seemed to act as local irritants, the stimulant action on the heart being not through absorption of ether into the blood, but by a reflex action. In profound shock, which resists other measures, strychnine may be injected, or digitalis or atropine may be used. In the "erethistic" form, chloral, the bromides, and opium are to be avoided or used with great caution. Genuine msk is the best remedy, say fifteen grains by the rectum; as a substitute for it, valerian or fluid extract of hops may be given. In chronic cases rest is required, prolonged far beyond the apparent needs of the patient's condition. For neurasthenia Weir Mitchell's method is the best. A sharp lookout must be kept for symptoms of chronic inflammation of the spinal cord and for concealed disease of the vertebral column.

## MINOR PARAGRAPHS.

### REFLEX DISTURBANCES FROM A WISDOM TOOTH.

How small an irritation may give rise to the most painful and most widely distributed of reflex neuroses is well illustrated by a case cited in the "Deutsche Medizinal-Zeitung" from the practice of a dentist, Dr. Herrmann, of Halle. A man of forty-seven had suffered for twenty years with an intense pain which began in the frontal region, but afterward involved the whole right side of the face and neck, and ultimately resulted in periodical mental excitement accompanied by delusions. A score of doctors and the most varied remedial measures had been ineffectual in affording him relief. Finally he sought admission to an asylum, where the physicians hit upon a misplaced wisdom tooth as the probable cause of the morbid manifestations, and called in a dentist to extract it. In addition to malposition, its roots had large exostoses, as was seen upon its successful removal under chloroform narcosis. The wound healed under antiseptic precautions in two weeks, and the reflex disturbances, neurotic and psychic, gradually disappeared altogether. They have not returned in the year now elapsed since the dental operation. This cure of a psychosis by extracting a tooth is in curious contrast with the not infrequent cases of insanity set down in many of our asylum reports as due to the extraction of teeth.

### "NELLY BLY" AND HER DOCTORS.

A SPRIGHTLY contributor to the "World" doubtless amused that paper's readers last Sunday by her account of visits made in rapid succession to a number of well-known New York physicians, ostensibly for headache for which she professed not to be able to assign a cause, but really, it is to be presumed, to "fake" for the article in question. Her story is thoroughly good-natured, if not in good taste, and its setting is entirely suitable. A London newspaper once remarked of a like performance in Boston that it illustrated not so much the incapability of the town's doctors as the degradation of the journal in which the account appeared. It is to be supposed that, when Miss "Nelly" really wants medical advice, she will adopt different tactics.

### ARTIFICIAL EYES MADE OF CELLULOID.

THE Paris correspondent of the "Journal of the American Medical Association" mentions an intense foetor which sometimes results from the use of celluloid artificial eyes. The odor resembles that of bromine; the material is said to contain monobromide of camphor. The writer suggests that there is a liberation of bromine under certain conditions of its contact with the tissues beneath it, and that the extraordinary odor thus arises. These artificial eyes are said to come from Germany, but the place of their manufacture is not known to the writer. Professor Gayet, of Lyons, is the observer of the facts noticed.

### TYPHOID FEVER AT YALE UNIVERSITY.

THE death of three students of Yale by typhoid fever seems to indicate that a grave type of the disease has attacked that community. Fever is not an uncommon occurrence among the students in the early part of the autumn session, after which time it gradually dies out. The medical officers of the college rather expect some cases after the students rejoin their classes in the autumn, and they are in the habit of regarding it as "vacational" or imported. Commonly the type of the fever is light, and it is rarely fatal, whether the student remains in town or is conveyed to his home. The authorities of the college con-

sider the water-supply used by the students as pure and above suspicion. If the present condition of things persists, a bacteriological examination of the drinking-water and a survey along its sources will become necessary.

#### THE BROOKLYN HEALTH EXHIBITION.

It is proposed to keep the exhibition of sanitary appliances open until December 1st, and to give free admission to everybody interested in such displays. Being the first attempt of the kind, the undertaking has been tentative, and some things devoid of sanitary merit have been admitted, which simply help to pay expenses; but meritorious objects are to be found there, and very few persons will go there without discovering something instructive. A course of lectures will be given, at about weekly intervals, on sanitary subjects. The exhibition hall is at the junction of Fulton and Pineapple Streets, a short distance from the bridge.

#### THE ART OF COOKING.

MR. EDWARD ATKINSON lately spoke before the American Public Health Association on the economics of cooking. He not only gave the audience a sample of the work performed by his single-lamp-power ovens, but he gave to each person desiring it a reprint of his paper, prepared for him by the publishers of the "Popular Science Monthly," a day in advance of the regular appearance of the magazine.

#### "HYMEN AND ÆSCULAPIUS."

UNDER this heading a paragraph appears in the "British Medical Journal" for October 19th, which relates the fact of the marriage of the illustrious statistician, Dr. Bertillon, to a lady graduate in medicine, Mademoiselle Schultze, who had recently passed her examination for the doctorate with distinction and brilliancy. Other instances are not wanting where bright young medical women have been married to men already eminent in Parisian practice. The profession there shows an inclination to absorb them into the ranks as well by marriage as by the diploma.

#### A FATAL INJURY IN LAWN TENNIS.

A DEATH from injuries incurred in lawn tennis has been reported from Staten Island. The accident occurred in the course of the regular play of the game, two of the players coming violently into collision. One of them, a young lady, was knocked down and stunned, but her injuries were at first regarded as not very serious. She was injured internally, however, and death ensued in about a week after the accident.

#### ITEMS, ETC.

**The New York Neurological Society.**—At the next meeting, on Tuesday evening, the 5th inst., Dr. Ira Van Gieson will read "A Contribution to the Pathology of the Laryngeal and other Crises in Tabes," and the Commission on the Treatment of Epilepsy and Chorea by the Correction of Ocular Defects will present a report.

**The late Dr. James B. Hunter.**—At a meeting of the Practitioners' Society of New York, on October 4, 1889, it was

*Resolved*, That the members of this society express their deep regret at the sudden and untimely death of their late colleague, Dr. James B. Hunter. They recall the fact that Dr. Hunter was one of the founders of the society, that he was its first president and always took an especial interest in the suc-

cess of its work, to which he made practical and original contributions. Dr. Hunter was esteemed for his social qualities as well as for his eminence as a physician, and in his unfortunate death the members feel a sense of great personal bereavement.

W. T. BULL,  
R. F. WEIR,  
C. L. DANA, } Committee.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 29, 1889:

DISEASES.	Week ending Oct. 22.		Week ending Oct. 29.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	58	13	42	16
Scarlet fever.....	32	4	41	4
Cerebro-spinal meningitis .....	0	0	4	4
Measles.....	27	1	42	2
Diphtheria.....	79	26	80	12
Small-pox .....	0	0	1	0

**The Philadelphia Polyclinic and College for Graduates in Medicine.**—The ceremony of laying the corner-stone of the new hospital, with Masonic offices, has been set down for to-day.

**The "Gazette de gynécologie."**—It is announced that Dr. P. Ménière has retired from the editorship and from medical practice, on account of failing health, and that the "Gazette" will hereafter be edited by Dr. Philippeau.

**The Death of Isaac E. Taylor, M. D., LL. D.**—As we go to press we learn of the sudden death of Dr. Taylor, President of the Faculty of Bellevue Hospital Medical College, which occurred on the evening of Wednesday, October 30th. An appropriate notice will appear in our next issue.

**Changes of Address.**—Dr. John A. Fordyce, to No. 66 Park Avenue; Dr. John B. Hamilton (Washington), to No. 924 McPherson Square; Dr. Faneuil D. Weisse, to No. 46 West Twentieth Street.

#### Society Meetings for the Coming Week:

**MONDAY, November 4th:** New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morrisania Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica Medical Library Association; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., City Medical Association; Chicago Medical Society.

**TUESDAY, November 5th:** New York Obstetrical Society (private); New York Neurological Society; Elmira Academy of Medicine; Buffalo Medical and Surgical Association; Ogdensburg Medical Association; Hampden, Mass., District Medical Society (Springfield); Hudson, N. J., County Medical Society (Jersey City); Androscoggin, Me., County Medical Association (Lewiston); Baltimore Academy of Medicine.

**WEDNESDAY, November 6th:** Society of the Alumni of Bellevue Hospital; Harlem Medical Association of the City of New York; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond (Stapleton), N. Y.; Penobscot, Me., County Medical Society (Bangor); Bridgeport, Conn., Medical Association.

**THURSDAY, November 7th:** New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua; Medical Society of the County of Orleans (annual—Albion), N. Y.; Boston Medico-psychological

Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington).

**FRIDAY, November 8th:** New York Academy of Medicine (Section in Neurology); Yorkville Medical Association (private); Medical Society of the Town of Saugerties.

**SATURDAY, November 9th:** Obstetrical Society of Boston (private).

"Hand-book," speaks of E. W. Clark's using a strong ligature in a case at the New York Hospital. I take it that his ligature was silk, which I should think would be harder to tie in this location than a wire would be to twist. I had not received the "Hand-book" at the time I operated, but neither in it nor in Knight's paper am I able to find any reference to a ligature, silk or wire.

J. S. BUTLER, M. D.

## Letters to the Editor.

### POLITZER'S POWDER-BLOWER.

NEW YORK, October 28, 1889.

*To the Editor of the New York Medical Journal:*

SIR: Under the head of "New Inventions, etc.," in the Journal for October 26th, Dr. John O. Roe, of Rochester, describes an improved powder-blower. He has evidently overlooked an identical powder-blower, invented by Politzer and described by him in his "Treatise on Diseases of the Ear," p. 469. I have used one for a number of years, which I obtained of Reynders & Co.

GORHAM BACON, M. D.

### HAEMORRHAGE AFTER REMOVAL OF THE TONSILS.

SUPERIOR, NEBRASKA, October 21, 1889.

*To the Editor of the New York Medical Journal:*

SIR: I have read with much interest the paper of Charles H. Knight, M. D., viz., "Note on the Galvano-cautery in the Treatment of Hypertrophied Tonsils," in the Journal for October 12th. In speaking of serious haemorrhage following the operation of amygdalotomy and means to check it, he says "the loop of a cold-wire snare may be applied, possibly with the aid of a transfixion needle." Since reading his paper I have thought a little personal experience in this direction might be worthy of publication. Last July I removed partially a hypertrophied tonsil of the right side from a girl aged fourteen, using Mathieu's amygdalotome. Considerable resistance was met with in drawing the knife of the instrument through it, and haemorrhage was not marked at first, but in about fifteen minutes became alarming. Tannogallic acid, cold, and pressure were used, but still it continued increasing. The patient was in my office and handy to what few instruments I possessed, a Jarvis's snare among them, but I had not read Dr. Knight's paper, or I should have used the "loop of the cold-wire snare." But the following is what flashed through my mind and what I did do: By the assistance of a tenaculum I drew the stump toward the median line and transfix it with a needle and passed a loop of No. 24 silver wire over it; then, by the use of Sims's shield and Wyeth's needle-holder for a wire-twisting forceps, I succeeded in bringing such a pressure upon the circumference of the stump as to check all haemorrhage. The wire made a groove for itself, so I removed the needle and cut the wire short, and left it in position for two days, when it was removed. This was another method of using the "cold-wire loop" without the snare, and perhaps as practicable, as it was the means of allaying a great deal of excitement on the part of the parents as well as relieving a little anxiety in another direction. I learned after the operation that repeated applications of tincture of iodine had been made to the enlarged tonsil on the recommendation of another physician without appreciably diminishing its size. The haemorrhage was from numerous arterial twigs, their mouths being kept open in all probability by the fibrous condition of the gland. Delavan, in the "Reference

## Proceedings of Societies.

### MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Eighty-fourth Annual Meeting, held on October 28, 1889.*

The President, Dr. ALEXANDER S. HUNTER, in the Chair.

THE business of the evening was devoted entirely to the reception and adoption of reports by various committees, and the election of officers for the ensuing year. Considerable discussion was elicited by a clause contained in the report of the Comitia Minora. In it the committee recommended that physicians who for a period longer than two years were delinquent in the matter of fees should have their names omitted from the printed list of the society's members. Upon a vote this clause was retained, but it was explained that the names would not be withheld entirely, but would be printed in a separate list.

The treasurer's report showed a balance in hand of \$1,176.

The report of the Committee on Hygiene contained information as to many of the more glaring defects in the methods of conducting the work of the public schools, in so far as concerned the health, cleanliness, and general well-being of the pupils during school hours. The following is a list of the officers elected for the ensuing year: President, Dr. Alexander S. Hunter; vice-president, Dr. J. Leonard Corning; secretary, Dr. Charles H. Avery; assistant secretary, Dr. William E. Bullard; treasurer, Dr. John S. Warren; censors, Dr. Daniel Lewis, Dr. George H. Fox, Dr. Laurence Johnson, Dr. N. G. McMaster, and Dr. George A. Abbott; delegates to the Medical Society of the State of New York, Dr. D. H. Goodwillie, Dr. William Stevens, Dr. Albert S. Newcomb, Dr. Frank B. Carpenter, Dr. Samuel Lloyd, Dr. Peter A. Callan, Dr. Ralph Waldo, Dr. Urban G. Hitchcock, Dr. William A. Dayton, Dr. Charles A. Powers, Dr. Willy Meyer, Dr. Henry D. Chapin, Dr. George R. Elliott, Dr. John Dorning, Dr. Seneca D. Powell, Dr. Robert T. Morris, Dr. Francis Valk, Dr. David D. Jennings, Dr. William C. Jarvis, Dr. Malcolm McLean, Dr. Egbert H. Grandin, Dr. William P. Northrup, Dr. R. C. M. Page, and Dr. Robert B. Talbot.

### NEW YORK STATE MEDICAL ASSOCIATION.

*Sixth Annual Meeting, held in New York, September 25, 26, and 27, 1889.*

The President, Dr. W. T. LUSK, of New York, in the Chair.

(Concluded from page 470.)

**Forced Respirations; Additional Observations.**—Dr. GEORGE E. FELL said that last year he had presented before the association his method of inducing forced respirations in the narcotized human subject. The mechanical apparatus by which he effected this consisted of a bellows, an arrangement for heating the air, and an air valve with tracheal and other connecting tubes. The object of the present paper was to set forth more definitely the encouraging results which had followed the use

of his contrivance. He reported a number of cases of opium narcosis in which breathing had been performed for the patients for periods varying from two to twenty-one hours, their lives being thereby saved.

**Alcoholic Paralysis.**—Dr. T. D. CROTHERS, of Hartford, Conn., read a paper with this title which went to point out the direct connection existing, in the author's opinion, between chronic alcoholism and such pathological changes in the brain as were concerned in producing many of our cases of insanity with paralysis.

Dr. E. M. MOORE said that the paper marked a new departure. Great difficulty always surrounded the incarceration of persons undoubtedly unable to control themselves in the matter of alcoholic stimulants. The condition had come to be regarded as only temporary. The author, in his paper, however, had taken a true view of the case. There might be such cerebral change as would make it impossible for the tendency to alcoholism ever to pass away in certain subjects. There would be no difficulty in controlling such people if physicians could make up their minds to designate such persons as insane. The law would be sufficient for this, and it would be an immense boon to society to be able to deal with them. He hoped this paper would be an entering wedge.

Dr. A. L. CARROLL thought that before the alcohol habit could be acquired there must exist a predisposing vulnerability. Thousands were never apparently injured by its use, while others would be led away by a glass of wine at dinner. While with one class drinking was a vicious propensity which might be cured by shutting them up, with another the tendency was a neurosis and beyond control. Such people would remain all right for months, and then came the neurotic craving which overmastered them, and very heart-rending cases they were.

**A Few Fads.**—Dr. H. D. DIDAMA, of Onondaga County, in a humorously caustic paper, touched in chronological order on many of the medical vagaries of recent times. After reviling the "blue-glass fad," he went on to speak of the sulphurated-hydrogen fad. This he characterized as an attempt to cure a dire disease with medicated wind. Consumption was, however, a disease of obstinate fixity. Its bacilli—had they not resisted carbolic acid and bed-bug poison, and grown fat upon "Rough on rats"? Even when surprised by a rear attack, they did not "silently steal away," but died at their posts. Beings of whom the world never heard before or since recorded lots of cases cured. Gas generators, at ten dollars a machine, were found in thousands of offices. And now—well, the bacilli and the scoffers wore a triumphal smile.

**Some Uses of the Transfixion Ligature.**—Dr. T. H. MANLEY, of New York, in this paper went deeply into the earlier and most recent methods for the control of haemorrhage. He did not think that the management of haemorrhage kept pace with the advance of surgery. While operating one day in the region of the great vessels for the removal of strumous glands of the right side of the neck, and while teasing out the last of these, a gush of blood occurred. Every pressure and means were used to control the bleeding, but to no purpose, and the patient soon began to show alarming symptoms. Just then the author was inspired with an idea, and seizing a needle-holder armed with needle and silk, he plunged the needle into the wound near the thyro-hyoid membrane, carried it sufficiently low to pass under the great vessels, and then, making a sharp turn, brought the point out through the middle of the sheath of the mastoid muscle, and tied the whole mass embraced by the ligature. The condition of the veins immediately suggested that the internal jugular and common carotid artery had been tied. He then closed everything. The patient rallied fairly well. The transfixion ligature was removed

the next day, and the patient went on to an uneventful recovery and was discharged with the wound solidly healed on the tenth day. It had been gratifying to him to hit on any contrivance at a time when his patient might have bled to death. It had occurred to him that the employment of a ligature, by transfixing the parts and inclosing the nearest available and suitable point of a bleeding vessel within it, was a method which might be followed with advantage and safety. With this idea he had entered upon a series of experiments upon the cadaver and upon living animals for the purpose of demonstrating the regional topography and points of selection for the passing of ligatures, what was likely to be included in such ligatures, and the disturbed functional or the pathological result to be looked for by the temporary embrace of important vessels and nerves by ligature. He had also put the plan into successful practice whenever occasion had offered. His inferences were in favor of the method being one which should commend itself to surgeons in selected cases, and for military purposes he should deem it of great value.

**A New Urethrogram.**—Dr. STEWART exhibited a recent modification of his urethrogram and described the operation of obtaining diagrams of the general conformation of the urethral canal.

Dr. GOULEY said the instrument, while not a perfect one, was a vast improvement on any of the others.

**The Bacteriology of Drinking-water.**—The author, Dr. E. K. DUNHAM, commenced his paper by going fully into the principles involved and the procedures adopted in the estimation of the bacteriological element in drinking-water. He then traced the history of a given sample of water, giving some typical illustrations of the application of the principles underlying the bacteriological test of water as met with in actual practice. His conclusions were that the bacteriological examination of water alone could not, save under exceptional circumstances, furnish the data for a direct verdict as to its sanitary value.

**New Hypnotics: Sulphonal, Amyl Hydrate, Hydrobromide of Hyoscine, Hypnone, Paraldehyde, and Urethrane—their Therapeutic Applications, Contra-indications, Toxicology, and Methods of Administration.**—Dr. W. H. FLINT, of New York, opened the discussion on this subject by a paper which evidenced most exhaustive research. He had collected from all the sources at command, both here and abroad, the experience, observations, and deductions from experiments with this class of new drugs. Physicians, he said, recognized natural sleep as an invaluable ally in combating disease, and regarded hypnotic medicines as among the most effective weapons of their therapeutic armamentarium. They cordially welcomed and tested new soporific remedies. The number of valuable sleep-producing medicaments had happily been augmented of late by new discoveries in the domain of synthetical chemistry, and by the utilization of certain compounds long known to science.

The object of the present discussion was to give a summary of the therapeutical applications, contra-indications, toxicology, and modes of administration, and in some cases to give the physiological action of these hypnotics with a view to throw some light upon the relative merits of the individual remedies. The writer desired to accomplish his part of the discussion by presenting a résumé of the most important papers on this subject which had come to his notice, adding thereto the results of his own observations. The group of somnifacients to which attention was invited comprised sulphonal, amylen hydrate, paraldehyde, urethrane, and hypnone. In respect to sulphonal he could report thirty-three cases treated, with the following conclusions arrived at: That sulphonal, even in single doses of twenty or thirty grains, was in the main a safe and reliable hypnotic, free from unpleasant concomitant effects, and usually from all unde-

sirable sequelæ. The only objectionable after-effect witnessed by himself was moderate somnolence on the morning following its administration; in none of the cases was there derangement of the appetite or digestion, nor was the circulation or respiration appreciably affected. The cutaneous and renal secretions were neither increased nor diminished, and nausea, vomiting, or constipation did not follow the use of the drug. The average length of the time in which sleep ensued after the administration of sulphonal was about an hour. The average duration of the sleep was a little over six hours, and success attended the use of the drug in about 87 per cent. of all the cases. Since his early experiments with the drug had been published about a year ago, he had constantly employed it in private and hospital practice, and it had continued to favorably impress him. Reviewing his own experience and that of others, he concluded that the physiological action of sulphonal had not yet been satisfactorily established, although notable contributions on this subject had been made during the current year. Sulphonal was chiefly valuable in nervous insomnia, in some forms of insanity, notably in acute maniacal conditions, in acute sthenic febrile diseases, the opium habit, in conditions of gastric irritability, at least temporarily in neurasthenia, and in some cases of anaemia. The effects of the remedy had been generally better in his experience where the patients were strong and plethoric, and in these cases the after-effects were most frequently absent. Sulphonal was contra-indicated because of its comparative uselessness in insomnia from pain, cardiac dyspnoea, gastrectasis, congested stomach, etc. The causes of this failure in the presence of pain, cough, and dyspnoea seemed to be its slight narcotic action, and in gastrectasis, chronic gastritis, and gastric congestion its slow solubility. It seemed to be contra-indicated on account of its possible hurtful effects in great physical prostration, in acute melancholia, and in insanity after abortion, after labor, and perhaps in sclerosis and in angina pectoris. Clinically, toxic symptoms did not generally follow the use of sulphonal in adult cases until thirty grains or more had been given at one dose, or in doses quickly succeeding each other. It must, however, be conceded that small doses did sometimes act unfavorably owing to individual idiosyncrasies. The milder toxic symptoms from sulphonal were fatigue, depression, tinnitus aurium, and nausea. The writer had also seen marked pallor and oedema beneath the eyelids in several cases in patients waking from sleep after taking sulphonal.

The graver symptoms thus far reported were diarrhea, peripheral aphasia and ptosis, a cutaneous eruption like that of rubeola or urticaria, brachycardia, inco-ordination, semi-coma, and collapse. Sulphonal should be administered by the mouth in hot beverages or in hot liquid foods an hour or more before its effects were desired. Its use by the rectum was not generally satisfactory. He would urge the necessity of employing only the pure sulphonal, as some bad results had come, no doubt, from the use of a spurious article.

There was no need for alarm at the sensational statements of some authors who had used too large doses, or had used the drug when it was contra-indicated. The dose should be carefully adjusted to the requirements and peculiarities of each case, and since the effect of a full dose was often felt on the second or third night after its administration, it was well to decrease the dose on these nights whenever the drug must be given uninterruptedly for days or weeks. He had not seen evidence yet that the sulphonal habit existed, nor had he seen any cachexia or dyscrasia which could be fairly attributed to the drug. Favorable effects had resulted in about eighty per cent. of his cases. Children took it readily and tolerated it very well.

*Amylene Hydrate.*—This hypnotic, the speaker said, he had

employed in thirty-eight cases of insomnia from various diseases. In these, success had resulted in sixty-seven per cent. Upon the basis of his own experience and that of the authorities, he had reached the following conclusions: The physiological action of amylene hydrate was similar to that of alcohol. In therapeutic doses it produced sleep by its soporific action on the cerebrum. In toxic doses it paralyzed the cord and medulla, finally abolishing the reflexes, arresting the respiration, and paralyzing the heart. It was applicable, therapeutically, to insomnia from nervousness, from excessive mental exertion, from anaemia, fevers, insanity, cardiac diseases, the opium habit, and from the withdrawal of narcotics that had been constantly employed. It was contra-indicated because not efficacious in insomnia from pain, cough, and often in cardiac and nraemic dyspnoea. Its use by the mouth was contra-indicated in gastric diseases attended with irritation or nausea, because of its irritating character, but it might be given by the rectum in such cases. It should not be given to fastidious patients on account of its taste and odor, and children did not generally tolerate it, for the same reason. The toxic effects from therapeutic doses were generally unimportant, consisting of headache, slight nausea, gastric distress, and thoracic oppression. Serious symptoms sometimes followed, as loss of reflexes, paralysis of the extremities, mydriasis, low temperature, feeble pulse, and superficial respiration. Amylene hydrate was best given by the mouth, in soft capsules, or in mixture, or solution, disguised by peppermint water, raspberry syrup, or extract of licorice. The mixture should be thoroughly shaken before being used in order to avoid an overdose being taken. The dose for adults was thirty to forty-five grains by the mouth and forty-five to seventy-five by the rectum. The author had never seen any cases in which an amylene hydrate habit had been engendered or a cachexia due to the remedy developed.

*Paraldehyde* had been used by the author in thirty-five cases of insomnia from a variety of causes for the purpose of comparing its effect with other hypnotics. The doses had varied from sixty to ninety minims. Successful results were obtained in 72 per cent. of the cases. The writer's inferences, drawn from his own studies, were as follows: The remedy in moderate therapeutic doses acted like ethyl alcohol, producing sleep by its hypnotic action on the cerebrum. This sleep was, however, preceded by a brief period of excitement, during which the reflexes were augmented. In larger doses it paralyzed the spinal cord and abolished the reflexes, finally arresting respiration by paralyzing the medulla. It also exerted a paralyzing action on the vaso-motor centers. Like amyl nitrite, it caused central myosis and stimulated intestinal peristalsis. In full doses it slowed and tranquillized the respiration. It did not notably affect the temperature, but sometimes caused a slight diaphoresis; the blood-pressure was slightly reduced by small doses, more markedly so by large ones, and the pulse was somewhat slowed. Paraldehyde did not particularly irritate the stomach. It was not yet decided whether it produced methæmoglobinæmia. The remedy was not indicated in the insomnia of acute and chronic melancholia, epileptic dementia, acute alcoholism, the opium habit, hypochondriasis, hysteria, neurasthenia, chronic gout, exhaustion from over-work, dyspnoea, or the cough of pulmonary diseases. Paraldehyde was contra-indicated in cases of cyanosis with depression of the respiratory center, as in advanced emphysema and cardiac dilatation, in painful diseases, gastric ulcer and gastritis, or in pharyngeal and laryngeal ulceration, and was to be used cautiously in anaemia, as it might reduce the oxyhaemoglobin of the blood. The milder toxic effects were headache, nausea and vomiting, vertigo, and slight cerebral congestion. In powerful toxic doses it produced deep sleep with anaesthesia, then abolition of the re-

flexes, and death from paralysis of the respiratory center. Paraldehyde might be given a long time in moderate but yet effective doses, with no harmful results. If, however, too large doses were given for a long time, tremor of the hands, oedema, anaemia, delirium, and a condition resembling chronic alcoholism might be developed. In a rabbit poisoned by relatively large doses of this drug, fatty degeneration of the liver was produced. It was best given in soft capsule or disguised with cinnamon water or compound tincture of cardamom. The average dose for an adult was one drachm. It should not be given subcutaneously on account of the local irritation and pain which it produced, nor could it be given by inhalation, as it acted too slowly and was apt to be irritating. It did not seem to have an accumulative effect, nor was tolerance of the remedy established.

*Urethrane* the author had tried in forty-two cases of insomnia, and found it to be possessed of moderate hypnotic qualities, although insufficiently powerful to successfully rival the remedies already mentioned. In regard to the physiological action of urethrane we had the authority of Schmiedeberg for the statement that large doses of the drug produced loss of mobility with insensibility and unconsciousness. The respirations were increased in depth and frequency, and the heart-beat steadily sustained the blood-pressure at the normal point. Sensation persisted much longer than motion, and the temperature fell. The reflexes were but little affected in the urethrane sleep. Diuresis and diaphoresis sometimes occurred. Urethrane was best applied therapeutically to insomnia in cardiac diseases without great dyspnoea and to cases of moderate mental excitement. When sulphonate, amyl hydrate, and paraldehyde were too powerful, it might render good service in insomnia from melancholia. Urethrane was contra-indicated in insomnia from pain and cough, as it had no anodyne properties, nor was it powerful enough for use in delirium tremens or in mania. It could scarcely be said to have toxic effects until very large doses—as, for instance, 180 grains—were taken. In some cases it had been known to cause nausea, somnolence, and gastric distress. Being soluble in two parts of water and being very free from offensive taste, urethrane might be given by the mouth or by the rectum. In aqueous solution it might also be used subcutaneously. The adult dose varied from 15 to 30 grains, and for children from 12 to 18 grains was a fair dose; from two to three years old, 8 grains, and from four to fourteen years, 15 to 20 grains. The average dose for subcutaneous use was 4 grains.

*Hypnone*.—The author's experience with this drug was too limited to justify him in formulating conclusions based upon his own observations. From that of others he decided as follows: Therapeutically, it might be used in the absence of a better hypnotic in primary or nervous insomnia, but its effects were very uncertain, and, tolerance being soon established, larger doses were required than at the beginning of the treatment. It was contra-indicated in sleeplessness from cough, and was not to be given to patients with feeble stomach. It was best administered in doses of from 3 to 7½ grains, in capsules or almond-oil. His own experience with hypnone had, however, been so disappointing that he had practically abandoned its use.

CHARLES RICE, Ph. D., of New York County, reviewed the general points in the chemical history of the new hypnotics. Sulphonate was, he said, at present the most favored, but it had great disadvantages both pharmaceutically and therapeutically. It was almost insoluble in water, and its effect therefore was too slow. Recent experiments in Germany had resulted in the production of several more compounds of greater intensity from the sulphonate group. Of these, tetranol was the most intense of all. We should probably soon have the market flooded with a whole series of these compounds, each more powerful than its

predecessor. The conflict was also imminent as to who should be the lucky manufacturer of the drugs, because it was thought there were "millions in it."

Dr. SQUIBB said any remarks he might make would be in the line of conservative policy. These new hypnotics had been alluded to as having millions in them. It seemed to him that the more largely they were advertised the more they were used, and perhaps successfully used. The search for such remedies was entirely wrong, in his mind. Sulphonate was quoted at about \$1.35 an ounce in the market, and cost about 15 cents. It was controlled by a patent in this country, though not so abroad. It would be observed that there was no one of the hypnotics discussed which was susceptible of being used subcutaneously.

Dr. CARROLL said he had been struck by the discrepancy between the hypnotic effects reported from similar doses by different authors.

The subject was still further discussed by Dr. TRUAX, who, while drawing inferences favorable to sulphonate, did not think that the new drugs, so far, took the place of those already in use.

Dr. L. H. SAYRE presented a patient from whom he had amputated the right leg at the level of the junction of the upper and middle thirds of the femur. The patient was a young man, who had suffered for a long period with bone disease of the lower right extremity, commencing at the knee joint. Resection of this joint failing to arrest the process of necrosis, and the femur becoming involved, amputation had been performed, having for its special provision the leaving of a useful stump to which might be attached a practicable artificial limb. At the level referred to a circular cut was made, dividing the soft parts to the bone. A longitudinal incision was then made, enabling the operator to disarticulate the head of the femur from the cotyloid cavity. The result of the operation had fully justified the expectations, as the patient was now before them, wearing, for the second time only, an artificial leg the movements of which he was already able fairly to control.

#### AMERICAN DERMATOLOGICAL ASSOCIATION.

*Thirteenth Annual Meeting, held at Boston, on Tuesday, Wednesday, and Thursday, September 17, 18, and 19, 1889.*

The President, Dr. I. E. GRAHAM, of Toronto, in the Chair.

(Continued from page 473.)

**Officers for the Ensuing Year.**—The following officers were elected: President, Dr. P. A. Morrow, of New York; vice-president, Dr. G. N. Tilden, of Boston; secretary and treasurer, Dr. G. T. Jackson, of New York.

Dr. J. T. Bowen, of Boston, and Dr. C. W. Allen, of New York, were elected members of the association.

Dr. Bulkley presented the report of the Committee on Statistics.

It was voted to hold the next meeting of the association at Hot Springs, N. Y.

**Lupus Erythematosus.**—Dr. W. A. HARDAWAY, of St. Louis, presented the history of a case. The patient, twenty-three years of age, had been well until October, 1887, at which time some spots were noticed upon the nose. These were treated with chrysarobin salve by the attending physician, who considered it a case of eczema. The treatment brought on an acute dermatitis, which obscured the real disease for a time, but, on clearing it up under soothing ointments, it was found that the disease was lupus erythematosus. The patient went to the Hot Springs of Arkansas after six weeks, and there it was

considered to be eczema. In March, 1888, the eruption occupied the same area, and was of a dusky-red color, the borders being sharply defined. Some improvement followed the use of sulphur and salicylic acid. For some reason a lead salve was ordered, and, by a mistake of the apothecary's, crystals of the acetate were put in it. The reader was called to see the patient, and found him with a temperature of 103° F., with great swelling of the lymph glands in the front of the neck, and with the upper lip incrusted. On the second day the swelling of the neck was very hard, and there were some spots of eruption on the forehead, not quite reaching the hairy scalp. On the third day there were pustular and bloody crusts upon the cheeks, resembling those of pustular eczema, and some oedema of the throat. The temperature was 104.5°, probably due to the adenitis. During the next two weeks the lower lip lost its crust and the fever abated, and within a month the disease had undergone complete involution. The glands became involved in a tubercular process all over the upper part of the chest. Hectic supervened, and he died suddenly of pneumonia after some days.

Dr. TAYLOR was skeptical about the acute attacks of lupus erythematosus of Kaposi. In one case which Dr. Bulkley had had in New York many of the clinical features of Kaposi's description had been absent. It seemed to him that Kaposi had got hold either of cases of syphilis or of quasi-acute cases of iodide-of-potassium poisoning.

Dr. GREENOUGH would question whether the fatal result had not been due to the violent dermatitis that had twice been set up and had resulted in affection of the lymph glands rather than to the lupus erythematosus itself.

Dr. SHEPHERD thought if the lupus had been left alone there would have been no glandular affection. In patients with a tubercular family history small irritations would sometimes set up glandular disease.

**A Hitherto Undescribed Form of New Growth of the Vulva.**—Dr. R. W. TAYLOR, of New York, read a paper on this subject. (To be published.)

Dr. GREENOUGH, referring to one of the author's cases, asked if the growth in parts free from pressure showed any tendency to exuberant growth.

Dr. TAYLOR replied that it did not. It was entirely flat.

Dr. BRONSON said that he had seen the case, and at first glance it had had the appearance of epithelioma. He could hardly conceive that an irritation acting for a time and then ceasing would start a process which could prove so rebellious. It seemed to him that there must be some specific cause at the bottom of it.

Dr. HEITZMAN said that the clinical picture and the microscopic study were entirely at variance in this case. The process, he believed, was malignant. He had studied the sections, and found that the rete mucosum was not thickened, but, on the contrary, very much thinned. The papillæ were very much enlarged. The tumor was certainly a sarcoma. The history of lack of ulceration and attempts at cicatrization, and the fact that the lymphatics were not affected, tallied with the view that it was sarcoma. As no autopsy was made, it would be impossible to say that there were not metastatic formations.

Dr. ROBINSON agreed with the last speaker that the case was one of sarcoma.

Dr. TAYLOR said that, while he could vouch for the clinical features, he had awaited with a good deal of interest the opinions of the last two gentlemen. It seemed to him, clinically, that it was something more than an inflammatory growth. The specimens had been carefully examined during a period of six months by Dr. Van Gieson, at the laboratory of the College of Physicians and Surgeons, and there had been nothing hasty in the conclusions offered.

### Some General Suggestions in Dermatological Therapy.

—Dr. S. SHERWELL presented a paper on this subject. (To be published.)

Dr. BULKLEY had been especially interested in the matter of eczema upon the lip. He had been through with all varieties of treatment, and had come to conclusions identical with those of Dr. Sherwell. He could recall many patients who came for treatment each winter, and who were better during the warm months. He would go a step further than Dr. Sherwell, and look at the general condition of the patient, for some persons of catarrhal habit needed proper internal medication. In regard to the cases of anal eczema, he had seen fissures touched with nitrate of silver, and he was very cautious about the use of this remedy, for he had seen one case of general eczema set up, and the man had been kept in bed for three or four weeks.

Dr. ZEISLER believed that many cases of eczema of the lip were due to a diseased condition of the roots of the hairs, and in his hands the best treatment was by depilation. He was positive that the catarrh excited the eczematous condition and the syrosis. He had no doubt that the catarrh was of mycotic origin, although it was not yet proved. The treatment by depilation was efficient and cheap and did not cause any dermatitis.

Dr. TAYLOR spoke of the fact that dry sulphur was used to rub into the so-called "mange" of dogs, one variety of which was parasitic.

**What Real Value have the Natural Mineral Waters in the Treatment of Diseases of the Skin?**—Dr. L. D. BULKLEY, of New York, read a paper with this title. It was, he said, the popular impression that natural mineral waters helped certain skin diseases; that some were to be applied on the outside, and some were to be taken internally, for the purpose of washing out the noxious agent. No doubt many cases were benefited, but any one who had seen many cases of the effects of natural mineral waters must have been many times disappointed. The water was but one element in the case; hope and faith might play an important part. Then there were the change of scene, rest from ordinary occupation, and perhaps the enforcement of regular hours. In Europe most of the springs had resident medical advisers, but, unfortunately, there were few of them in this country. It should be remembered that in certain instances other appropriate remedies were being taken at the same time; witness the treatment of syphilis at the Hot Springs of Arkansas. But in any case it was the water, pure and simple, which contributed most to the cure. Most of the waters had little effect upon the skin, but touched especially the kidneys, liver, bowels, etc. We could not always predict the effect of the water from its chemical analysis. Certain mineral waters were taken hot at the springs, but cold, or even with ice, when at a distance. In the case of iron, arsenic, and bromine springs the results were rather indefinite. Sometimes cutaneous diseases depending on debility were improved. Everybody had seen cases of eczema which had been treated at the sulphur springs in vain. Where there was a rheumatic element back of the cutaneous lesion no doubt some good could be received, but in those cases it was the alkaline water and not the sulphur which was of benefit.

Like all other remedies, the use of springs must be carefully prescribed in order to be of the greatest use. Probably more benefit was derived in eczema than in other diseases, and even then it should be toward the close of the case. First should be used the alkaline and moderately purgative waters, and then a tonic course. Carlsbad was advisable where there was much abdominal plethora. In acute cases the hot springs should be used. Care must be taken lest acute eczema be excited by the springs, for some very severe cases had been lighted up in this manner. In psoriasis sometimes sea-bathing was of far more

benefit than the mineral springs. In syphilis little benefit followed unless other treatment was kept up. Acne would often be benefited somewhat, and the iron springs were better than the sulphur. The chief difficulty in the use of this treatment was the fact that the patients were not under supervision, and were apt to follow their own fancy or the guidance of the attendants at the baths.

Dr. HARDAWAY had lived in the vicinity of several springs, and had seen a large number of patients who had tried the treatment. A large part of the benefit, it seemed to him, was due to the fact that the patients were away from their business. Undoubtedly some were helped by the water simply as water. In various gastric and intestinal disturbances which might lie at the root of an acne of the erythematous form in people who were lithæmic the water would act well. There were some persons who gave up a dissipated, irregular life, and spent the time quietly and regularly when at the springs. He had never seen any specific effects from the waters.

Dr. KLOTZ thought it a pity that the natural springs in this country, which he considered equal to those of Europe, should be so neglected.

Dr. TAYLOR spoke of the fact that there were so many social attractions at Saratoga that the patients were apt to be led away from the purpose of their visit. He had never seen any marked effects from the waters at Saratoga, but he had seen bad results, and he would advise persons with any renal or any commencing vesical or urethral trouble to leave the Hathorne water alone. In some of the patients who had what we called portal congestion the iron waters acted very harmfully; some patients had been brought to the verge of death by persistently drinking the water.

Dr. SHERWELL had had a patient with erythematous eczema much injured by a trip to one of the sulphur springs. The patient had returned in a pitiable condition.

Dr. DENSLAW had found that eczema in his cold climate tended to become chronic, and patients had to be sent to a warmer locality. Those that were benefited most, as a rule, did not have much to do with the waters of the springs. He advised patients with acute disease to have nothing to do with them at all. Where there had been any benefit it had been in the old chronic cases, and the acute cases had been aggravated. Even in that case it seemed to him that the chronic cases would have been just as much benefited by the change to a warm climate, leaving the waters alone.

The PRESIDENT, in answer to an inquiry made by Dr. Bulkley, said that the St. Catherine Springs and the Preston Springs had given good results, but generally in rheumatic cases, and he preferred the latter place for this class of patients.

(To be concluded.)

## Book Notices.

*The Diseases of Children, Medical and Surgical.* By HENRY ASNBY, M. D. Lond., M. R. C. P., Physician to the General Hospital for Sick Children, Manchester, etc., and G. A. WRIGHT, B. A., M. B. Oxon., F. R. C. S. Eng., Assistant Surgeon to the Manchester Royal Infirmary, etc. London and New York: Longmans, Green, & Co., 1889. Pp. xix-681. [Price, \$6.]

THE original feature of this work is one which commends itself strongly to us; it is written conjointly by a physician and a surgeon, and so presents a consideration of the diseases peculiar to children as viewed from the standpoint of each. It is not

merely a compilation, but is based upon the personal experience of the authors and is written in a practical manner. Pathology is not greatly dwelt upon, and the diseases which are not peculiar to children, or are not modified by their occurrence in early life, are either omitted or briefly mentioned.

The arrangement is fair. A short space is given to the most important facts in the physiology of infancy and childhood, then the diseases incident to birth are considered, together with the hygiene and diet. Next are the diseases of the digestive and other systems of the body, general diseases, fevers, diseases of the bones, joints, nose, ear, and skin, and tumors and injuries, concluding with a short but valuable chapter on the administration of anaesthetics to children. In this arrangement we do not understand why the authors have decided to place the specific fevers between the diseases of the respiratory and those of the circulatory systems, and the general diseases between those of the circulatory and those of the nervous systems. They seem rather out of place, but there may be good reasons which induced the authors to assign them these positions. Still it would seem better to place them either before or after the diseases of the special systems.

The book is fairly well got up, the cuts are very clear and good, and the work commends itself as a useful addition to the library.

*Hygiene of the Nursery.* Including the General Regimen and Feeding of Infants and Children and the Domestic Management of the Ordinary Emergencies of Early Life. By LOUIS STARR, M. D., Clinical Professor of the Diseases of Children in the Hospital of the University of Pennsylvania, etc. Second Edition, with Twenty-five Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. x-17 to 280. [Price, \$1.]

THE ounce of prevention is essentially the principle underlying Dr. Starr's directions for the maintenance of health during infancy and childhood. Realizing that the little things of life are great things, he presents in forcible fashion practical suggestions not to be found thus aptly expressed in other books relating to the care and training of children. A conscientious study of these ten chapters will enable any young mother to successfully rout Mesdames Brown, Jones, and Robinson on their own ground, and render all gratuitous advice concerning the new baby a work of supererogation. The author tells the truth about sleep, bare legs, roller-skates, and bicycles, and utters a protest against the indiscriminate bathing that washes infants into heaven. An excellent dietary is given, and hints for emergencies constitute one valuable feature of this admirable little treatise, which everywhere aims to be of use to that helpless, hapless, yet loving and lovely creature, the young mother who is striving to act well her part without any previous education in the practical duties of life.

*Lectures on Obstetric Nursing.* Delivered at the Training School for Nurses of the Philadelphia Hospital. By THEOPHILUS PARVIN, M. D., Professor of Obstetrics and Diseases of Women and Children at Jefferson Medical College, etc. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. viii-9 to 104. [Price, 75 cents.]

THE lectures that are contained in this little hand-book present much that is interesting and useful. The style is clear and often graceful, and the subject-matter treated intelligently, with an absence of exaggeration that is refreshing and reassuring. The multiplication of little books that are good is always to be commended, for little books are read. The perusal of this one is both pleasant and profitable.

## BOOKS AND PAMPHLETS RECEIVED.

A Text-book of Animal Physiology, with Introductory Chapters on General Biology and a Full Treatment of Reproduction. For Students of Human and Comparative (Veterinary) Medicine and of General Biology. By Wesley Mills, M. A., M. D., L. R. C. P. (Eng.), Professor of Physiology in McGill University and the Veterinary College, Montreal. With over Five Hundred Illustrations. New York: D. Appleton & Company, 1889. Pp. xxii-700. [Price, \$5.]

The Cerebral Palsies of Children. A Clinical Study from the Infirmary for Nervous Diseases, Philadelphia. By William Osler, M. D., Fellow of the Royal College of Physicians, London; Professor of Clinical Medicine in the University of Pennsylvania, etc. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. 103. [Price, \$2.]

An Experimental Study in the Domain of Hypnotism. By Dr. R. von Krafft-Ebing, Professor of Psychiatry and Nervous Diseases in the Royal University of Graz, Austria. Translated from the German by Charles G. Chaddock, M. D., Assistant Physician, Northern Michigan Asylum. New York and London: G. P. Putnam's Sons, 1889. Pp. viii-129. [Price, \$1.25.]

Hypnotism: Its History and Present Development. By Fredrik Björnström, M. D., Head Physician of the Stockholm Hospital, etc. Authorized Translation from the Second Swedish Edition. By Baron Nils Posse, M. G., Director of the Boston School of Gymnastics. New York: The Humboldt Publishing Co. Pp. 126. [The Humboldt Library.]

Studies in Intestinal Surgery. By W. B. Van Lennep, A. M., M. D., Philadelphia, Pa. [Reprinted from the "Hahnemannian Monthly."]

A Case of Cerebral Syphilis following an Attack of Thermic Fever. By Lewis H. Adler, Jr., M. D., Philadelphia. [Reprinted from the "Boston Medical and Surgical Journal."]

A Case of Loreta's Operation for Stricture of the Pylorus. By T. W. Huntington, B. A., M. D., Sacramento, Cal. [Reprinted from the "Occidental Medical Times."]

The Case of Mrs. Wilhelmina C. D. Lebkuchner. By Matthew D. Field, M. D., New York. [Reprinted from the "Medico-legal Journal."]

The Pine Belt of New Jersey. A Region of Sandy Soil and Pine Forests. By Isaac Hull Platt, M. D., of Lakewood, N. J. [Reprinted from the "Transactions of the American Climatological Association."]

Scientific Work by Alienists. By F. B. Stephenson, M. D., Surgeon, United States Navy. [Reprinted from the "Boston Medical and Surgical Journal."]

The Purulent Conjunctivitis of Infants, and Blindness in New York State. By Lucien Howe, M. D., Buffalo. [Reprinted from the "Transactions of the New York State Medical Society."]

A Report of Three Interesting Cases, viz.: Case I—Adenoid of the Vault of the Pharynx. Case II—Strumous Ozæna. Case III—Tubercular Phthisis; Secondary Tubercular Ulcer of the Tongue (Presented before the Kings County Medical Association, May 7, 1889). By Sidney Allan Fox, M. D. [Reprinted from "Gaillard's Medical Journal."]

The Value of Creasote in Fifty Cases of Disease of the Air-Passages. By William Perry Watson, A. M., M. D., Jersey City, N. J. [Reprinted from the "Virginia Medical Monthly."]

Atropine in Enuresis. By William Perry Watson, A. M., M. D., Jersey City, N. J. [Reprinted from the "Archives of Pediatrics."]

Diphtheritic Paralysis. By Lewis H. Adler, Jr., M. D. [Reprinted from the "American Lancet."]

Prolapse of the Womb, with Especial Reference to the (so-called) Hypertrophic Elongation of the Supra-vaginal Portion of the Cervix, with Report of a Case. By Lewis H. Adler, Jr., M. D. [Reprinted from the "Medical News."]

The Early Diagnosis of Extra-uterine Pregnancy. By J. M. Baldy, M. D., Philadelphia. [Reprinted from the "Medical Record."]

Abstract of a Paper on the Choice of Treatment of Urinary Concretions. By John W. S. Gouley, M. D. [Reprinted from the "Journal of the American Medical Association."]

Leprosy, with a Report on Two Cases. By George Dock, M. D., Galveston, Texas. [Reprinted from the "Transactions of the Texas State Medical Association."]

A Clinical Atlas of Venereal and Skin Diseases, including Diagnosis, Prognosis, and Treatment. By Robert W. Taylor, A. M., M. D., Surgeon to Charity Hospital, New York, and to the Department of Venereal and Skin Diseases of the New York Hospital, late President of the American Dermatological Association. Illustrated with One Hundred and Ninety-two Figures, many of them Life Size, on Fifty-eight beautifully colored Plates. Also many large and carefully-executed Engravings through the Text. Parts VII and VIII. Diseases of the Skin. Philadelphia: Lea Brothers & Co., 1889.

## Miscellany.

**Sectarianism in Medicine.**—The question of the expediency of open affiliation with homœopathic practitioners—to the degree, at least, of obliterating any antagonism recognizable by the public—has lately been under discussion at two meetings of the Philadelphia County Medical Society, having been introduced by Dr. Edward Jackson. Dr. Solomon Solis-Cohen's closing remarks in the debate were as follows:

"I have not sought this controversy. Dr. Jackson has thrust it upon the society. We are compelled to plead 'not guilty' to his charge of narrowness. Homœopathy purports to be a new revelation in medicine; to embody the perfect truth, unknown before. It is, therefore, not only proper but necessary to quote from the 'Organon' of its founder to determine what is entitled to the name. If I want to know what Judaism is, I must go to Moses and the prophets. If I wish to learn about Christianity, I must go to the New Testament. If I wish to find out in regard to Mohammedanism, I must consult the Koran. Nor am I justified in believing, in opposition to the New Testament, that Christianity is truthfully represented by the man who cheats all the week and goes to church on Sunday; or in accepting, in opposition to his sacred books, as an exponent of Judaism the man who practices chicanery all the year and fasts on the Day of Atonement. Just as little can I accept as interpreters of homœopathy, in opposition to its founder, the men who find their profit in professing it, but hourly violate its canons in their practice. The 'Organon' clearly defines what should be called homœopathy, and as explicitly, and with the utmost opprobrium, condemns and rejects the 'mongrel system' which Dr. Jackson attributes to the Hahnemann College and its alumni. But later authorities than Hahnemann do the same thing. There are very many honest homœopathists, sincere in their delusions. Almost the last utterance of the late Dr. Adolph Lippe, who has not been dead two years, was a most scathing denunciation of those whom Dr. Jackson would have us believe are truthfully called homœopathists. As to recantation of each mistake a man may make in his lifetime, the cases are not parallel. The errors of the homœopathic system are not mere individual errors in detail, to which all of us are liable. They are fundamental; and they have been systematized into a creed; a veritable confession of faith. It is a faith that meets a public demand, and hence has a commercial value that unfitts a man for the profession of medicine, because it imprisons his judgment. Such a faith in systematized error must, if professed, be lived up to. Or it must needs be repudiated before one can be acknowledged as fitted for a calling which, above all others, demands absolute freedom from prejudice and untrammeled liberty of action. Science and 'tenets' are incompatible. Tenets are fixed. Science is progressive. Dr. Jackson has asserted that certain men do not practice homœopathy, yet they belong to homœopathic county and State societies; and it was their allegation of the existence of 'schools'—not ours—which defeated the bill for State examinations. We tried to ignore sects or schools. They declared it was an 'allopathic' scheme to suppress trade rivalry. It seems to me that, with a perversion of logic worthy of Hahnemann himself, Dr. Jackson, in endeavoring to remove from these men the stigma of ignorant dogmatism, has brought against them a much more serious accusation. If science forbids us to consult with the unqualified, surely honesty equally prevents fraternization with those who make false professions. How we are open to the charge of sectarianism I can not see. It is another specimen of

Hahnemannian logic. Because a crank chooses to flock by himself in a corner, are all the rest of mankind sectaries? We prescribe no opinions, but hold ourselves free to act or refrain from action, as our best judgment may dictate. We 'ostracize' no one. We repudiate not particular 'tenets,' but the very idea that there can be 'tenets' in medicine. It is by refusing to admit tenets that the profession has advanced in spite of past errors, and will continue to advance in spite of present errors. The door by which the members of this society entered the temple of a profession whose only demand upon its votaries is that they earnestly seek truth and honestly follow it, that same door is open for all who may elect to enter. But if, turning back from that door, men have chosen to band themselves under the title invented by the man who said that previous to him all medicine was folly, and that he had discovered the eternal and infallible law beyond which there could be no progress, such men must accept the consequences of their voluntary action. As for the scientific text-books, cited as taught at the Hahnemann College, they and Hahnemann's 'Organon' can not be fruitfully studied in the same school. You can not teach the New Testament and the doctrine of the Thugs from the same pulpit. If such were attempted, human nature would take the lower, because the easier course. It seems to me that this is wholly a matter of conscience. If the conscience of a man will allow him to take part in what I must deem deceit, that is his personal affair. It is not my place to attack or upbraid him. But when this society is asked to indorse his conduct, it becomes a different matter; and I have the right to oppose such stultification."

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the abstract of sanitary reports received by him during the week ending October 25th:

CITIES.	Week ending—	Estimated population.	Total deaths from all causes.	DEATHS FROM—									
				Cholera.	Yellow fever.	Small-pox.	Syphilis.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Miasms.	Whooping-cough.

The Ohio State Sanitary Association will hold its seventh annual meeting in Dayton, on the 21st and 22d inst., under the presidency of Dr. D. H. Beckwith, of Cleveland. The programme includes the following items:

"The Relations of Theologians to Sanitarians," by Dr. D. J. Snyder, of Scio; "Sanitation vs. Medication," by Dr. S. P. Bishop, of Delta; "Recent Advances in Aetiological Science," by Dr. E. R. Eggleston, of Mount Vernon; "Sanitation in Small Villages," by Dr. Austin Hutt,

of Waverly; "Bodily Comfort as a Sanitary Object," by Dr. G. C. Ashmun, of Cleveland; "The Influence of Climate upon so-called Malarial Fevers," by Dr. W. Owens, of Cincinnati; "The Cadaveric and Vital Alkaloids," by Professor C. C. Howard, of Columbus; "Will General Sanitation ever become Popular?" by Dr. John McCurdy, of Youngstown; "Bacteria, or the Flies we Feed on and the Bugs that Kill us," by Dr. W. S. Battles, of Shreve; the president's address—1. "The Use of Pork; its Relations to Scrofula and Consumption." 2. "Mosaic Prohibition of Pork as taught by the Scriptures, and the Prejudices of most of the Ancient Nations to its Use as Food." 3. "Description of *Trichina spiralis* and its Dangerous Effect on the Human Body"; "Food as a Therapeutic Agent," by Dr. H. J. Herrick, of Cleveland; "The Best Food for Man," by Dr. J. D. Buck, of Cincinnati; "The Relation of Water-supply to Disease," by Dr. H. J. Sharp, of London; "The Necessity of Uniform Rules, Regulations, Reports, and Records of Local Boards of Health," by Dr. F. Gunsallus, of Columbus; "The Sanitary Teachings of the Bible," by Professor E. T. Nelson, of Delaware; "The Hygiene of the Chronic Insane," by Dr. J. W. Scott, of Cleveland; "Garbage and Night-soil Crematories from a Financial and Practical Standpoint," by Dr. George I. Garrison, of Wheeling, W. Va.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

## Original Communications.

### THE TREATMENT OF THE RUPTURED PARTURIENT UTERUS, WITH A REPORT OF TWO CASES.\*

BY CHARLES A. L. REED, M. D.,

PROFESSOR OF DISEASES OF WOMEN AT THE CINCINNATI COLLEGE OF MEDICINE AND SURGERY AND AT THE CINCINNATI POLYCLINIC; FELLOW OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNÆCOLOGISTS.

TREATMENT of the ruptured parturient uterus has not as yet been formulated into definite principles, although Trask, after his first critical study of the subject in 1848, earnestly contended for some rule which would serve as a guide to the practitioner in this unfortunate emergency. It is true that he made an attempt at framing rules which would serve this important end, and did indeed take a step in advance of his time by clearly indicating his preference for abdominal section in this class of cases, stating that "neglect of this mode of delivery augmented the mortality from this accident." Yet, clear as Trask's convictions manifestly were on this subject, he could not divest himself of the conservatism of his era, and presented the conclusions of his classical research in the following words : †

" 1. When rupture occurs, where there is no disproportion between the pelvis and the head of the child, and the head remains in the cavity of the pelvis, the child being ascertained to be living, the careful employment of the forceps should be attempted; if the head retreat, perforation is to be preferred. An impaction of the head in the hollow of the pelvis would, of course, require the use of the perforator.

" 2. Should the fetus have escaped into the peritoneal cavity, the feet may be sought, and the child delivered by turning, provided there be a pelvis beyond doubt ample, a head of moderate dimensions, and the edges of the uterus uncontracted, or the rent confined chiefly to the vagina.

" 3. But as contraction of the uterus almost uniformly takes place upon the escape of the child, it will prove an obstacle to almost every case of escape of the child in which the vagina is not also involved to a very considerable degree. The performance of gastrotomy will then offer the best chances of success."

Although the foregoing conclusions were promulgated over thirty years ago, and although the researches of Jolly and Harris have since confirmed the value of abdominal section in these cases, I am convinced that the practice of to-day is practically in accord with the teachings of Trask. My warrant for this statement is not found in the details of reported cases, which are generally furnished to the journals by progressive surgeons, but it is found rather in the fact that, with few exceptions, the text-books on obstetrics teach practically the same principles of practice which were current before the modern triumphs of abdominal surgery.

Parvin, one of the latest as he is one of the ablest of

our obstetric writers, after alluding to gastrotomy in these cases, adds : \*

" But it does not follow that abdominal section should be made in all cases of uterine rupture when the foetus can be readily delivered through the normal passage, but only in those in which there has been haemorrhage or escape of amniotic fluid into the abdominal cavity; even in the latter good results have been had in some cases by washing out the peritoneal cavity through the rent with an antiseptic fluid, and securing drainage."

Lusk, in connection with the report of a recent case, says : †

" When the child can be removed through the natural passage without increasing the extent of the rupture, and the latter is confined to the lower segment, laparotomy is of doubtful value. In many such cases recovery *quoad vitam* has been obtained by the employment of antiseptic irrigation and filling the gap with antiseptic gauze. . . . The plan of treatment recommended is, of course, only effective where no infection of the abdominal cavity has taken place at the time of rupture."

It is but a few years since Leishman's work was on the text-book list of nearly all the American medical schools; in many instances it still holds its place, and consequently it has exerted, and still exerts, an important influence in molding the practice in this country. His summary of treatment is, therefore, of extreme importance. I believe that he fairly epitomizes the treatment—the average treatment—of to-day in the following words :

" On the whole evidence we must pronounce in favor of gastrotomy when the child is in the peritoneal cavity; of turning when it has remained in the cavity of the uterus; and of the forceps or perforation when the head can be easily reached within the pelvis."

These extracts from current authors are presented to show that there has been but little progress in the management of these cases since the days of Trask, and to give a brief *exposé* of a treatment which I do not believe to be in harmony with the well-established canons of modern surgery.

The points at issue can best be studied by responses to queries which occur, with practical pertinence, to the mind of the unfortunate consultant in cases of ruptured parturient uterus.

*What shall be done with the child which is yet within the ruptured uterus?*

Most cases of rupture of the uterus occur in vertex presentations, and the first objective evidence of the occurrence of the accident is recession of the head. Contraction of the longitudinal fibers is the next phenomenon, and the head, following the direction of least resistance, is forced into the rent. In some cases, however, instead of contraction of the longitudinal fibers, inertia supervenes, and labor, for the time, comes to a standstill. If, happily, the rent be now incomplete, the timely inertia arrests the extrusion of the head and saves the peritoneal cavity from invasion. It is pre-

\* Read before the American Association of Obstetricians and Gynæcologists, at Cincinnati, September 17, 1889.

\* "Science and Art of Obstetrics."

† "New York Medical Journal," September 14, 1889.

cisely this latter contingency which should dictate the treatment: *Apply the forceps and deliver at once.*

The usual alternative of the treatment is turning, as advised by Leishman. It is against this alternative that I desire to enter my protest. It should be remembered that at this juncture, as a rule, the differential diagnosis between complete and incomplete rupture can not easily be made. In this case we should always act upon the presumption that the rupture is incomplete; and our practice should be adopted with reference to saving the peritonæum. In the cases of Trask, Jolly, and Harris, turning figures as one of the primary causes of rupture. Ought we, therefore, in a case in which at least partial rupture has already weakened the uterine wall, to adopt a manœuvre which has been known to produce rupture of the uninjured wall? Clearly the proposition is as irrational as the practice is disastrous.

But there are instances in which delivery by the forceps *per vias naturales* is impracticable—*e. g.*, cicatricial bands at the internal os, and extreme kyphosis, as in Lusk's recent case already alluded to. What should be done under such circumstances? I contend that all efforts at delivery by any expedient whatever should be at once abandoned. The attempt at applying the forceps should not be made if pelvic contraction or other insurmountable obstacle to delivery is manifest; and if a single application of the forceps demonstrates the impracticability of delivery by that method, the verdict should be accepted at once. Repeated efforts at applying the forceps should be avoided, as each effort will do more or less damage to an already damaged uterus, and may thus interfere with the resolution of that organ. Turning should not be thought of. At this juncture either craniotomy or embryotomy has been practiced. The ascertained mortality of the procedure but confirms the condemnation which a rational contemplation of it furnishes. What, then, should be done? I advise that the patient be at once submitted to abdominal section, and delivery effected either by incision of the uterus, if the rupture is incomplete; through the (if necessary) enlarged rent, if the rupture is complete; and that the uterus be then treated according to either Sanger's or Porro's method, as may be indicated.

*What shall be done in cases of rupture of the uterus in which the child and after-birth have been successfully extracted by the natural passage?*

The first thing that ought to be done after successful delivery by the natural passage should be to determine, by cautious and gentle manipulation, whether or not the case is one of complete or incomplete rupture. If found to be incomplete, the case should be treated by antiseptic irrigations. I do not employ chemical antisepsis in aseptic surgery, but in this case we have to deal with an open and absorbent surface, and, very shortly, with the products of putrefaction in contact with that surface; hence it becomes eminently proper to employ either a phenolic or a mercuric-bichloride solution.

But in the event that the tear is found to communicate with the peritoneal cavity, we are at once brought face to face with one of the moot questions connected with the subject. It is just here where Parvin asserts that ab-

dominal section would not be justifiable unless "there has been haemorrhage or escape of amniotic fluid into the peritoneal cavity"; and it is precisely in these cases that Lusk tells us that "recovery *quoad vitam* has been obtained by employment of antiseptic irrigation," etc., but warns us that this plan of treatment is "only effective where no infection of the abdominal cavity has taken place at the time of rupture." How are we to know whether "there has been haemorrhage or escape of amniotic fluid into the peritoneal cavity?" By what process can we determine whether or not "infection of the abdominal cavity has taken place at the time of rupture?" Clearly, the only rational recourse at our hand is exploratory incision, and I may go a step further and say that exploratory incision, in the ordinary acceptance of the term, falls far short of the requirements of the case. Those of us who are familiar with making the toilet of the peritonæum after a bloody ovariotomy know with what facility even large clots may elude the finest tactile sensibility. It is manifest that in cases such as that under discussion nothing short of copious flushing can at once establish the diagnosis of intraperitoneal extravasation, and rid the cavity of the offending stuff.

In illustration of the importance of abdominal section under these circumstances I beg leave to call attention to the following case:\*

CASE I.—Mrs. D., aged twenty-eight, had borne three children in rapid succession and without difficulty. When seized with her fourth labor, she was compelled to rely for a time upon a midwife, as her attending physician was temporarily absent. The case was one of shoulder presentation, one arm having come down. When the physician arrived, the patient had been in active labor about three hours. Pains were excessive. Ten minutes later symptoms of shock were suddenly manifested, the presenting shoulder receded, and there was relaxation of the soft parts. With commendable presence of mind the arm was replaced, the forceps applied, and the child delivered alive. Delivery having been effected, hold was retained on the cord, and, as was then thought, a successful effort made to deliver the placenta.

I arrived five hours after the accident. With the assistance of Dr. Smolly, the abdomen was opened with an incision five inches in length, and a laceration of the uterus was found, four inches in length and involving nearly the entire anterior wall. In the rent a piece of placenta of about the size of three fingers was found. This had been torn off, probably during the efforts at dislodgment. No clots of consequence were found in the abdominal cavity. The peritoneal rent corresponded with the muscular tear. It was not so extensive as that in the other case which occurs in this report. The edges of the wound were relieved of all fringes of tissue, carefully approximated, and closed with twelve deep interrupted sutures of silk. The peritonæum was then closed by continuous catgut suture, and the abdominal incision closed in the ordinary way. The patient made an uninterrupted recovery.

If there is any case at all in which a reasonable presumption of non-contamination of the peritonæum would obtain, it would certainly be in this one; yet section revealed the existence of an altogether unsuspected condition, which, had it not been removed, would in all probability have induced septic peritonitis and death. But it is not

\* "Lancet Clinic," 1888, vol. ix.

alone to remove existing infection of the peritoneal cavity that abdominal section should be done in these cases, but it is to close the rent, and thus prevent, if possible, the migration of the germs of putrefaction from the cavity of the uterus into that of the peritonæum. It is true that this can not be done in all cases, tears low down in the posterior wall being beyond the range of operation; but, when it can be done, the edges of the wound should be carefully trimmed, approximated, and securely closed by the Czerny-Lembert suture.

*What shall be done in cases in which the child has been born, but in which the placenta has escaped into the peritoneal cavity?*

This complication occurs with relative frequency, and when it does occur it is the next in order of events to claim attention. In this class of cases we have a condition in which it would seem that removal of the placenta could be readily effected through the rent; but that it is, on the contrary, a very difficult manœuvre, is shown in the following case, which, when I was called to it, presented exactly the problem indicated in the question at the head of this paragraph. I take the liberty of presenting the case in the language of Dr. Shaller, the attending physician, as employed by him in his report to the Cincinnati Academy of Medicine: \*

"On Saturday, April 29, 1888, at 6.30 A. M., I was called to see Johanna M., in labor with her fifth child. She was a well-built, strong German woman. I learned that pain had set in at eleven o'clock Friday night, a midwife being called in at 4 A. M., though after her arrival no uterine pains occurred.

"The abdomen, while tender to pressure, was not abnormally so, and the pulse at 100 was good and full. Digital examination revealed the head engaged in the superior strait, clearly defined in its entire circumference. There was no flooding, and, abdominal pains prevailing, I gave morph. sulph., gr.  $\frac{1}{2}$ , hypodermically, and left the patient. Returning within an hour, I found her bleeding freely.

"Examination at this time showed that the head had receded. Introducing my hand, and finding the feet within easy reach, I brought them down, and the child was delivered in one hour, with bearing-down pains. The abdomen being tender, I forbore external pressure, and in this way failed to observe uterine contractions. The child was dead when born.

"After cutting the cord, I waited a short time for the expulsion of the placenta. There being no pains, I thought to take hold of the cord in order to make traction, but there was no cord to be found. Examination of the bed failed to offer any clew to the missing cord, and a digital vaginal examination met with no better success. The hand was then passed into the vagina; the cervix uteri could not be defined; and, on passing the hand higher, it suddenly seemed to have entered into an infinity of space. Never before had I realized the magnitude of the abdominal cavity, for, normally, the hand while in the vagina is grasped and limited by the surrounding tissues. For the hand to pass suddenly from a confined area into a boundless region, under the circumstances mentioned, produces rather a weakness in one's knees. To the right and anteriorly the contracted uterus was felt. The placenta could not be found; and, giving the patient two drachms of fluid extract of ergot, I left to procure assistance. I fortunately succeeded in

finding Dr. C. A. L. Reed, who proposed abdominal section for the removal of placenta and clots."

The following description of the operation is in the words of Dr. Reed:

"The operation was actually begun about 1 P. M., four hours after the discovery, and nine hours after the occurrence of the rupture; Drs. Shaller, Wenning, Mayer, and Marsh present and assisting. An incision was made about five inches in length. The uterus was found to extend well up to the umbilicus.

"While making a preliminary exploration the cord was found; taking it as a guide, the placenta was easily found lying low down in the pelvis and back of the uterus. It was now removed, and with it a number of clots. The abdomen was carefully cleansed. Search was now made for the rupture. The position of the placenta and the knowledge that the majority of such ruptures occur in the posterior aspect of the organ attracted attention in that direction. The apparent homogeneity of the structures, whether felt through the vagina or through the abdominal incision, led to further confusion. It was not until Dr. Shaller introduced his hand into the vagina and thrust his finger through the rupture that the latter could be made out. It was found on the anterior surface of the uterus, extending longitudinally from a point midway through the cervix and involving a part of the anterior vaginal wall. This description applies only to the rupture as it existed in the muscular structure; the peritoneal rupture began coincidently with the upper angle of the deeper rent, but extended off to the left, involving the anterior layer of the broad ligament and a portion of the serous covering of the bladder, leaving quite denuded an area of muscular tissue, triangular in shape, three inches and a half in perpendicular, with a base quite two inches in extent. This ragged curtain of peritonæum was turgid with extravasated blood, held firmly in the meshes of the yet adherent subserous cellular tissue.

"Two lines of sutures were employed—one deep, involving the muscular structure; the other superficial, involving the peritonæum. The sutures in the muscular tissues were of sterilized silk, interrupted, and twelve in number; the peritoneal sutures, also of sterilized silk, were thirty in number, and, with the exception of the last half-dozen applied low down in the pelvis, were after the Czerny-Lembert method. Suturing low down in the pelvis was extremely difficult, so that the double-in-and-out stitch or the so-called 'seroserosous' suture could not be applied, the simple interrupted suture being substituted. The abdominal cavity was again cleansed, and the incision closed in the usual way, a drainage-tube being left in position.

"*After-treatment.*—After the operation the pulse never went below 110, the patient resting comfortably the first twelve hours, after which, severe pain and vomiting setting in, I gave morph. sulph., gr.  $\frac{1}{2}$ , hypodermically. On Sunday, twenty-four hours after the operation, the pulse was 130; temperature, 101°; eructations frequent, no stool or flatus; the urine was drawn twice, after which it passed without pain and normally. There was no bloody discharge from the vagina; the abdomen was tender and tympanitic. Hot-water injections were given every three hours. The drainage tube was emptied of blood and cleansed with sulphurous-acid solution (one fifth) every six hours. Ice, iced milk, and brandy were given freely.

"Thirty-six hours after the operation vomiting set in, with increase of pain and tympanites. The second dose of morph. sulph. was administered. Calomel,  $\frac{1}{2}$  grain every half-hour. Temperature, 102°; pulse, 140. Slight bloody discharge from vagina. A rectal injection of pure glycerin, later hot water, and still later the introduction of a rectal tube, failed to pro-

\* "Lancet Clinic," 1888, vol. ix, p. 515.

duce stool or wind. Grains xx of calomel were given in one dose. Forty-eight hours after the operation the extremities became cold, pulse feeble, slight delirium, tympanites very great, no stool. The patient died Monday at 6 p. m., fifty-four hours after the operation, from the effects of peritonitis."

This case is one which demonstrates the serious nature of injury to which the uterus is subject by rupture. There can be no doubt but that the parenchyma of the organ sustained serious damage by the contractions which ultimately provoked the rupture, that this damage existed in the fibers of the uterus in an area much more extensive than that involved by the tear. I have often felt that I should have done a Porro operation in this case, but I was deterred by two considerations—viz., first, all of the damaged tissue could not be removed by supra-vaginal amputation of the uterus; and, secondly, I did not go prepared to do the latter operation. It has occurred to me that the long retention of the placenta and clots before the operation had already given rise to peritonitis, which proved to be the fatal factor in the case.

*What shall be done in cases in which the child, or the placenta, or both, have escaped into the peritoneal cavity?*

It would seem that the duty of the practitioner is clear under these circumstances. Yet, when he turns to our authors, he finds himself led in both directions at once. He finds himself taught that abdominal section should be done in cases of evident contamination of the abdominal cavity; he is told that the operation should not be done in all cases in which "the foetus can be readily delivered through the natural passage"; and he is reminded of recoveries from antiseptic irrigations and antiseptic gauze packs; and then he wonders whether, indeed, it be possible to gain direction out of indirection. He is left entirely on his own responsibility, and to solve the problem strictly on its merits.

The first fact to claim attention is that the uterus, in the act of rupturing, must have discharged some blood into the peritoneal cavity; and the next is, that the child and placenta must have carried with them more or less of detritus. Amniotic fluid may have found its way into the abdomen. These considerations alone should prompt abdominal section—if not for the purposes of delivery, yet for the purposes of cleanliness. If the abdomen is to be opened for the purpose of flushing, why not effect delivery through the incision at the same time? There are other considerations prompting to this course. The advice of Parvin, that abdominal section should not be done when the foetus can "be readily delivered through the natural passage," is liable to a dangerous interpretation at the hands of practitioners who are anxious to evade the responsibilities of the knife. With them "ready delivery" is liable to imply not merely the introduction of the hand, which is not devoid of danger; nor the mere grasping of the presenting part, which is not always easy; nor the mere turning in the abdominal cavity, which is always hazardous; but a test of the tactile power of the operator and the resistant power of the patient. In this way patients may be subjected to a hazard which the knife in the hands of a skillful operator could not incur.

But we are "informed" that good results have been had

in some cases by "washing out the peritoneal cavity through the rent with an antiseptic fluid and securing drainage"; and, again, we are told of recoveries by "employment of antiseptic irrigation and filling the gap with antiseptic gauze." I will not dispute the fact of such recoveries, for they are well authenticated, but I can not but concur with Harris that every such recovery is to be looked upon as a misfortune, tending, as it does, to stimulate others to persist in a practice that is essentially unscientific.

The only danger to life, however, does not come from extraperitoneal infection, which may have found its way into the cavity at the time of rupture, or that may have been carried thither by the child, or the placenta, or both, nor yet that may have subsequently traversed the wound in the form of lochia. It must be remembered that the parenchyma of the uterus has sustained serious damage (1) by its own violent contractions, (2) by the rupture, (3) may be by the use of the forceps, (4) by the escape of the child through the tear, (5) by repeated digital examinations, (6) by the introduction of the hand, (7) by efforts at traction to determine the feasibility of delivery *per vias naturales*, and (8) by the forcible withdrawal of the child through the rent. All these influences may have been brought to bear upon a uterus before the surgeon is called. What prospect has such a damaged uterus for resolution? Is it not much more liable to become the breeding-ground of septic germs that may have originated in the first instance at the placental site? And, if we thus have established a suppurative parenchymatous metritis, is not the death of the patient from septicæmia almost a foregone conclusion? In the light of these considerations extirpation of the uterus is clearly indicated, and should be recognized as a definite probability in undertaking abdominal section in these cases.

The conclusions to which my brief studies and limited experience force me are as follows, viz.:

1. In cases of rupture of the uteruses, with the head presenting, delivery by forceps should be attempted, but should be abandoned if not found easily practicable. Turning should not be undertaken, but the ease should be at once recognized as one for either the Cæsarean or Porro operation.

2. In cases of ascertained incomplete rupture, treatment should be by antiseptic irrigations and rest.

3. All cases of ascertained complete rupture should be submitted to abdominal section so soon as the condition of the patient with reference to shock will admit, for the following purposes—viz., (1) to explore the abdomen, (2) to remove all foreign bodies, (3) to cleanse the peritoneum, (4) to close the rent if the labor has been short and the uterus not seriously damaged, and (5) to remove the uteruses if the labor has been long and the uterus seriously damaged.

---

**Hydrocephalus.**—Dr. Rodionoff mentions in the 'Meditinskoë Obozrenië' a somewhat remarkable case of recovery from chronic hydrocephalus in a child of eleven months old. The mother took good care of it until it was two years old, and then left it to itself. It was thus exposed to a hot sun for many weeks, and, strange to say, a year later the size of the head had diminished, and the child was able to creep about. When it was four years old the hydrocephalus had disappeared, and the child was able to talk. Dr. Rodionoff seems disposed to refer the cure to the action of the sun's rays."—*Lancet*.

## ABSCESS OF THE BRAIN.\*

By T. M. MARKOE, M.D.

A. R., aged twenty-two, native of Syria, peddler, was admitted to the New York Hospital October 2, 1888. He was found in a cellar in a stupid condition, and could give no satisfactory account of himself, nor could he explain how he got into the position in which he was found. It was ascertained, however, that a year before the present accident he had received, while in Havana, an injury of the head. Of this injury there existed as evidence a crucial cicatrix, considerably depressed into the thickness of the scalp, but not suggesting depression of bone. Near the center of this cicatrix is a soft spot, as if at that point the bone was deficient. This scar, which is from an inch and a half to two inches in its longest diameter, is situated parallel to and about half an inch behind the fissure of Rolando, and is firm and sound, and free from any sign of inflammation. His mental condition is dull and apathetic. Pupils normal and react naturally to light. The face gives some signs of paralysis in the obliteration of the wrinkles of the forehead on the right side, slight drooping of the right upper eyelid, and some drawing of the right corner of the mouth. Extrusion of tongue normal. The right arm shows no difference in sensation from the opposite side, but there is a marked indisposition on the patient's part to move it, especially as high as his head. Right leg, some sluggishness of movement, not so marked as in the right arm. His pulse was 68, respiration 21, temperature 100.6° F. He is in a condition of active salivation, but for what the mercury was administered he could not explain.

He was kept quiet in bed and bromide of sodium and iodide of potassium, in doses of thirty grains of the former and ten of the latter, were given three times a day. On the 4th he was occasionally delirious, the delirium not being of a violent character.

*October 5th.*—To day he had a convulsion which was repeated five times, at intervals of from an hour and a half to three hours. Each convolution began with twitching of the muscles of the right side of the face, then of the right arm, extending to the right leg, and then becoming general. Each attack lasted about five minutes, during which there was no change in the pupils.

*6th.*—Two more convulsions to-day of the same character. In the intervals no change could be noticed in his mental condition, the pulse and temperature remaining almost unchanged.

Under the conviction that the symptoms depended upon a meningeal inflammation in the region of the scar of the old injury, vesication with blistering collodion was established over the injured region, covering a space as large as the palm of the hand.

*11th.*—Since last note the temperature has been normal. He has otherwise remained in the same condition as before. He has had an occasional convolution of the same character as those described above. The temperature to-day has risen to 101.6°. He also complains of pain in his head, and is more restless than he has heretofore been. The sensation both of arm and leg on the affected side lessened distinctly.

*12th.*—Both pulse and temperature increased. Examination of scalp showed a fluctuating tumor within the region of vesication, just in front of the old cicatrix, extending over the frontal and parietal region. The left eye closed by oedema of the lids from the proximity of inflammatory swelling. The abscess was opened by a free incision, through which the finger detects bare

bone. Much relief was given by the release of the pus, so that the patient seemed a little brighter. Before the abscess was opened the temperature reached 101°; now about normal.

Taking into consideration the facts that no real improvement had taken place in the man's condition, that the signs of pressure were rather increasing than diminishing, and that the progression of the symptoms gave reasonable ground for believing that intracranial suppuration had already taken place, it was decided that an operation was not only justifiable, but that it afforded the only prospect of relief. After more than usually careful and thorough antiseptic preparation of the shaven scalp, the operation was performed October 13th.

The incision already made for the evacuation of the subcutaneous abscess was enlarged so as to expose the region of original bone injury. The skull was found to be deficient over a space oval in shape and covering more than two square inches. This bone deficiency was filled by a firm, thick, fibrous-looking membrane in which no bone could be detected. The appearances were those of a skull which had been trephined and in which the deficiency had been filled by the usual fibrous cicatrix. Everything about the external surface of this cicatrix was normal. The next step of the operation was to remove this cicatrix and expose the surface of the brain, for it was rightly judged that the cicatrix involved both dura mater and pericranium, and was therefore in direct contact with the cerebral surface. While doing this very carefully with the scissors, and before it was more than half completed, pus began to ooze out and soon flowed freely. About three ounces were evacuated of thick, curdy pus. The removal of the remainder of the cicatrix disclosed the orifice of a cavity extending nearly three inches into the substance of the brain, the walls of which cavity, as far as could be ascertained by the finger passed over them, consisted of unaltered brain substance. After the full evacuation of the abscess cavity a large drainage-tube was introduced, the cutaneous flaps were approximated by a few sutures, and a light antiseptic dressing was applied.

*14th.*—Some improvement seems to have followed the evacuation of the cerebral abscess. He is more intelligent, and takes more notice of what is going on about him; is less restless, and in every way more comfortable. The dressings were changed after thirty-six hours, and the tube shortened an inch.

*15th.*—Temperature rose to 101° yesterday, but to-day it is nearly normal. Tube found in the dressings. Discharge free, saturating the dressings. Decided improvement in mental condition. He recognized me to-day, and tried to say he felt better, and to put out his hand to shake mine.

*16th.*—Has had no convolution since the operation. There is marked protrusion of brain-substance into the wound, in the center of which protrusion is an opening, which discharges freely, from which the tube has been removed.

*17th.*—Without any marked change of symptoms, the wound is assuming more and more distinctly the character of fungus cerebri of the non-reparative and unfavorable kind. Discharge quite free.

*20th.*—No new features have presented themselves till this afternoon, when he became very restless and complained of a great deal of pain in his head. Slight delirium returned for the first time since the operation. His temperature rose rapidly to 105°, and the pulse reached 130, the pupils at the same time becoming contracted.

Thinking that this sudden inflammatory access might depend upon retention of pus in the cavity of the abscess, the opening was enlarged, and a small drainage-tube pushed into the cavity. This gave issue to some retained pus. The drainage-tube penetrated to the extent of three inches. This gave slight temporary improvement of pulse and temperature, but the evidences

\* Read before the New York Surgical Society, October 9, 1889.

of paralysis became more and more marked. In fact, the symptoms of general meningitis became more and more distinctly recognizable. Temperature ranged from  $102^{\circ}$  to  $105^{\circ}$ . Stupor deepened daily. Cheyne-Stokes respiration, and death on October 25th, twelve days after the operation.

*Autopsy.*—There are two incisions in the scalp crossing each other over the center of the left parietal bone, each incision being about four inches in length. Beneath the flaps thus made there is an opening through the calvaria, from which a fungoid mass protrudes. This opening is situated in the left parietal bone, is oval in shape, its long diameter being an inch and five eighths, and its shortest being an inch and an eighth. It extends from about half an inch to the left of the interparietal suture, and reaches within a few lines of the temporal ridge. Anteriorly it approaches the coronal suture within about half an inch. The precise situation of the abscess cavity is the most important feature of this description. The cavity has a diameter of an inch and a depth of an inch and a quarter. This shows a diminution of at least two thirds since the evacuation of the abscess. The orifice of the cavity would admit easily the little finger, and is surrounded, and in fact formed, by a mass of granulation-substance, which projects from the surface of the hemisphere about an inch, more abundant anteriorly than posteriorly. The meninges are consolidated and adherent to brain-surface all round the orifice of the cavity, most extensively on its front boundary. No evidence of general meningeal inflammation. The topography of the abscess cavity brings it anterior to the fissure of Rolando, which its posterior border skirts very closely for about an inch. It approaches the longitudinal fissure within perhaps four lines, and anteriorly it occupies the posterior part of the second and a portion of the first frontal convolution, reaching downward to, and perhaps encroaching on, the third frontal convolution. The main development of the abscess, therefore, was in the middle portion of the ascending frontal convolution, with the boundaries above indicated.

The case thus presented offers several points worthy of special note. In the first place, it illustrates the general law, so strongly insisted on by von Bergmann, that abscess of the substance of the cerebral lobes, exception being made of metastatic and tubercular abscesses, is never primary or idiopathic, but always depends upon some traumatism, or upon some focus of suppuration outside of the brain substance itself. In this case the abscess was undoubtedly the result of a double trauma, first an old compound fracture with its resultant cicatrix, and second a recent injury, probably caused by his fall into the cellar in which he was found. That these injuries were the starting-points of the suppuration seems to be indicated not merely by their juxtaposition, but also by the fact that the cicatricial disc which closed the old trephine hole was in fact the superficial or external wall of the pus cavity. In the second place, it is well to note that the absence of high temperature does not necessarily exclude the diagnosis of cerebral abscess. In this case the temperature remained near the normal point throughout, except for two or three days, when it rose nearly to  $102^{\circ}$  in consequence of an acute suppuration under the scalp after the blistering. It will be noted that after this superficial abscess was opened the temperature fell nearly to the normal point. The pulse also during the whole observation was not materially accelerated. Just before death the sudden rise of temperature to  $105^{\circ}$  and of the pulse to 130 seemed to indicate general men-

ingitis, which, however, on post-mortem, could not be verified.

A third point of interest in the case is its bearing on the doctrine of cerebral localization. The clinical symptoms pointed unmistakably to the seat of the lesion as revealed by the autopsy; but it may be noticed that the paretic symptoms were at no time strongly pronounced. He could at all times move both arm and leg, but the movements were so feeble and so imperfect, particularly of the arm, that a moderate degree of paralysis could not be doubted. The convulsions, also, beginning in the face, then attacking the arm, and finally the leg, pointed to the middle portion of the fissure of Rolando as their anatomical seat; but, inasmuch as, with the extensive lesion discovered after death, the symptoms during life were so very slight, so far as paralysis is concerned, some explanation seems desirable of the want of quantitative correspondence between the two. It has occurred to me, in thinking over these features of the case, that perhaps the position of the lesion might help us to this explanation, and I have reasoned in this way. All the experimentalists on localization seem to agree in stating that the centers for face, arm, and leg lie in the convolutions on each side of the fissure of Rolando, and not on either one side or the other alone. Thus, to quote from Landois: "The center for the face occupies the lowest third of the ascending frontal convolution and reaches also on the lowest fifth of the ascending parietal. The arm-center occupies the middle third of the ascending frontal and middle three fifths of the ascending parietal convolutions, while the leg-center lies at the upper end of the sulcus and extends backward into the parietal lobule and perhaps on to the superior frontal convolution." This being the accepted view of the extent of the different centers on both sides of the fissure, the fact that the lesion we are studying occupied only one side of the fissure—namely, the ascending frontal convolution, while the ascending parietal convolution on the other side was not involved—seems to me to be a possible and even a probable explanation of the marked want of correspondence between the clinical and the pathological features of the case.

It is to be regretted that no satisfactory examination of his speech condition could be made. He could not speak or understand a word of English, and was, besides, of so low an order of intelligence that in the half-comatose condition induced by the injury we could draw no reliable inferences from his slow and half mumbled expression. This observation would have been the more valuable as the lesion closely approached the posterior part of the third left frontal convolution.

#### SOME OF THE MANIFESTATIONS OF SYPHILIS OF THE UPPER AIR-PASSAGES.\*

By THOMAS AMORY DE BLOIS, M. D.,  
BOSTON.

In bringing before you this well-worn subject, it is merely to chronicle a few of the different forms of cases as

\* Read before the American Laryngological Association at its eleventh annual congress.

seen by the laryngologist in his daily practice, perhaps showing what we may do and what we had better leave undone, with a view of preventing some of the horrible deformities which are so often the sequelæ of syphilis in its nasal and buccal lesions.

It would be most natural to divide the subject into three local varieties—according to whether it occurs in the nasal passages, the pharynx, or the larynx; and these in turn according to its attacking the soft or the deeper or hard structures—call it secondary or tertiary if you will.

The “plaque muqueuse” of the nose is rare compared to the occurrence of “patches” in other localities. I have never known it to resist the ordinary astringent treatment. But when the cartilaginous septum of the nose is attacked it is a very different matter; perforation inevitably follows, and it is with great difficulty that the necrosis is arrested, the process creeping along beneath the mucous surface, and it is generally not checked until it reaches the surrounding bony structures. The falling in of the end of the nose does not necessarily follow; I have seen many cases where the nose was to outward appearance intact, but was within a ruin.

The turbinates and vomer frequently die and remain entombed, the nares being too small to allow of their removal whole.

Two years ago, at the Boston City Hospital, I had a case of this kind, the sequestrum being too tough to be cut with the forceps, and it was without sufficient support to allow of being drilled through with the dental engine. It was found necessary to split up the nose, and I then removed the vomer and one turbinate with the forceps. Long drills will frequently be found convenient for detaching and removing these fragments. Perforations into the antrum are most disastrous in their results, because it is so difficult to properly treat and cleanse these localities and remove what necrosed tissue may exist.

J. W., a fireman by occupation, contracted syphilis six years previous to my seeing him. He had a large perforation into the right antrum. Neerosis was still progressing rapidly; the foetus was fearful. I removed pieces of dead bone many times, and curetted whenever and wherever possible. He was obliged to leave the fire department on account of the disagreeable odor, and he disappeared unrelieved.

When the destruction of bone extends from the anterior nares down around the incisor teeth, these should be removed, and the necrosed alveolar plates drilled out with the dental burr. It will be found that this operation is an exceedingly bloody one. Iodoform and tannin blown with a great deal of force up into the empty tooth cavities is a good antiseptic dressing.

A. F., an Italian, a Boston Dispensary patient, had syphilis of unknown duration even to himself. One central incisor tooth had come away and one was removed; the drill passed easily up into the nares, through the alveolar processes, which were easily removed, shortening the dental arch considerably. He improved somewhat under large doses of iodide of potassium, the bichloride pill, and cod-liver oil.

The loss of the anterior nasal spine of the superior maxillaries is followed by the frog-like deformity which

disfigures so much. If any treatment short of excision of the bone is possible, it certainly should be diligently followed, for the aspect of the face is more repulsive than when the cartilaginous septum is entirely gone.

In the mouth and pharynx we find our most usual field of syphilitic affections, and, although the destruction of the soft parts advances with lightning-like rapidity, yet it seems as if Nature were here more lavish in her restoring processes.

The perforating ulcer of the velum is the ordinary form which the lesion takes, and, as the part is in such constant motion, the healing is rendered doubly difficult.

It is useless to employ any form of local treatment before the patient is fully under the influence of medicines, and, although mercury is necessary, yet the greatest reliance must be placed on the potassic iodide. Its quick effect upon the symptoms of syphilis is certainly the greatest help we have at our command. In most cases the destructive process may be retarded or checked in twenty-four hours, but sometimes a much longer period is required.

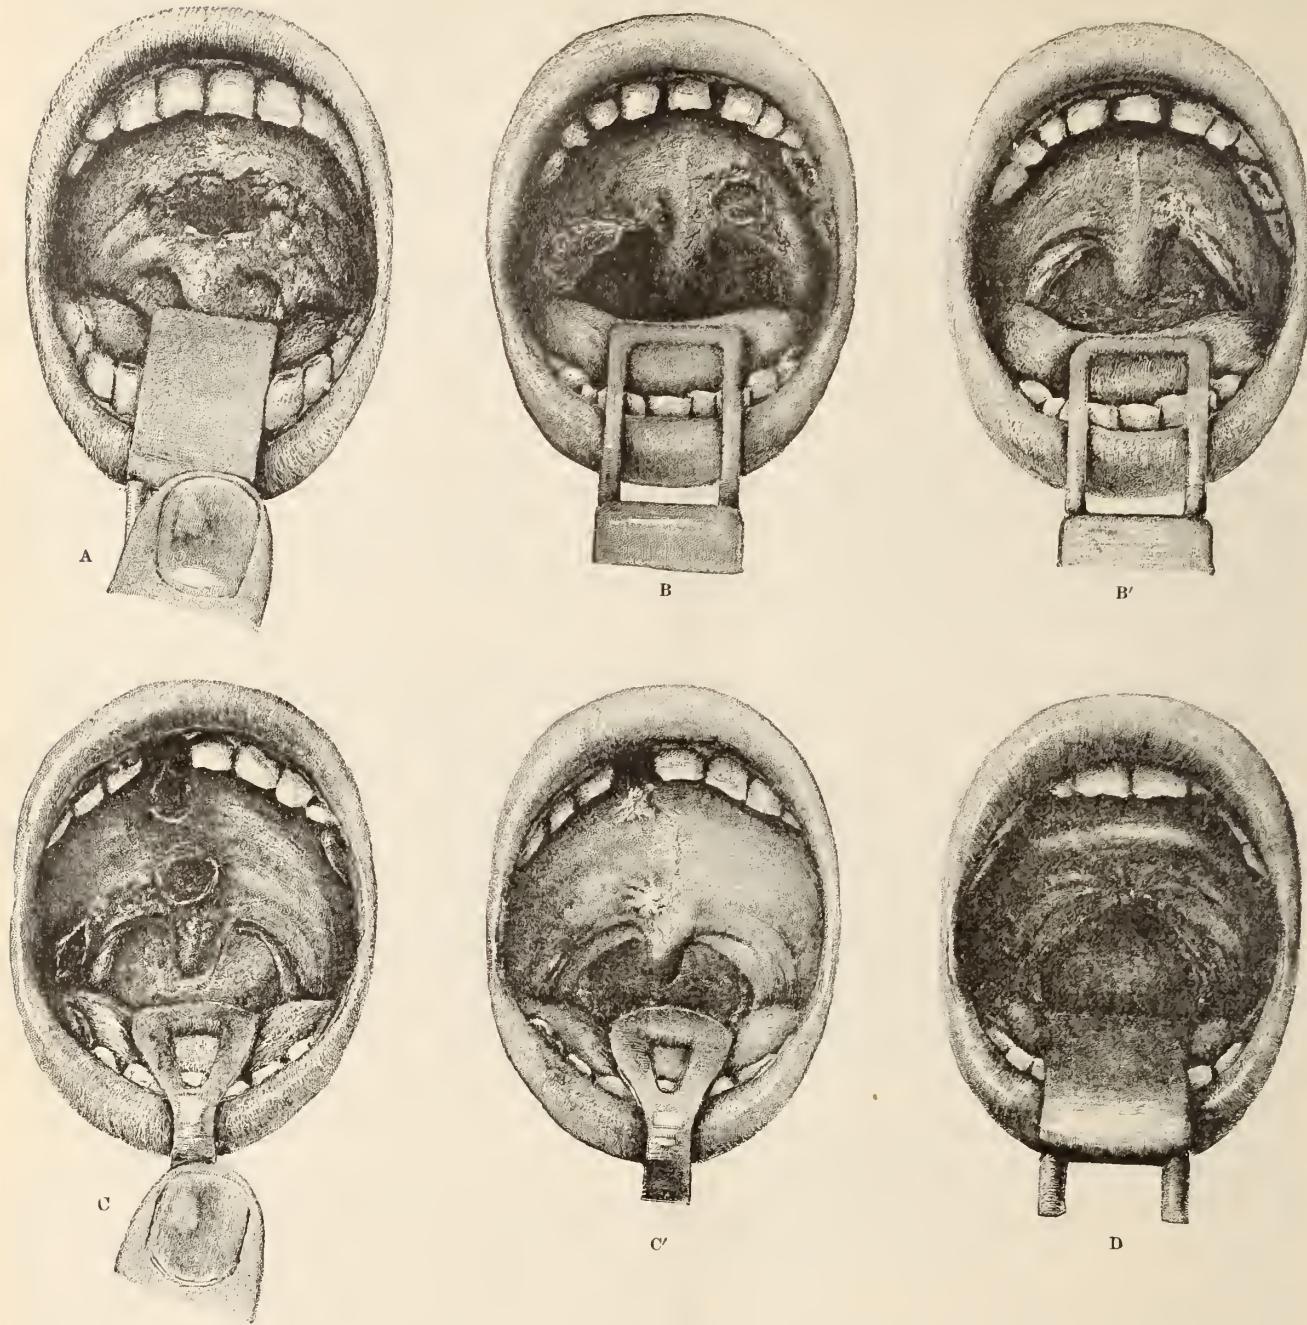

The sketch (A) is from the ease of Mr. C., a theatrical manager, who was sent to me, having been under treatment with stillingia for some weeks, during which time the largest single perforation I ever saw had progressed to the size shown in the diagram. After he had been on the iodide for about forty-eight hours I freshened the edges of the ulcer and brought them together with silk sutures; at the end of another day these had completely sloughed out. I attributed my want of success to having been too hasty in my procedures. I then increased the iodide and used the stick nitrate of silver as a caustic and stimulant; under this treatment the perforation closed gradually. I never allowed the edges to harden, and finally, although the opening never closed entirely, it was reduced to such a size that a probe could with difficulty be passed through it, and speech and deglutition were normal.

In a few other cases, where the perforation was not so large, entire closure was effected without suturing.

Mrs. K., a married lady, who had contracted syphilis and concealed it from her husband, and whose palate I was very anxious to save, I had the same experience with. As the transverse perforation was very large, I was afraid one of the two isthmuses would slough, so I sutured very soon after seeing the ease. But the sutures sloughed out, and one isthmus also, so that the semi-detached portion hung down on one side, and finally, after causing a great deal of trouble in swallowing, was to a great extent absorbed, and remained as a kind of excrescence at the side of the tonsil excision having been declined.

Mrs. R. (sketches B and B') showed another example of a perforation which did not heal until the isthmus had been cut through, treatment not having been commenced soon enough. The deep ulcer behind the right pillar was prevented from forming cicatrical adhesions by frequently being stretched open with a probang.

Mrs. T. (sketches C and C'), also a married lady. In this ease there was a perforation of the soft palate, with one through the anterior pillar, and a third through the mucous membrane and involving the bony palate. In this case the perforations were treated with nitrate of silver, and the denuded and necrosed palate was curetted with a sharp scoop; the openings healed rapidly, except the one near the tonsil, which, although it healed, never closed.

Of three other cases involving the hard palate, in two the opening healed, in one after curetting and in one after being burred out with the dental burr. In one case, after being burred out under ether and once with cocaine, it did not heal, and finally, after a good deal of neerosis had taken place, the palate plate was removed with forceps at the Boston Dispensary by my colleague, Dr. J. W. Farlow.

Miss N. H., an actress, came to my office complaining that a furuncle had ruptured in her mouth. On examination, I found that there were two syphilitic ulcers involving and exposing the bones of the hard palate. The lower surface was cut out with the burr and the edges were stimulated with caustic, and they healed quickly under iodide of potassium and the corrosive chloride of mercury.

Mrs. O. D. B. (sketch D) had had loss of substance of the soft palate, which had adhered to the pharyngeal wall, quite high up. This closed the posterior nares and occasioned great

discomfort. In syringing through the nose I found that there was, as is usual in these cases, a very small opening into the mouth. This I carefully stretched until the nozzle of a syringe could be passed through. I refrained from detaching the velum from its new adhesions, for, whereas phonation was almost normal (as is invariably the case where the attachment is high) and deglutition all that could be wished, yet I knew that, if the palate were even successfully detached, neither function would continue, without the use of an obturator plate, on account of the great shortening of the velum.

Passing on to the larynx, we find that the worst results in this locality are from the cicatricial adhesions which so frequently take place.

Mr. G. F. had had a certain loss of substance on the tip of the epiglottis, and also bands of cicatricial tissue binding it down on the left side as far as the arytenoid, which was thus greatly crippled in its action. When I first saw him, ten years after

the first infection, he was almost voiceless. Very little effect, except to increase the inflammation, was derived from such operative measures as dilating and stretching the parts. Medication, and the consequent absorption which took place, was of great benefit, and his voice is now quite audible, the motion having been greatly increased and vicarious action from the other side set up.

I might, in conclusion, draw attention to my poor results in any attempt at operative procedures during the activity of the ulcerative lesions of syphilis, for at that time the vitality of the parts seems to be much more feeble. But when, through the action of medicine, the ulceration is apparently arrested, it is the proper time to endeavor to correct or prevent deformities.

In removing necrosed portions of the hard palate with the drill, burr, or trephine, it seems advisable not to perforate the bone, for not only would a fistulous opening be very apt to follow, but, should this not be the case, there would be much more scar contraction than if the outline of the bony parts was left.

## INTESTINAL SUPERDIGESTION.

BY W. S. CHRISTOPHER, M. D.,

DEMONSTRATOR OF CHEMISTRY, MEDICAL COLLEGE OF OHIO, CINCINNATI.

THERE is a very prevalent misconception of the conditions of the so-called intestinal fermentation. The idea seems to be very general that fermentation is opposed to digestion—that is to say, that a food may either be digested or undergo a fermentation, but can not be both digested and fermented. Fermentation, broadly speaking, includes digestion, which is the normal or physiological fermentation which food undergoes previous to its absorption. But the fermentation referred to above is not used in this sense, but in the narrower one of pathological fermentation. In studying this subject it must, however, be borne in mind that the digestive processes are fermentations; that they are induced by soluble or unorganized ferments,\* and that the pathological fermentations are maintained by organized ferment—different micro-organisms.

Many organized ferments require that the substances which they are to act upon shall first have been modified by some other ferment, either soluble or organized, before they can exert their peculiar action. For instance, the yeast-plant can not ferment cane-sugar directly, while it can induce the alcoholic fermentation in the glucoses. In the fermentation of cane-sugar by the yeast-plant, the sugar is first inverted—that is, transformed into dextrose and levulose, two glucoses—before the alcoholic fermentation occurs. The inverting of the cane-sugar is accomplished by a soluble ferment which accompanies and is probably produced by the yeast-plant itself. At all events, its action precedes the alcoholic fermentation induced by the plant. Similarly, according to Schützenberger, the butyric fermentation is usually, perhaps invariably, preceded by the lactic

fermentation. It seems that certain changes in the albuminous constituents of milk are produced by the lactic ferment, which fit these albumins to nourish the butyric ferment, and thus enable it to grow.

Another illustration of this peculiarity of ferments is found in the different organisms which prevail at different times during the progress of a putrefaction. To what extent the varying susceptibility of individuals to infectious diseases illustrates this phenomenon is not yet known.

In the gastric digestion of proteids the process ends with the formation of peptones, but in pancreatic (tryptic) digestion of proteids the decomposition of the albuminoid molecule is more profound, and we find in addition to the peptones leucine, tyrosine, hypoxanthine, aspartic acid, and glycocoll. With these products the fermenting action of the pancreatic juice probably ends, but this action has paved the way for the growth of micro-organisms, which flourish among the products of the tryptic digestion, and, as the result of their action upon these products, there are produced such bodies as indol, scatol, phenol, fatty acids, ammonia, hydrogen, sulphuretted hydrogen, carbonic acid, and ptomaines (Ewald, Charles, and Landois).

In making artificial digestion experiments, the readiness with which putrefaction sets up in the pancreatic digestion of proteids is very striking, particularly when compared with gastric processes.

Now, since this putrefactive process is impressed upon the products of the digestion, and is not a change produced in the original food-stuff itself, but rather a continuation of the decomposition processes set up in the albuminoid molecule by the digestive ferment proper, it seems to me that the term superdigestion fitly characterizes it. Certainly the term indigestion is eminently improper and misleading.

In general terms, superdigestion may be defined as pathological fermentation of the products of normal digestion. It is always induced by micro-organisms, and varies according to the food.

We may therefore have—

- a. Superdigestion of proteids.
- b. Superdigestion of fats.
- c. Superdigestion of carbohydrates.

*a. Superdigestion of Proteids.*—Proteids are digested both by the gastric and by the pancreatic juices, but hyperdigestion of the products of gastric digestion is infrequent, at least in the stomach, while further change of the pancreatic products is exceedingly common. This difference is probably due less to any doubtful antiseptic action on the part of the gastric juice than to the difference in extent of the digestion or decomposition of the albuminoid molecule produced by the two juices. We may dismiss stomachic superdigestion of proteids and confine ourselves to that which occurs in the intestine. The most interesting of the intestinal decomposition products of proteids, for our present purpose, are the fatty acids, the ptomaines, and the gases, which latter comprise carbonic acid gas, ammonia, nitrogen, hydrogen, marsh gas, and sulphuretted hydrogen. Certain of the gases unite with each other and form non-volatile salts, and others are formed in relatively small amount, so that in this form of superdigestion glutin-

\* Fermentations by micro-organisms, producing the same products as the soluble digestive ferments, have no bearing on the present discussion, and are not here referred to.

lence is not a marked symptom, excepting in certain cases of diarrhoea-producing pntrefactions, and then the origin of the gas is by no means certain.

The fatty acids do not accumulate in sufficient quantity to produce a strong acid reaction in the intestine, and probably, therefore, do not cause pain. In their further decomposition the fatty acids give rise to gases. The ptomaines are the important products of the hyperdigestion of proteids. These bodies are alkaloids, and, like the vegetable alkaloids, produce their effects through the agency of the central nervous system. They are partly excreted with the faeces, and in part absorbed. After absorption they have another gantlet to run in the liver, one of whose functions, as Schiff has shown, is to destroy these bodies. Consequently, it is only when they are formed in excess, or the liver fails to destroy them, that they gain entrance to the general circulation and produce general effects. The nature of the symptoms produced by the ptomaines varies according to the physiological properties of the ptomaine produced. A not uncommon group of symptoms produced in this way comprises constipation, headache, drowsiness, and listlessness, or even a marked depression—the so-called biliousness. Here there seems to be at work a ptomaine or ptomaines possessing the properties of morphine and curare. In infants to whom no opium had been given, but in whose intestines a proteid superdigestion was present, I have occasionally seen the following symptoms: Constipation, coma, contracted pupils, slow and shallow respiration, and a depressed heart-action.

It is exceedingly common to find, particularly in young children, a sudden high fever, often preceded by a convolution, which can be attributed to nothing else than an intestinal putrefaction, and which disappears completely and finally when a brisk cathartic has removed the putrid contents of the bowel. In infants, conditions closely resembling typhoid fever, but only lasting two or three days, may be attributed to a similar cause.

Certain eruptions on the skin betoken poisoning from the intestinal canal, particularly erythematous eruptions.

I have elsewhere ("Medical News," March 3, 1888) expressed my belief in superdigestion being the important factor in the etiology of summer complaint.

Generally speaking, the superdigestion of proteids plays a more important rôle in infants and young children than it does in adults.

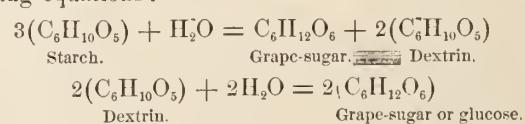

The treatment of the condition follows from its pathology, and consists, first, in the use of a cathartic—preferably calomel—to remove the putrefying masses from the intestine; second, in the administration of an intestinal antiseptic, of which naphthaline is my own favorite, but good ones are found in salol, bismuth salicylate, quinine tannate, and small doses of calomel; and, finally, in withholding all albuminous food until the abnormal process in the intestine has entirely ceased. Of these three steps, the most important is the one relating to diet. By it alone many cases can be controlled. The least important is the use of intestinal antiseptics, and much disappointment arises from depending upon this means alone.

*b. Superdigestion of Fats.*—The great bulk of the fats

ingested are normally rendered absorbable by emulsification. Normally a small proportion of the fats and abnormally a larger one undergoes a decomposition into glycerin and the corresponding fatty acid. As already indicated, the fatty acids themselves break up under the influence of certain organized fermentations, yielding gases—to wit, carbonic-acid gas, hydrogen, and marsh gas. It is somewhat doubtful whether even the small amount of fats which is decomposed into glycerin and fatty acids, under apparently normal conditions, is a process essential to the digestion of these substances, and when a large proportion of the fats ingested undergoes this decomposition, either before or after emulsification has occurred, it must be regarded as a superdigestion. The subsequent gaseous decomposition of the fatty acids is unquestionably a superdigestion. Owing to the comparatively small amount of fat taken as a food, the gases resulting from its fermentation do not of themselves constitute an important clinical factor; but when they go to increase the flatulence produced by other decompositions they must be taken into consideration.

For reasons which will appear further on, the gaseous fermentation of fats occurs most frequently in connection with the gaseous fermentation of carbohydrates.

*c. Superdigestion of Carbohydrates.*—The carbohydrates used as foods are starch, cane-sugar, maltose, lactose, and glucose. Cellulose is a carbohydrate which is found in connection with other carbohydrates in many substances used as foods. It has a pathological but not a physiological importance. Starch is digested both by the saliva and by the amylolytic ferment of the pancreatic juice. The action of the saliva occurs in the mouth, and continues, to some extent at least, in the stomach, for the experiments of Chittenden and Griswold show that the presence of 0·005 per cent. of hydrochloric acid increases the diastatic action of the saliva, while a stronger acid diminishes it, 0·1 to 0·4 per cent. being sufficient to completely stop the action of the saliva. Nevertheless, even in the presence of the comparatively stronger acid, peptones which are found in the stomach in the digestion of proteids are capable of stimulating the saliva to increased action (Charles, "Physiological Chemistry"). This fact plays an important rôle in the treatment of the superdigestion of carbohydrates in the intestine. The digestion of starch by the saliva, by the pancreatic juice, and by diastase may be represented by the following equations:

According to Mering, the action of saliva on starch produces dextrin and maltose,  $C_{12}H_{22}O_{11}$ . But whether grape-sugar or maltose is produced by this action is immaterial to our present purpose, as both may subsequently undergo the same pathological fermentations.

Cane-sugar and lactose, both of which are saccharoses and have the same formula, are digested by being inverted, that is, by being broken up into dextrose and levulose, both of which are glucoses. The action occurs in the intestine and may be represented as follows:

It will thus be seen that all the carbohydrates in their normal digestion are converted into glucoses.

It now remains to be seen what abnormal fermentations the glucoses may undergo in the small intestine. In the first place, glucose, under the influence of one or other of the many lactic ferments, is transformed into lactic acid, which substance, when present in the intestine in large quantity, seems to be a cause of pain.

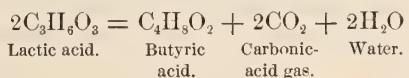

The reaction is as follows:

Lactose may break up directly into lactic acid, thus:

The lactic acid is then acted upon by the butyric ferment, if it be present, with the following result:

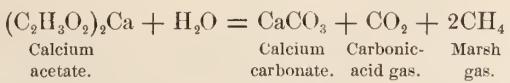

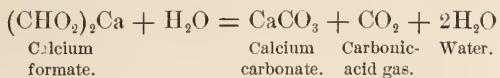

The alcoholic fermentation under the influence of yeast may also occur:

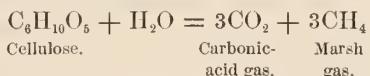

The alcohol may then undergo the acetous fermentation thus:

The following fermentations of the lime salts of fatty acids, which are induced by micro-organisms, should also be noted:

Cellulose, which has been referred to as a carbohydrate ingested with certain food-stuffs, undergoes the following gaseous fermentation under the influence of some micro-organism not as yet isolated:

In summing up, we find that glucose may undergo the alcoholic fermentation with liberation of carbonic-acid gas, or it may be converted into one of several fatty acids, and these, breaking up in their turn, give rise to carbonic-acid gas, and either hydrogen or marsh gas. Bringing together the first and last of this long string of processes, we may say that the carbohydrate foods, in superdigestion, produce large quantities of gas in the intestine.

The clinical features of the superdigestion of carbohydrates are very well exhibited by the following cases:

**CASE I.—**J. L., aged thirty-three, had been sick about three weeks with severe pain, which could ordinarily be referred to the abdomen, but at times seemed to spread over a much larger

region, so that it was difficult to say where there was not pain. Distress had been constant, but at times during the day was more marked than at others. These times could not be fixed with any reference to meals, but paroxysms of marked severity were very certain to occur at night. From this cause much sleep had been lost. During ten days the gentleman had been able to present himself at his office but two or three times, and was then so weak as to be utterly unable to attend to business. There had been no fever throughout the trouble. His physical appearance was one of emaciation, with features pinched and drawn. The emaciation was so marked as to lead to the suspicion of tuberculosis, but an examination of the lungs revealed them to be perfectly healthy. The abdomen was considerably distended and tympanitic, bowels slightly costive. He had been advised to take a "light" diet, under which ambiguous term was included toast and tea, rice, blanc mange, and other farinaceous foods. Carbohydrate superdigestion being diagnosed, he was given a saline laxative, and his diet limited to albumins—viz., meat, fish, and white of egg, while starches, fats, and sugars were strictly prohibited. Milk, as it contained sugar, was among the foods forbidden. After being deprived of carbohydrates for only two meals, his pain disappeared and did not recur. He was able to sleep the first night, and reported the next day as feeling better than he had for three weeks. This freedom from pain continued throughout the case. Here it was perfectly evident that the withholding of carbohydrates kept out of the intestine those substances which could maintain the abnormal fermentations there going on. The problem then was simply one of withholding this kind of food until the offending micro-organisms had been removed from the intestine, either by the aid of remedies or by their own death from starvation. At the end of a week a small piece of bread was allowed, but the return of gas and a slight colic, a few hours after its ingestion, showed that the intestine was not yet ready to receive food of this character. A strictly albuminous diet was then observed for another week, when an attempt showed that the carbohydrates could be borne. During the period of dieting, intestinal antiseptics were administered, but whether any advantage was gained from their use is very doubtful.

A strictly albuminous diet is quite difficult to maintain, the craving for bread being so great that nothing short of the tortures of this form of dyspepsia will keep the patient's courage up to the required pitch. I have frequently ameliorated this trouble by allowing the patient, toward the end of his period of dieting, a small piece of bread with each meal, and immediately after the meal administering a diastatic ferment. The choice of a diastase is by no means unimportant. The pancreatic ferments should be avoided, lest by their action upon the proteids they pave the way for more trouble. An active malt diastase is to be preferred, and I have found in these conditions an efficient agent in the substance known as maltine. By this means we are enabled to digest starch in the stomach, from which organ it is absorbed, so that little or none of it can reach the seat of the trouble in the intestine. If the patient take more bread than can be handled in this way, he is reminded of his indiscretion some two or three hours after his meal. Instead of using diastase, I have had patients swallow saliva, promoting its secretion by the use of chewing-gum, but the practice has not been followed by any beneficial results.

**CASE II.—**M. T. had been troubled more or less continuously for two years with constipation, flatulence, and abdominal pain.

The pain appeared usually a few hours after meals, and of late the paroxysms of flatulent colic had become frequent and severe. He was very anaemic, had an anxious expression of countenance, but was not so emaciated as might have been expected from the long duration and severity of his trouble. The principal symptom for which he applied for relief was constipation, and he said that he had not had a stool for two weeks, although he had been taking cathartics continuously. Physical examination revealed an abdomen enormously distended and tympanitic, but not tender. There was no fever and there were no gastric symptoms. He was given ten grains of calomel to take at bedtime, and to be followed by Epsom salts in the morning. He reported the next evening, stating that he had taken the calomel and three doses of salts, but had had no movement from the bowel. Resort was then had to croton-oil, with the effect of producing a copious discharge of gas and liquid and solid faeces. The stools were exceedingly offensive in odor, indicating that a superdigestion of proteid material had occurred as well as superdigestion of the carbohydrates. The carbohydrate trouble being the more pressing, attention was directed to it, and the patient put on a strictly albuminous diet. Owing to the long continuance of the gaseous fermentation, the bowels had become enormously dilated, with corresponding muscular atony, producing a complication peculiarly unfortunate, because of the difficulty of keeping the intestine cleared of the fermenting masses. This difficulty was overcome, however, with suitable cathartics. The necessary period of abstinence from carbohydrate food was in this case unusually protracted, lasting some five weeks, for which reason the plan of digesting bread in the stomach was peculiarly useful. Notwithstanding the greatest care in diet, he had during this period one severe attack of flatulent colic, and, at another time, for several days he required washing of the stomach, but practically he was free from pain throughout the whole period. Some two or three weeks after he was enabled to return to a general diet, and before he had regained completely his strength, he developed an hysterical condition, which baffled handling. The bowel trouble had, however, been entirely overcome.

The condition often occurs in an acute form, and yields readily to proper dietetic treatment. I have seen a good diastase, administered so as to digest the starches in the stomach, quickly arrest a very severe case, even when the starchy foods were only limited and not absolutely prohibited. In a mild form, superdigestion of carbohydrates is a very common affection and yields readily to treatment, a cathartic alone being often sufficient to break up an attack.

All forms of superdigestion are apt to recur.

**The Thymus in Cases of Sudden Death in the Water.**—"Dr. Nordmann, of Basle, describes a case of sudden death while bathing of a healthy young soldier, who, though a good swimmer, was seized with sudden rigidity and dyspnoea, sinking at once to the bottom. All attempts at restoration to life were fruitless. At the post-mortem examination nothing noteworthy was found except an enlarged and hyperplastic thymus. Dr. Nordmann has since collected three other cases recorded by von Recklinghausen of sudden death in the water, and in all of them an enlarged and pathological thymus was found. Why an enlarged thymus which had given rise to no symptoms during life should suddenly cause death under the circumstances in question is not at all clear, but Dr. Nordmann suggests that it is possible that an acute swelling occurs in the gland, due to the collection of a large quantity of secretion in the follicles of the gland, similar to the condition observed by Friedleben during the process of digestion and assimilation."—*Lancet.*

## A CASE OF PTOMAINE POISONING.\*

BY JAMES P. MARSH, M. D.,  
TROY, N. Y.

"It is true, without exception, so far as we know, that the excretions of all living things, plants and animals, are poisonous to the organisms which excrete them."—VAUGHN AND NOVY.

This patient was a bright boy, five years of age, and, although delicate, had never suffered from any severe illness or injury. He had had, somewhat more frequently than other children, short attacks of febrile movement, which had usually been attended by gastro-intestinal irritation and followed in a few days by the expulsion of intestinal worms. One month previous to his fatal illness he had been attacked by measles, which pursued a regular course. His convalescence had been uneventful, excepting that he had occasionally complained of abdominal pain, which, being transitory in character, I had attributed to slight functional disturbance of the bowel and had not considered of enough moment to demand active medication.

During the night of December 6th he was taken with severe abdominal pain accompanied with vomiting. I was called to him at 9 A. M., December 7th, when I found him in the following condition:

Pulse 122, temperature (axilla) 104.5° F., respiration 48. His countenance is flushed and very anxious. Severe paroxysmal abdominal pain is present. Says his head aches. I prescribe bromide of potassium and morphine for the headache and abdominal pain, also antipyrine for the pyrexia.

12 Noon.—Pulse 144, temperature 104° F., respiration 52. He is vomiting. The abdomen is very hot and painful. The headache is severe and he has a slight cough. There is pain over the lower lobe of the right lung, accompanied with a slight friction murmur in this region.

5 P. M.—Dr. E. D. Ferguson calls as consultant. Pulse 140, temperature 102.5° F. He is still vomiting and quite delirious. The abdomen is very "board-like," tympanitic, and painful. The patient has assumed the position of peritonitis. A diagnosis of ptomaine poisoning is reached and a large single dose of calomel and soda ordered, to be followed by five-grain doses of salol. The former treatment is to be continued with the administration of whisky.

8 P. M.—Pulse 148, temperature 100.5° F., respiration 36. The bowels have moved, the passage being very yellow. He is still vomiting, but not suffering from much cough.

December 8th, 12 Midnight.—The temperature having increased, a five-grain powder of antipyrine is given. [This was the last antipyrine administered.]

7 A. M.—Pulse 110, temperature 102.75° F., respiration 38.

3 P. M.—Pulse 152, temperature 100.5° F., respiration 48.

Has had a short sleep, the first since the attack began, and he wakes rational.

6 P. M.—Pulse 134.

8 P. M.—Pulse 118, temperature 101° F., respiration 48. He is very delirious. The bowels are moving constantly. Although considerable flatus escapes by the anus, the abdomen is so greatly distended by gas that I order enemas of turpentine and glycerin.

December 9th, 8 A. M.—Pulse 136, temperature 101° F., respiration 80. Has just vomited black vomit. The breathing is costal. The countenance, position, and general condition are exactly like those of peritonitis.

1 P. M.—Pulse 132, respiration 80. Is throwing up black vomit constantly.

\* Read before the Medical Association of Troy and Vicinity, October 2, 1889.

8 P. M.—He is sinking into collapse.

December 10th, 12 Midnight.—He is in a state of collapse.

6 A. M.—He dies.

5 P. M.—Autopsy. Present, Dr. Ferguson, of Troy, Dr. Lyons, of Plattsburgh, and Mr. John Cathill, medical student. Rigor mortis is present but not marked. The abdomen is very much distended and "board-like" to the touch. There are absolutely no evidences of peritonitis. The small intestines are moderately distended with gas and very translucent. The transverse and descending colon are empty and their circular fibers contracted to a remarkable degree. There is no evidence of intestinal ulceration. The mucous coats of the small intestine are congested, but not inflamed. Peyer's patches are normal. No lesions characteristic of typhoid fever are to be found. The stomach is not inflamed, but the veins of the mucous coat are dilated and the organ contains a large quantity of black vomit. The gall-bladder is full, but there is no obstruction of the gall-ducts. The liver is large and hyperæmic, and near the suspensory ligament are areas of infarction. The kidneys are normal. The lungs are healthy excepting slight hypostatic congestion and slight pleural roughness of the lower right lobe. There are faecal masses in the appendix, but not any appendicitis. No intestinal worms have been discovered.

When first called to this case, the condition was one which impressed upon me the fact that it is not always possible to reach a diagnosis, although all the ante-mortem evidence is in. It occurred to me that the case might be one of febricula, of the prodromes of scarlatina, of gastritis, of typhoid fever, of typhlitis, of meningitis, or of peritonitis, either from perforation of the bowel or from an abscess rupturing into the peritoneal cavity. A febricula could be excluded by reason of the initial intensity of the symptoms. Scarlatina, at first, could not be distinguished, but, as neither rash nor nephritis appeared subsequently, it must be eliminated. As a rule, gastritis does not have so intense a fever nor tympanitic and "board-like" abdomen. Typhoid fever rarely begins so abruptly, and its clinical history does not tally at any point. The bowel symptoms were manifestly too prominent to allow of a diagnosis of meningitis. Rapidly perforating typhlitis, when present, produces more of the symptoms that obtained in this case than any other disease with which I am familiar. Yet, however, there was no history of inguinal tenderness. The abdomen became so hard, tympanitic, and painful to pressure that at no stage of the disease could I entirely free myself from the idea that the peritoneum was more or less involved. But now, that I can deliberately weigh all the symptoms and facts connected with the case, I can find no supposition that accounts for so many of the symptoms as that of ptomaine poisoning.

But the main evidence for the diagnosis must rest upon the post-mortem. Vaughn and Novy declare that "post-mortem examination after sausage poisoning shows no characteristic lesion."\* However, in autopsies made upon persons who had died from the effects of eating poisonous mussels, Schmidtmann found haemorrhagic infarctions of the liver. Dr. George A. Hendries, in a report by him of a post-mortem made upon a fatal case of tyrotoxicon poisoning, says: "The caecum, ascending, transverse, and descend-

ing colon were empty, and their circular fibers were tightly constricted, except at intervals where the intestine was distended with gas." This peculiar contraction of the colon was present in my case, and I have never seen it so marked in any other condition. It seems to me that future investigation will show that the contraction of the circular fibers of the colon and the peculiar translucency of the intestines, together with hepatic infarction, constitutes true pathological evidence of ptomaine poisoning.

As regards the exact chemical substance which produced the death of this little patient, I can not declare definitely. However, as hyperthermia was one of the signs, I am inclined to think that the active agent was one or more of the "extractives." The symptoms were somewhat similar to those of tyrotoxicon poisoning; but this substance is excluded by reason of the high temperature. It seems to me that it is a tenable hypothesis that, the emunctories having been left in an enfeebled state by the attack of rubeola, there occurred a cumulative storing at some point in the child's system, which came into rapid and fatal action upon the slightest functional disturbance of the stomach and bowels.

And, finally, this case contains for me a grave warning. Inasmuch that of late the surgical dictum to open the belly and make the diagnosis when in doubt and life is threatened has been almost universally accepted and acted upon several times, I almost felt that I was doing wrong to let this child perish without doing a laparotomy. Within the last year, in three cases similar to my own, I have known the practitioners to make a diagnosis of peritonitis with the greatest confidence, and yet a subsequent post-mortem absolutely refuted their position. Had I done laparotomy in this case it would but have added one to the fatal operations; it would not have saved the child, and would have added additional momentum to that feeling of hostility toward abdominal surgery which is so rapidly growing in the lay mind.

#### 57 FOURTH STREET.

**Compression of Pulmonary Artery in the Course of Acute Pneumonia.**—Dr. E. Tordieu ("Journal de médecine," No. 14) records the case of a child, five years of age, admitted into hospital for well-marked acute lobar pneumonia of the left upper lobe, who presented a loud systolic murmur in the second left interspace, and traceable toward the axilla. The bruit persisted when the patient was discharged, but so also did the dullness and bronchial breathing at the left apex. The notion of congenital narrowing of the pulmonary artery was unsupported by any collateral evidence; and it was shown that similar bruits have been described which were subsequently proved to have been due to pressure upon the pulmonary artery by enlarged glands or phthisical consolidation. It was therefore surmised that a like causation explained the bruit in this case—a notion which was borne out by the fact that the bruit completely disappeared later, when a soft haemiac apex murmur alone was audible."—*Lancet*.

**Tubercle Bacillus.**—G. W. Watson, in the "Ohio Journal of Dental Science," says: "I have very good authority for saying that diseased roots and teeth have a great deal to do in starting tubercular trouble in the lymphatic glands of people predisposed to this disease. Tubercle bacilli, gaining admission to the jaw through the diseased teeth, speedily infect the structures in their neighborhood. It would be right, therefore, for us to look well to the teeth of patients having a tubercular tendency, and see that they keep their mouth in a thoroughly healthy and aseptic condition."

NEW YORK, SATURDAY, NOVEMBER 9, 1889.

GONORRHOEAL RHEUMATISM.

In the "Normandie médicale" for September 1st, M. Buffet publishes some interesting observations upon this subject. He calls attention to the fact that the affection fails to follow the classic type, as regards its being confined to single joints and attacking the large joints only. On the contrary, it affects the small joints as well; and may invade other tissues—such as the sheaths of tendons, the muscles, nerves, and areolar tissue. There is much in common in this disease with acute articular rheumatism. Several joints are successively attacked. But there is not the same mobility, there is no appreciable fever, no profuse perspiration, and no urinary changes. The form of disease under consideration lasts longer than classic articular rheumatism, its duration sometimes extending over months. Resolution is not its only termination. There may be ankylosis, complete or partial, and muscular atrophy. It may terminate in rapid suppuration, as in a case cited in which death ensued in eight days as a sequence of suppurative inflammation of the knee. One attack affords no protection against a second, several patients suffering from three or four attacks; which causes Jaccoud to predict for the unfortunate victim of gonorrhœa with articular manifestations a repetition of his woes should he chance to contract gonorrhœa again. This author also maintains that the treatment of the gonorrhœa present is without influence upon the development of the articular affection. The amount of discharge appears to bear no relation to it, either. And salicylate of sodium is positively without any effect whatever.

The physician's first duty is to place the limb in a good position, in view of possible ankylosis. As to other measures, revulsives and blisters are chiefly of value. When the effusion is abundant, the joint may be punctured. Tonic treatment is always indicated—quinine occupying the first place as a remedy—for the depression is great. Massage, sulphur douches, and electricity are useful in combating stiffness of the joints and muscular atrophy. To sum up: Gonorrhœal rheumatism may be confined to one joint, but may attack several joints. Small joints may be affected as well as large ones. Tendinous sheaths may be invaded as well as muscles, nerves, and cellular tissue. The clinical difference between this and ordinary articular rheumatism consists in the absence of fever and perspiration and in the fixity and duration of the lesions. The disease may terminate in ankylosis, suppuration, or muscular atrophy. Treatment consists in a good position for the limbs, revulsion, massage, and electricity. Salicylate of sodium and anti-gonorrhœal remedies are without effect. Tonics are indicated.

THE HYGIENE OF THE EYE.

GALEZOWSKI, through the medium of the "Gazette hebdomadaire des sciences médicales," gives excellent suggestions concerning the circumspect use of the eyes for close work. Spectacles are a medicine, the remedy for ametropia. Appropriate glasses should correct every error of refraction as soon as it is discovered. Only in this way can sight be preserved without further damage. In latent hypermetropia glasses are not necessary for distant vision. Established hypermetropia requires the constant use of glasses, especially when presbyopia exists. Myopic eyes, above all others, require the most rigid hygiene. Without it grave intra-ocular changes result that are beyond the reach of therapeutic measures. In marked myopia there is perpetual effort made by the eye to obtain binocular vision during work. Experience has proved that such vision is not secured when the distance for distinct vision is less than from 75 to 90 inches. Under such circumstances work soon strains the eye, bringing about muscular asthenopia. Intra-ocular disorders quickly follow, if this condition of myopia is not overcome. It should be corrected by the weakest glass that will secure good sight, which is exactly what the myopic patient avoids, preferring the strongest glass—one that calls accommodation and convergence into action, the most important thing not to do. When myopia exceeds 3·5 or 4 diopters, glasses should always be used for work. Ordinarily, a medium degree of myopia requires glasses of only half the strength of those used for seeing at a distance. They must be suitable for the kind of work and the wearer, who should not use them for greater distances than from 75 to 90 inches. Other damage is done by calling accommodation and convergence into play. Eyes that are sensitive, strained, or affected with opacities require glasses of neutral tint, that allow no yellow rays to pass, which diminish the intensity of solar light without altering its composition. In the choice of a profession, attention must be paid to the visual power of the individual, as it is impossible to make a good soldier of a man who has myopia to the extent of 6 diopters; so, also, is it impossible to make such a man an engraver or a type-setter. Rest should be given the eye during work. If this precaution is followed, steady reading or writing is possible without producing congestion, partial closing of the lids, and sensitiveness to light. In every occupation the most comfortable and convenient posture is the one to choose, for thus strain is averted. Persons who write much should avoid bending over, as this quickly causes fatigue. It is well to write sitting for a time, and then to write standing. Reading in bed is an abomination, tending to provoke strain and asthenopic disorders.

MINOR PARAGRAPHS.

OBESITY AND STERILITY.

In the "Revue générale de clinique et de thérapeutique" Dr. Philbert gives some interesting facts concerning the relation of obesity to sterility, and the favorable results obtained by hygienic measures for the reduction of fat. In the male, ex-

cessive embonpoint retards the development of the generative organs, producing atrophy in certain cases, while in others the conditions are similar to those that obtain in childhood. After adult age, polysarcia notably diminishes sexual desire, which returns with the loss of the superfluous flesh. In the female, amenorrhœa and dysmenorrhœa result from excess of fat. An accumulation across the abdomen exerts mechanical pressure that impedes utero-ovarian function. Possibly ovulation fails of accomplishment in consequence of defective nerve excitation. The requisite loss of flesh puts the organs into their normal state, rendering fecundation possible. Five cases are recorded of very stout women married several years without offspring, who became mothers in consequence of treatment that did away with obesity. This treatment included a course of baths and mineral waters, such as those of Brides and Salins-Montiers. Fertility ceased whenever the obesity returned. Some of the women gave birth to several children, the first usually arriving during the year following the beginning of treatment.

#### THE SANITARY EFFECTS OF BURNING RUBBISH.

THE secretary of the Michigan State Board of Health has issued a circular in which he mentions an unusual deficiency of ozone in the air of Lansing and a sense of want of air felt by the inhabitants, accompanied in some instances by weakness of the heart's action, which he thinks are attributable to vitiation of the atmosphere in consequence of numerous fires in swampy places, due to the drouth, and to fires kindled in the streets for destroying refuse. He even suggests that an increased prevalence of certain diseases, such as inflammation of the tonsils, pleurisy, cerebral inflammation, and croup, may have been partly due to these fires. He thinks they are chiefly noxious at night, when the wind commonly dies out, and asks that such fires as are necessary be kindled in the morning. His inferences, it will be seen, are quite at variance with the old practice of building bonfires against pestilence. Coming from such a careful observer, they are, however, worthy of attention.

#### THE REPORT OF THE STEVENS COMMISSION.

THE commission appointed about two years and a half ago by the New York Neurological Society to investigate the feasibility of curing epilepsy and chorea by the correction of ocular defects, maintained by Dr. George T. Stevens, made its report on Tuesday evening of this week. The commission consisted of Dr. Edward C. Seguin, chairman, Dr. M. Allen Starr, secretary, Dr. Charles L. Dana, Dr. W. R. Birdsall, Dr. David Webster, Dr. W. Oliver Moore, and the editor of this journal. The plan of procedure was for the neurological members of the commission to furnish Dr. Stevens with a certain number of epileptics and choreics, and to report upon the results of their treatment by him. The commission could not report a single cure, but it reported a number of instances of improvement. Dr. Stevens protested against the commission's report as premature, and read a reply in which he maintained that the inquiry had been improperly conducted, and that the results had not in all instances been fairly recorded in the report. A general discussion was begun, but was adjourned to the next meeting.

#### THE DIGESTIVE ORGANS AND MELANCHOLIA.

BEFORE the recent Congrès international de médecine mentale, Dr. Beltencourt-Rodrigues, of Portugal, read a paper upon this subject, an abstract of which is given in the "Progrès médical." While not overlooking the general causes of insanity, he said, it was also of extreme importance to understand its proximate

causes. In a certain number of persons suffering from melancholia the writer had observed gastro-intestinal disturbances which, according to recent theories, were produced by toxic elements circulating in the organism. This had led him to imagine that infection from the alimentary canal might be a cause of melancholia—an hypothesis that was sustained to a certain degree by the complete recovery of several patients suffering from this form of mental disease, after antiseptic treatment directed to the digestive tract.

#### RABIES AMONG DEER.

THE deer of Ickworth Park, England, having become diseased, Mr. Adami, the demonstrator of pathology at the University of Cambridge, was invited to study the causes of the trouble. An inquiry by the agents of the Privy Council had already been made, which had declared the disease to be anthrax. Mr. Adami was not able to confirm this decision, but after a thorough study reported the cause to be rabies, a disease that has not often been found among deer. The "British Medical Journal" states further that Mr. Adami was so unfortunate as to inoculate himself. On the seventeenth day after this accident he resorted to Pasteur's Institute at Paris, and was treated for inoculated hydrophobia. On the ninth day after the beginning of the treatment he had premonitions of the disease, but these did not progress, and the unfortunate pathologist now considers himself cured and protected.

#### CORNELL UNIVERSITY'S MEDICAL ASPIRATIONS.

A RECENT report by President Adams, of Cornell University, seems to put forth a "feeler" after a medical department, in order that Ithaca may have a full-orbed university, *totus, teres atque rotundus*. President Adams is reported to have expressed the wish that such a department, with a large endowment, might be established in New York or Brooklyn, which might very properly be styled "the College of Medicine of the Cornell University." Is this a bid to the Bellevue Hospital or the Long Island school to come in under the aegis of Cornell? They are about the only ones remaining that have not a placental attachment; but neither of them can be said to enjoy "a large endowment."

#### SICKNESS FROM POLLUTED WELL-WATER.

AT West Albany there are 1,200 men employed in the car-shops. Among them there has been much sickness of a febrile character, called "malarial," but which seems to be referable to a bad quality of drinking-water taken from wells. There have been absent as many as 200 workmen in twenty-four hours. Dr. Balch, secretary of the State Board of Health, has condemned the wells formerly in use, and they have been closed. Since then the number of new cases has been much reduced.

#### THE NEW YORK PHYSICIANS' MUTUAL AID ASSOCIATION.

WE would call the attention of those of our readers who are members of the association to the notice, in our list of "Society Meetings for the Coming Week," of the annual meeting, on Thursday evening, at the Academy of Medicine. The importance of the association's work can hardly be over-estimated, and it is desirable that it should receive the personal attention of all the members.

#### THE TENTH INTERNATIONAL MEDICAL CONGRESS.

IN a letter to Surgeon-General John B. Hamilton, of the Marine-Hospital Service, dated October 7th, Professor Virchow

says: "The organizing committee of the Tenth International Medical Congress is now constituted. I myself am elected president, and Dr. Lassar (Karlstrasse, 19, N. W.), secretary-general. We shall be very happy to receive the 'Transactions of the Ninth International Medical Congress,' and we hope to see you and many of your countrymen at the new session."

#### THE CARTWRIGHT LECTURES.

It is announced that Dr. Billings, of the army, is to give the course this year, on the 14th, 20th, and 22d inst., at 8 p. m., at the College of Physicians and Surgeons, on the subject of "Vital and Medical Statistics." In ordinary hands the importance of this theme would stand in inverse ratio to its attractiveness, but nobody needs to be told that Dr. Billings's genius will invest it with liveliness.

#### THE "MEDICAL MIRROR."

This is the title of a "Monthly Reflector of the Profession and its Progress," the first number of which is announced for January, 1890, to be edited by Dr. I. N. Love, of St. Louis. The prospectus states that, while the new journal will be made of interest to physicians in general, it will earnestly endeavor to accomplish the complete organization of the profession of the Mississippi Valley. Dr. Love seems specially qualified to carry his undertaking to a successful issue, and we look to see it done.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending November 4, 1889:

DISEASES.	Week ending Oct. 29.		Week ending Nov. 4.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	42	16	32	9
Scarlet fever.....	41	4	35	1
Cerebro-spinal meningitis.....	4	4	2	2
Measles.....	42	2	13	1
Diphtheria.....	80	12	74	16
Small-pox.....	1	0	0	0

**Hygiene at Gettysburg.**—A professorship of hygiene and physical culture has been endowed, in the sum of \$25,000, at the Pennsylvania College, at Gettysburg, by the parents of the late Dr. Charles H. Graff.

**The American Association for the Study and Cure of Inebriety** will give a dinner to its president, Dr. Joseph Parish, at his home, in Burlington, N. J., on Tuesday, the 12th inst., on the seventy-first anniversary of his birth.

**Changes of Address.**—Dr. Edward J. Birmingham, to No. 23 East Forty-sixth Street; Dr. Louise Fiske Bryson, to No. 38 West Thirty-eighth Street.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 20 to November 2, 1889:*

MEARNS, EDGAR A., Captain and Assistant Surgeon. Granted leave of absence for two months. Par. 5, S. O. 244, A. G. O., October 19, 1889.

KENDALL, WILLIAM P., First Lieutenant and Assistant Surgeon. Leave of absence extended one month. Par. 6, S. O. 244, A. G. O., October 19, 1889.

So much of Par. 2, S. O. 241, October 16, 1889, from this office, as directs BRECHEMIN, LOUIS, Captain and Assistant

Surgeon, to report for duty at Fort Apache, Arizona Territory, is revoked. He will report in person to the commanding officer, Presidio of San Francisco, Cal., for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

CLENDENIN, PAUL, First Lieutenant and Assistant Surgeon. Relieved from duty at Fort McIntosh, Texas, and will report in person to the commanding officer, Camp Eagle Pass, Texas, for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

CHAPIN, ALONZO R., Captain and Assistant Surgeon. Relieved from duty at Newport Barracks, Kentucky, and will report in person to the commanding officer, Fort Yates, Dakota, for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

SHANNON, WILLIAM C., Captain and Assistant Surgeon. Relieved from duty at Fort Yates, Dakota, and will report in person to the commanding officer, Fort Apache, Arizona Territory, for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

RAYMOND, HENRY I., First Lieutenant and Assistant Surgeon. Upon being relieved from duty at Fort Bidwell, California, will report in person to the commanding officer, Newport Barracks, Kentucky, for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

DAVIS, WILLIAM B., Captain and Assistant Surgeon. Relieved from further duty at Fort Porter, New York, and will report in person, upon expiration of his present sick leave of absence, to the commanding officer, Fort Preble, Maine, for duty. Par. 6, S. O. 248, A. G. O., October 24, 1889.

WAKEMAN, WILLIAM J., Captain and Assistant Surgeon. Relieved from duty at Fort Walla Walla, Washington Territory, and will report in person to the commanding officer, Fort Bidwell, California, for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

EGAN, PETER R., Captain and Assistant Surgeon. On being relieved from duty at Camp Eagle Pass, Texas, will report in person to the commanding officer, Fort McIntosh, Texas, for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

By direction of the Secretary of War, so much of Par. 2, S. O. 24, October 16, 1889, from this office, as relates to HEGER, ANTHONY, Lieutenant-Colonel and Surgeon, is amended to read as follows: Lieutenant-Colonel Anthony Heger, surgeon, is relieved from further duty in the Division of the Atlantic, and will at once report to the Major-General commanding the army for duty in this city. Par. 5, S. O. 252, Headquarters of the Army, A. G. O., October 29, 1889.

By direction of the Secretary of War, Par. 3, S. O. 24, October 16, 1889, from this office, is so amended as to grant O'REILLY, ROBERT M., Major and Surgeon, leave of absence for six months, with permission to leave the United States, to take effect November 1, 1889. Par. 6, S. O. 252, A. G. O., Washington, D. C., October 29, 1889.

FORWOOD, WILLIAM H., Major and Surgeon, by direction of the President, is detailed as a member of the Army Retiring Board at St. Paul, Minn., convened by War Department Order dated January 12, 1889, published in S. O. 10, January 12th, from Headquarters of the Army, vice MEARNS, EDGAR A., Captain and Assistant Surgeon, hereby relieved. Par. 12, S. O. 254, A. G. O., October 31, 1889.

GIBSON, JOSEPH R., Major and Surgeon. Granted leave of absence for seven days, to take effect from date of being relieved from duty at Fort Sheridan, Illinois. Par. 9, S. O. 249, A. G. O., October 25, 1889.

GORGAS, WILLIAM O., Captain and Assistant Surgeon, by direction of the Secretary of War, is relieved from temporary field

duty in the Department of the Missouri, and will join his proper station (Fort Barrancas, Florida). Par. 2, S. O. 251, A. G. O., October 28, 1889.

**MAUS, LOUIS M.**, Captain and Assistant Surgeon. Granted leave of absence for two months on surgeon's certificate of disability. Par. 11, S. O. 249, A. G. O., October 25, 1889.

By direction of the Secretary of War, so much of Par. 10, S. O. 242, October 17, 1889, A. G. O., as directs **MAUS, LOUIS M.**, Captain and Assistant Surgeon, to report in person for duty at Fort Stanton, New Mexico, to relieve **MARCUS E. TAYLOR**, Assistant Surgeon, is revoked, and Captain TAYLOR will proceed to Boise Barracks, Idaho Territory, as directed in said order, as soon as medical attendance shall be provided for Fort Stanton. Par. 10, S. O. 249, A. G. O., October 25, 1889.

**CABELL, JULIAN M.**, First Lieutenant and Assistant Surgeon. Granted leave of absence for two months, to take effect about November 10, 1889. Par. 7, S. O. 249, A. G. O., October 25, 1889.

By direction of the President, the Army Retiring Board convened at Vancouver Barracks, Washington Territory, by War Department Order dated December 15, 1888, published in S. O. 292, December 15, 1888, from Headquarters of the Army, is dissolved. Par. 1, S. O. 250, A. G. O., Washington, October 26, 1889.

#### *Appointments in the Medical Department.*

**WILCOX, CHARLES**, First Lieutenant and Assistant Surgeon, to rank from October 29, 1889.

**MCVAY, MARSHAL E.**, First Lieutenant and Assistant Surgeon, to rank from October 29, 1889.

**FRICK, C. B.**, First Lieutenant and Assistant Surgeon, to rank from October 29, 1889.

#### *Death.*

**TAYLOR, MORSE K.**, Major and Surgeon (retired), died October 20, 1889, at San Antonio, Texas.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending November 2, 1889:*

**NASH, F. S.**, Passed Assistant Surgeon. Detached from duty in the Bureau of Medicine and Surgery and ordered to the Petrel. November 14, 1889.

**BOGERT, E. S.**, Medical Inspector. Ordered to examination preliminary to promotion to medical director.

**NORTON, O. D., KITE, I. W., and STONE, E. P.**, Assistant Surgeons. Ordered to examination preliminary to promotion to passed assistant surgeons.

#### **Society Meetings for the Coming Week:**

**MONDAY, November 11th**: New York Academy of Medicine (Section in Surgery); New York Ophthalmological Society (private); New York Medico-historical Society (private); Lenox Medical and Surgical Society (private); New York Academy of Sciences (Section in Chemistry and Technology); Boston Society for Medical Improvement; Gynaecological Society of Boston; Burlington, Vt., Medical and Surgical Club (annual); Norwalk, Conn., Medical Society (private); Baltimore Medical Association.

**TUESDAY, November 12th**: Medical and Chirurgical Faculty of Maryland (semi-annual, first day, Hagerstown); New York Medical Union (private); Medical Society of the County of Rensselaer, N. Y.; Camden, N. J., County Medical Society (semi-annual—Camden); Newark, N. J., Medical Association; Trenton, N. J., Medical Association (private); Norfolk, Mass., District Medical Society (Hyde Park); Baltimore Gynaecological and Obstetrical Society.

**WEDNESDAY, November 13th**: Medical and Chirurgical Faculty of Maryland (second day); New York Surgical Society; New York Pathological Society; American Microscopical Society of the City of New York; Medico-legal Society; Medical Society of the County of Albany, N. Y.; Pittsfield, Mass., Medical Association (private); Worcester, Mass., District Medical Society (Worcester); Philadelphia County Medical Society.

**THURSDAY, November 14th**: Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society; New York Physicians' Mutual Aid Association (annual); Medical Society of the County of Cayuga, N. Y.; South Boston, Mass., Medical Club (private—annual); Pathological Society of Philadelphia.

**FRIDAY, November 15th**: Chicago Gynaecological Society; Baltimore Clinical Society.

**SATURDAY, November 16th**: Clinical Society of the New York Post-graduate Medical School and Hospital.

## Proceedings of Societies.

### NEW YORK ACADEMY OF MEDICINE.

#### SECTION IN THEORY AND PRACTICE OF MEDICINE.

##### *Meeting of October 15, 1889.*

Dr. R. C. M. PAGE in the Chair.

**Enteralgia and Chronic Peritonitis.**—Dr. A. JACOBI read a paper on this subject. He said that cases of primary peritonitis of any kind were very rare, and that these were mostly due to traumatism, or from wounds and probing of the same, and from paracentesis for ascites. Most cases, however, were of a secondary nature, with very numerous causes. These cases might arise under the influence of general diseases—rheumatism, alcoholism, scarlatina, measles, erysipelas, malaria, scurvy, tuberculosis, carcinoma, etc. Among the most frequent causes of peritonitis were the catarrhal and inflammatory diseases of the female sexual organs. The writer thought it was very easy to understand how an intestinal catarrh developed into an enteritis and then into peritonitis, if we remembered the facility with which anatomical changes took place in the mesenteric glands in the course of such a disease. The diagnosis of chronic peritonitis was frequently obscured by such conditions as adhesions around tumors, a movable kidney which had become fixed, and intestines which had become glued together—all of which had no recognizable symptoms. In chronic peritonitis the respirations were not necessarily accelerated. Particularly was this true in pelvic peritonitis. There might be occasional vomiting if there happened to be an existing acute catarrh. Constipation was frequent; diarrhoea not unusual. The abdomen was apt to be tumid. Chronic peritonitis was diagnosed with more or less certainty in the following manner: The patient should lie upon the back, with the lower extremities extended. Then flexion and extenstion of the limbs would often cause pain in the abdomen. Then, by palpation over the abdomen, much might be discovered which would point to adhesions or exudations. By pressure, very distinct and circumscribed pain might be felt by the patient. Pain was a very frequent symptom in chronic peritonitis. It might be mild, severe, of short duration, or permanent. Its variability depended often on the degree of irritation or congestion. Acute attacks were frequent when there was a cause for exacerbation. The seat of

pain varied with the location and extent of the lesion. Extensive peritonitis in the pelvis might not give rise to pain unless waked up by defecation, cohabitation, or micturition. In some cases the pain could not be diagnosticated from the enteralgia produced by other causes—such as flatulence, fermentation, and abnormal contents in the abdomen. Anatomical changes in chronic peritonitis gave rise to the very same symptoms and conditions. The results of this disease were varied. A simple attack of exudation might shape the future of the patient so far as health was concerned.

Tabes mesenterica was another form of chronic peritonitis the recognition of which the author considered of practical importance. The main symptoms common to every form and case of tabes mesenterica were atrophy and tumid abdomen. Emaciation and atrophy reached a degree hardly ever met with in any other morbid condition. The subcutaneous fat rapidly disappeared. The skin was flabby, thin, and inelastic; around the limbs it was loose and baggy. In the beginning the muscles could be recognized; afterward even they became emaciated to such an extent that their outlines disappeared, and those of the bones were distinctly perceptible. The eyes lay deep in the orbit, and had a peculiarly dry and hungry look. The bones of the face, with the thin, flaccid, dry, and scaly skin over them, furnished a terribly senile expression. The surface was mostly cool, the limbs were cold, the cutaneous veins were very distinct and blue, and much dilated over the chest, but still more so over the abdomen. The voice was thin and tin-like, the cry tearless, the pulse slow, from exhaustion of the heart muscle, or, more frequently, rapid, thin, and compressible. The lymph bodies of the neck and inguinal regions, sometimes also of the axilla, were tumefied. The preceding symptoms were more or less common to all cases. There were many, however, which exhibited numerous variations in important particulars. The appetite might be ravenous or entirely lost. Some cases began with little or no diarrhoea, but in all, the stools were foetid. The majority, however, commenced with a severe form of intestinal catarrh, attended with numerous offensive discharges. The peculiar foul, musty, pungent, ammoniacal odor was due in part to acids, formed by the fat which had not been absorbed, sulphides, and other products of putrefaction. In the further development of the morbid condition there might be constipation, but diarrhoea was more frequent. It might not be very copious or the evacuations very numerous. In some cases there was tenesmus, with but little substance; in others the quantity was large and expelled suddenly, in an instantaneous gush. The temperature varied. It might be normal or subnormal or elevated. The tumid belly was absolutely painless in some cases, but very sensitive in others, the latter mainly in those with elevated temperature. The large size of the abdomen, with its network of dilated veins, contrasted fearfully with the ghastly and atrophic limbs. It might be large enough to press the diaphragm upward and interfere with the function of the heart and lungs. The nature of the tumefaction varied. It might be tense or flabby, hard or soft, doughy or firm, uniform or irregular. Nodules or lumps of different shapes and sizes might be discovered by palpation. Gentle percussion would elicit tympanites. It was not unusual to find oedema, extensive dullness from fatty liver, albuminuria, local inflammations of the abdominal surface connected with abscesses in the peritonæum, and cough depending on tubercular disease of the lungs. The author thought that the variety of symptoms belonging to tabes pointed distinctly to different morbid processes, and that these symptoms appeared to prove that there were several distinct forms of tabes which depended on different causes, and were attended with varying anatomical alterations. He said that tabes mesenterica ought no longer to appear as a nosological entity in the text-books. The former

belief, that death was due to failure of absorption, was no longer tenable. Starvation might take place through imperviousness of the mesenteric lymph bodies. The first changes which took place in them were of a congestive and inflammatory nature, and secondary in character. Primary changes, when they did occur, were mostly neoplastic. As in other glands, the inflammation might be a simple one, or suppurative, fibrous, caseous, or tubercular. Simple adenitis was occasioned by any kind of irritation. The first process consisted in dilatation of the blood-vessels, with reddening, softening, and succulence of the tissue, endothelial changes in the lymph spaces, and new formation of cells. Afterward the red discoloration was replaced by a grayish-white color, now and then interrupted by small blood-points which would turn into pigment. The difference between the cortical and medullary substance would fade or disappear. The capsule became tense over its swollen contents. These were the cases in which a complete recovery could be expected. Besides the simple secondary hyperplasia of the mesenteric glands which resulted in obstruction, and the tubercular infiltration which terminated in the same disturbance of function, there was a third condition which led to the symptoms called tabes mesenterica—viz., chronic tubercular peritonitis. It was quite frequent, but its symptoms varied in duration and severity. The capability of recovery in this disease was sometimes surprising. The present justifiable belief was that only those cases of chronic peritoneal tuberculosis would have a chance of recovery which were local, and not the result of general tubercular infection. In estimating the size of a child's abdomen, it should be borne in mind that it was normally larger in proportion than that of the adolescent or adult. The diagnosis of tubercular peritonitis was apt to be difficult. There were many cases which could not be distinguished from non-infectious peritonitis and simple inflammatory processes. Many of the caseous tubercularizations were small and inaccessible to an accurate physical examination. Where the distension of the stomach appeared after an intestinal catarrh the stools either improved in character or remained offensive. If the temperature continued high and the symptoms exhibited a typhoid character, the existence of an acute attack of tubercular peritonitis was probable. The prognosis was always uncertain, except in the very worst cases. It was absolutely fatal when the tabes mesenterica meant peritoneal and glandular tuberculosis complicated with or depending upon generalized tuberculosis.

Dr. F. DELAFIELD said that he was in the habit of regarding these cases of peritonitis from an anatomical standpoint. He made the following distinctions: 1. Cases of chronic peritonitis in which the lesion was only a form of connective-tissue adhesion. 2. When there existed connective-tissue adhesions and also serous or purulent fluid. 3. Chronic peritonitis, with increased thickening, and fluid present in quantities. In the first class of cases there were no symptoms, and the adhesions were revealed only at an autopsy. The patients would have localized pain, referred to some part of the colon, and might have adhesions or not. It was very difficult to determine. To distinguish these cases from a tubercular peritonitis was also difficult, and when there existed waxy liver as a complication they became troublesome. Not infrequently such cases behaved like carcinoma of the liver. Chances of error also lay in stenosis of the pylorus, giving rise sometimes to an enormously dilated stomach, which might occupy almost the entire abdomen. Pain in different parts of the abdominal cavity was frequently misleading. Sometimes it was a reliable indication, but at other times could not be depended upon at all. Then chronic peritonitis, with both adhesions and fluid, was difficult to distinguish from tubercular peritonitis and from the various forms of carcinoma of the peritonæum. Very much depended

upon the particular shape that the peritonitis took. The intestines might be matted in some parts of the abdomen, there might be fluid in another part, and organized connective tissue might divide the abdominal cavity into several compartments. As to the third form, in which diffuse thickening existed with presence of fluid, but without adhesions, it was difficult to distinguish from tubercular peritonitis and from simple cancer of the peritoneum or cirrhosis of the liver. This latter was especially difficult when the peritonitis involved the capsule of the liver. The capsule would become enormously thickened and the liver diminished in size, as in true cirrhosis.

Dr. W. H. THOMSON thought the diagnosis of this condition extremely confusing. He had never made a diagnosis of chronic peritonitis without a mental reservation that the patient might really be suffering from something else. He remembered two cases of cancerous disease of the peritoneum which had in common a feature of some value in distinguishing the condition from that of tubercular peritonitis. The first case was that of a lady who, at forty-five years of age, gradually began to decline in health and present symptoms of ascites. The pains of which she complained were very fugitive, and the only local symptoms were rigidity of the abdominal walls on palpation and pressure. At no time was there any rise of temperature. The particular symptom was the extremely low percentage of urea in the urine. The autopsy showed acute carcinoma of the peritoneum. The pain which the patient had complained of most often, and which had been on the left side, was explained by the fact of the disease having involved two of the false ribs of that side. In the second case to which he had referred cancer of the peritoneum was found. The same condition of the urine existed before death. He believed Germain Sée's diagnostic points in cancer of the stomach and peritoneum were tenderness and enlargement of the post-clavicular glands. In one case of cancer of the peritoneum the speaker had been able to verify this suggestion. In cancer of the peritoneum there was no exacerbation of temperature, while in tuberculosis there was. He had a case at present in a youth nineteen years old, with a history of constipation and pain in the abdomen, hip, and knees. There was also considerable cutaneous hyperesthesia. For some weeks past there had been a temperature of 101° to 102° F. The striking feature was the progressive emaciation. There was very little doubt that the case was one of tubercular peritonitis. There was some redness about the umbilicus, which was a thing the speaker had not noticed before. When ascites complicated these diseases the difficulties of accurate diagnosis became insurmountable.

Dr. LEONARD WEBER said that he had not seen a case of chronic peritonitis which was not the result of infection. He was not inclined to believe that any such form existed, though it might. He looked at the conditions described in the first part of the author's paper—in which, at some time in the patients' histories, there had been acute attacks of peritonitis—as conditions consequent upon those attacks. Some of the cases described seemed to indicate the result of adhesions, lacerations and perforations, the patients dying of acute perforating peritonitis and not chronic peritonitis.

#### NEW YORK ACADEMY OF MEDICINE.

*Meeting of October 17, 1889.*

The President, Dr. ALFRED L. LOOMIS, in the Chair.

**On Gunshot Wounds of the Abdomen, with Special Reference to Wounds of the Intestines.**—Dr. L. A. STIMSON read a paper with this title. (See page 449.)

Dr. JOHN A. WYETH said it seemed that the question resolved

itself into one of operation or non-interference. The arguments used in the very able paper which had been read recalled to his mind a meeting held nine years before, in that same room. At that meeting a paper had been read by a man recognized as a leader, which had attracted great attention at that period. He referred to a paper on the "Progress of Peritoneal Surgery," read before the members of the Academy on October 6, 1881, by Dr. J. Marion-Sims, who had then said: (1) "Wounds of the peritoneal cavity have a common course to run." (2) "They have a common termination, and that is death by septicæmia." (3) "This is the general law in death after ovariotomy." (4) "It is the general law in death after gunshot and other wounds of the abdominal cavity." (5) "The septicæmia is the result of absorption of bloody serum found in the peritoneal cavity after wounds or operations." (6) "Gunshot wounds of the pelvic cavity are recovered from because of natural drainage afforded by the track of the ball." (7) "Patients with gunshot wounds of the abdomen die of septicæmia because there is no natural drainage and the bloody serum falls into the peritoneal cavity and is there absorbed." (8) "The effect of bloody fluid upon the abdominal cavity is such as to demand abdominal incision and suturing of the divided tissues." The speaker then went on to say that there could be no fixed laws in the matter of interference in gunshot wounds of the abdomen. It was necessary to be guided by the condition of the patient and the situation of the wound, as well as by the size of the missile. Gunshot wounds of the intestine made by small bullets, owing to the contractility of the gut, were not so likely, other things being equal, to be followed by the escape of the intestinal contents and by peritonitis. If called to a case in which the patient had been wounded by a small-sized bullet, which had passed from before backward through the abdominal wall, above the level of the umbilicus, he would prefer to wait rather than interfere. An injury such as this from a small-sized bullet was not so apt to wound the gut. If the bullet was a large one and had passed through the abdominal wall above the navel, and the patient had passed out of the period of shock, had a good pulse, and was in a generally fair condition, the speaker said he would be inclined to open the abdomen to see if there were any of the viscera wounded. But below the umbilicus the abdomen was full of the small intestines, and it was scarcely possible for a bullet to pass through the abdominal wall from before backward in this region without wounding the small intestines more or less. In such cases he would open and explore. In any event, if the caliber of the bullet was No. 38 or No. 40, he would not hesitate to operate, but would not invade the abdomen if the bullet used had been a small one. It was of vital importance to operate at the proper time, and that was when the patient came out of the condition of shock. This might mean a few hours, or even ten or twelve hours. He mentioned a case in which a boy had been shot below the navel, the bullet passing obliquely through the abdominal cavity. This patient had remained in a condition of shock for five hours, at the end of which time he had come out of it, and in an hour had been in excellent condition, remaining so for five hours more. When the speaker was called to see him, six hours later—in fact, at the "eleventh hour"—peritonitis had set in and the boy was practically comatose. In such a case, he thought, the patient would have had a chance of recovery if interference had been commenced at the proper time. As to drainage, if the abdomen was opened and the patient was still weak and there existed considerable extravasation, it was better to leave the wound open.

The CHAIRMAN said it seemed that in this country special and ample opportunity was afforded for the study of gunshot wounds of the abdomen. He thought this was proved by statistics, unless such statements exaggerated the facts. While

walking through a London hospital Sir W. MacCormac had remarked to him that American surgeons had considerable advantage in this respect because in America pistols were as commonly carried and used as toothpicks. The speaker thought that something should perhaps be allowed for the temperament of those who used the weapons. As to the size of the missile, he thought experience indicated that a .22-caliber bullet would make the more fatal injury, and cited a case in which a bullet of that size had made five intestinal perforations. He also thought that greater stress should be laid upon the part of the intestines which suffered perforation than upon the size of the bullet. If the wounds were near the mesenteric attachment they were more likely to close spontaneously than if inflicted at points distant from such attachment. He was firmly of the opinion that some operation should always be done. The shock from chloroform or ether anaesthesia, he contended, added enormously to that of the initial shock from the injury, and therefore, where only moderate searsh was indicated, he advocated the use of cocaine. The absence of blood in the urine did not prove that the bladder or kidneys were uninjured. Lateral anastomosis was not indicated as a part of the primary operation after gunshot wounds of the intestine.

Dr. W. MEYER related a case in which the patient had shot himself in the abdomen. The bullet could be felt at the left of the spinal column. The patient had expectorated and vomited blood. Finding that the man grew gradually worse, it was decided to explore the abdomen. No perforation of the intestines was found and none of the stomach. When, however, the stomach was pulled forward, an abrasion of its posterior surface was discovered. The injury had been so superficial that it did not require sewing, and it was merely dusted with bismuth. The patient sank gradually and died; and, unfortunately, no post-mortem could be obtained. It was a point to be noted that the bullet had entered the abdominal cavity, and had found its way to the back of the stomach without perforating either it or the intestines. Still the man had both vomited and expectorated blood. As to interference in cases of gunshot wounds, he thought for the first twelve hours it was better to let patients alone; then, if the diagnosis of internal haemorrhage was made, it would force the knife into the surgeon's hand.

Dr. CURTIS thought that the statistics of gunshot injuries, with the results of their treatment, were thoroughly unreliable. The high mortality rate might be the result of operations undertaken by inexperienced surgeons. The men who had been given the opportunity of operating in three or four cases were the men who were best able to handle them. He was glad that Dr. Stimson had emphasized the point that an operation upon patients in a moribund condition was unadvisable. No good could come to the patient, and great injury was thereby done to surgery.

Dr. T. H. MANLEY then narrated the history of a case of gunshot wound of the intestine in which he had operated and in which the patient had made a good recovery. The only difficulty which had presented itself in the case had been that of keeping the edges of the wound in coaptation, the thoracic and abdominal movements during respirations tending constantly to retard union.

#### NEW YORK SURGICAL SOCIETY.

*Meeting of October 9, 1889.*

The President, Dr. LEWIS A. STIMSON, in the Chair.

**Abscess of the Brain.**—Dr. THOMAS M. MARKOE read a paper with this title. (See page 509.)

Dr. L. A. STIMSON reported a case in corroboration of what

the author had said concerning the absence of fever and the relation between the formation of cerebral abscess and external injury. A case had come under his care of a man who had been struck on the head in a quarrel and received a scalp wound. He had been treated as an out-patient in one of the hospitals. After the lapse of some time, he had begun to suffer from pains in the head and had sought treatment at another hospital. When the man finally came under the speaker's observation he was entirely free from fever, but unconscious most of the time. On passing the patient one day when he happened to be conscious, the speaker noticed that there was paralysis of the left forearm. He trephined him the next day at the corresponding motor center, a little above the upper end of the scar which marked the site of the scalp wound alluded to. On removing the button of bone and introducing a hypodermic needle, pus was found. An incision was made and about an ounce of pus let out. The man died, and the autopsy showed that the abscess occupied the convolution immediately behind the fissure of Rolando and at about the middle of the fissure. The paralysis has been limited to the extensor muscles of the forearm and hand. An examination of the seat of injury showed that there had been no fracture, except possibly of the external table, but that a limited carious process had followed, with perforation of the bone at one point. Between this lesion of the skull and the brain abscess there was, however, no direct continuity, normal brain tissue intervening of one third of an inch in thickness. The position of the abscess corresponded very satisfactorily to the data furnished by experimentalists.

**Ligation of both External Carotids.**—Dr. MARKOE showed a specimen from a case in which he had tied both external carotid arteries for cirroid aneurysm of the scalp. The vessels had contracted well as the immediate result of the operation, and he had been inclined to hope for a good result and had intended to tie more vessels. His patient had, however, passed from under his notice, and last summer had been in the hospital, where the president had seen him.

Dr. STIMSON said the patient spoken of by Dr. Markoe had come under his care, having suffered from severe haemorrhages at a point on the scalp where an ulcer had formed. He dissected out and removed all the dilated vessels. The patient lost a good deal of blood at the operation, notwithstanding every precaution, including that of compressing the scalp by an elastic bandage. He was put to bed in fair condition. During the night he took enough liquid nourishment to have formed the equivalent of transfusion, and he did fairly well until about two o'clock in the morning, when he woke up very depressed, said he knew he was going to die, and asked to have a clergyman sent for. He died at 6 A. M., fourteen hours after the operation.

Dr. J. A. WYETH said he had noticed with surprise the rapidity with which the collateral circulation was established after ligation of these vessels. In Dr. Markoe's case the tumor had soon reasserted itself. He had recently treated a case of large retro-pharyngeal tumor. When he advised temporary removal of the upper jaw and total extirpation of the mass, the patient's father, a physician, declined to have so formidable an operation performed, on account of the scars that would remain, and its removal with the galvanic-cautery wire was therefore undertaken. The haemorrhage was so profuse that plugging was resorted to, which controlled it. The plug was afterward removed by the house surgeon. A few hours later, while the lad was sleeping, alarming haemorrhage occurred, and both external carotids were tied. On account of his exsanguinated condition, no attempt was made to remove the tumor at this operation. Five days afterward the speaker split the soft palate in the median line, sawed through the hard palate and ineb on each

side of the attachment of the vomer, and removed the included portion of bone, to which the growth was adherent. This procedure gave a good view of the neoplasm, and he gradually scraped the remnants of it off with a sharp spoon. The bleeding was so profuse that he could not take time to apply the cautery to the points of attachment, but was forced to plug the vault of the pharynx.

Dr. F. E. LANGE said that, about four weeks before, he had operated in a case of sarcoma of the alveolar process of the upper jaw which had developed in a nævus that involved the whole cheek. The vascularity of the region had caused a rapid growth of the sarcoma. Thinking that ligation of both external carotid arteries would render the bleeding insignificant, he had done this, and had operated with the head hanging. Still a good deal of blood was lost, the arterial haemorrhage being quite profuse. He slit the upper lip, and bleeding occurred from both sides of the incision and from the arteries of the bone, and the ligation did not seem to have so much effect as he had expected. Good, free collateral circulation had been established. He did not think he could have been mistaken about the vessels which he tied.

**Intestinal Strangulation.**—Dr. L. S. PILCHER, of Brooklyn, presented a specimen taken from a case in which the patient had died after a laparotomy for the relief of intestinal strangulation, with the following history: A man, aged thirty-seven, was admitted into the Methodist Hospital on September 14th, with symptoms of intestinal obstruction. The abdomen was tympanitic, rigid, and tender; pulse, 140; temperature, 100·4° F. He was vomiting frequently a greenish fluid, without feculent odor; his attending physician stated positively that on the preceding day he had vomited feculent matter. Ten days previously he had had his last normal stool; four days before admission he had had a slight movement of the bowels, described as black and tarry in character. Seven days before admission he had a transitory attack of severe colicky pain in the abdomen; previous to this time he had supposed himself well, as he always had been. This attack did not prevent him from working as usual for the next three days, after which time the colic returned, accompanied with vomiting, and these symptoms persisted until his admission into the hospital. Cathartics, opiates, and enemata had been used vigorously before his admission. After his admission another enema was administered, without result. The stomach was then washed out, after which laparotomy was proceeded with. Exposure of the intestines revealed a general peritonitis already present, with great distension of the small intestine throughout its whole extent. The incision was lengthened sufficiently to permit of the ready turning out of the small intestine; the large intestine, quite empty, was then traced backward, beginning on the left side; at the hepatic flexure it was found to be imbedded in a mass of old organized inflammatory material, which bound it to the posterior wall of the cavity. This formed a band an inch or more in breadth, gluing all the adjacent structures together; on the proximal side of the band there was the livid, softened, distended ascending colon. It was evident that any attempt at breaking up the inflammatory adhesions would be attended with great risk of rupture of the intestine, a risk that was increased by the depth of the involved parts from the surface. The speaker accordingly proceeded at once to circumvent the obstruction by forming an anastomosis by bringing the lower portion of the ileum up to the ascending colon a few inches beyond the point of obstruction. This was accomplished by the use of Dr. Abbe's catgut rings. Great difficulty was experienced in returning the distended small intestines, and a puncture was necessary to empty them. This being closed, they were returned into the abdominal cavity.

The patient never rallied from the shock, but died within an hour after his return to bed. The autopsy showed a chronic ulcer of the ascending colon, which had not perforated the peritoneum, but had nevertheless occasioned the local peritoneal exudation that had caused the obstruction. It was found that, so far as the anastomosis was concerned, everything had been accomplished that had been attempted at the operative procedure.

Dr. ABBE thought that in these cases of acute obstruction the operation for effecting anastomosis had better be delayed until after the colostomy. The shock was too much for the patient to stand. After obtaining relief from the colostomy there was no danger after a fortnight in anastomosis.

Dr. ABBE presented a specimen illustrating a typical case of internal intestinal strangulation by a band. A lady of thirty-five was suddenly seized with vomiting and hypogastric pain. She was attended by a physician who endeavored to bring about purgation. Enemata, calomel, and other purgatives failed. Not even wind passed the bowel. Vomiting increased, and on the third day became stercoreaceous. The abdomen became tympanitic, but showed no dull area to suggest the seat of obstruction. At the end of the fourth day, when she was first seen by Dr. Abbe, she had already for six hours shown characteristic apathy and exhaustion. Her temperature was normal, her pulse 100. Laparotomy was immediately resorted to under ether. The abdomen was found filled with distended and highly congested small intestines, among which was seen a small coil of pale and empty intestine. This and the distended gut both terminated in Douglas's *cul-de-sac*. The Fallopian tube on each side was turned upward and fixed by adhesion so as to form a tight pocket behind the uterus, in which was caught a strangulated knuckle of the ileum, with its adjacent coil for three inches. The attempt to remove it was futile, on account of its fixation, and, as the patient's strength began to flag, he was obliged to do an ileostomy of the lowest distended coil as rapidly as possible. The patient lived five hours and died of the shock of strangulation plus operation.

The gut was found gangrenous under the line of the strangulating band. Faecal vomiting occurred twice after the operation.

#### NEW YORK NEUROLOGICAL SOCIETY.

*Meeting of Tuesday, October 1, 1889.*

The President, Dr. GEORGE W. JACOBY, in the Chair.

**Lesion of the Pons Varolii.**—Dr. A. A. BOYER presented a case of this affection with a history, of which the following is a brief synopsis: C. W. B., aged forty-five, syphilitic, in June, 1888, while at work, suddenly felt a sensation at the back of his head as if he had been shot. The shock was not severe enough to cause him to fall or lose consciousness. It was followed immediately by intense headache. Afterward, nausea, vomiting, and insomnia became prominent symptoms for six weeks, and he was treated for gastritis; there was then an interval of two weeks without these symptoms, after which they returned in greater severity. On August 14th his left thigh suddenly grew cold and numb; then the condition extended to his foot, and during the night spread up the trunk, left arm, and left face. In the morning there were anesthesia and paralysis of the whole left side of the body. On examination eight months later, he had a hemiplegic gait, inco-ordination of the left arm, good equilibration, paresis of the left leg, paralysis of the left arm, drooping of left side of mouth, some atrophy from disuse on the left side, hemi-anesthesia, and hemi-analgnesia. The lesion would therefore seem to have been pretty definitely lo-

cated in the pons Varolii, to the right of the median line, above the line of Gubler, and involving the fillet, the reticular formation, and the pyramidal tract. The writer thought a lesion here would be high enough to produce paralysis of the facial muscles of the opposite side, and low enough to leave the ocular nerves unaffected. He believed the most reasonable theory as to the nature of the lesion was that of thrombosis as a result of obliterating endarteritis or hemorrhage. It could not be a tumor.

Dr. W. R. BIRDSALL saw no necessity for assuming a lesion of the pons Varolii to explain the symptoms, which seemed to be wholly unilateral. He usually expected something particularly characteristic in pontic lesions, such as alternating paralysis. He thought a capsular lesion would account for all the symptoms in this case, and the absence of other pontic features would strengthen that view.

Dr. M. A. STARR agreed with Dr. Birdsall as to the localization of the lesion. He thought the case one of ordinary hemiplegia with a lesion in the internal capsule. Unless there were certain cranial nerve lesions, alternating paralysis, or some other characteristic symptoms, there was no need to locate the disease in the pons.

Dr. BOYER said he had been led to locate the lesion in the pons, because there had been no loss of consciousness at the onset of the attack, although very decided and varied paralysis had been developed immediately. In his opinion this pointed strongly to a minute lesion, and nowhere above the pons would a small lesion be likely to produce such wide results. The inco-ordination now remaining after the disappearance of most of the motor symptoms indicated a lesion of the fillet or of the commissural fibers in its vicinity.

**The Curability of Locomotor Ataxia.**—Dr. L. C. GRAY then read a paper thus entitled (to be published).

Dr. C. L. DANA said that we had changed our conceptions as to the variations in clinical types and as to the pathological lesions of locomotor ataxia. Probably ninety per cent. of our cases were typical and answered to the classic descriptions of the disease. But there was a minority of cases which had a non-typical manifestation, types with optic atrophy, with latent spinal symptoms, with spastic symptoms, with peripheral lesions, etc., and the prognosis was different in these forms. For instance, the prognosis was not bad in the spastic variety, but exceedingly so where there was rapid emaciation of the lower extremities. He had recently examined his notes of cases, and the results of treatment in 56 cases (22 syphilitic) had been as follows: 10 very much improved (3 syphilitic); 6 improved (4 syphilitic); 14 stationary (3 syphilitic); 13 progressive (8 syphilitic), 2 fatal; 10 doubtful or unknown.

He believed locomotor ataxia to be a degenerative disorder, affecting nerve fibers primarily, not beginning at a single focus, but at several different places at various times. In order to cure the disease we should have to discover a drug that would stop this degenerative process. As to suspension, he had tried it in 22 cases, with 600 suspensions, since last April. Of these, 4 patients were very much improved, 6 improved, 6 unimproved, and 6 had discontinued the treatment. He thought there was no question as to very marked benefit being produced by suspension.

Dr. BIRDSALL, on hearing the title of Dr. Gray's paper, had been led to think that some new view of the hopefulness of cure was to be introduced by the author, but he coincided with the writer in the opinion he had expressed as to the incurability of the disease. Various physicians entertained different ideas as to what should be termed a cure of a disease. Some considered patients practically cured where the pathological process had been arrested under treatment, although many symptoms might remain. If this were true, possibly

some cases of locomotor ataxia might be called to a certain extent cured. In one of his cases ataxia had disappeared, and had not now returned in nine years, although the patient had of late suffered from various crises, gastric and laryngeal, and some cerebral symptoms, such as loss of consciousness. For five years the active symptoms had been referred to the trunk and upper extremities. It was a syphilitic case. He had had another case where the tendon reflex had returned after abolition for many months, and ataxia had also disappeared; but pains and numbness had subsequently become manifest in the upper extremities. He would not himself speak of any case as cured, but only as arrested in its progress. It was well that we were able to recognize the disease much earlier than formerly, and had better opportunities for early treatment. Our measures should be chiefly hygienic—the regulation of diet, avoiding of excesses, diminishing of labor, etc. He had tried suspension in a few cases, but with no favorable results. At the same time, he did not deem it wise to throw it altogether aside as yet. He had seen injurious effects from large doses of potassic iodide, and, in his opinion, tabetic patients were not so well able to tolerate this drug as some suffering from other disorders. We must modify our opinion somewhat of the varieties of tabes, since Déjerine and others had discovered peripheral nerve lesions in some cases of locomotor ataxia.

Dr. STARR said, with regard to the difficulty of diagnosis between peripheral and cerebral cases, that we must judge from the order of occurrence of symptoms as well as from the symptoms themselves. He referred to Déjerine's paper, where it was shown that peripheral cases were distinguishable by the rapidity of their development as contrasted with those of cerebral origin; alcoholic, lead, and arsenical disorders could scarcely be mistaken for actual locomotor ataxia, for a sharp line could be drawn between them; and, even in the cases of obscure cause, the course was much more rapid in neuritis. Some seven years before Dr. Austin Flint had read a paper on the self-limitation of phthisis. A similar description might apply to locomotor ataxia also. It was possible that the sclerosis of the cord might be a protective process, an effort of nature to arrest or provide against the effects of disease. A pathologist in New York had taught for two years that connective tissue was thrown out by nature as a defense. Thus locomotor ataxia might also be a self-limited disease like phthisis in many instances, although in the majority of cases it was not.

His own records showed some twenty-five cases seen in the last four years, seventeen of which were carefully detailed. In nine of the seventeen there had been periods of non-progression at times, while in eight there had been steady advance in spite of treatment; but, as similar treatment had been employed in all of these cases, the temporary arrest of the disease in some could not be ascribed to the therapeutics. He agreed with Dr. Dana that eye cases manifested atypical symptoms. In three of his cases with blindness there had been no progress subsequent to the failure of sight. He thought it worth while to try specific treatment in patients with a history of syphilis, but he had little faith in its efficacy, as in his experience—as in that of continental observers—it afforded less benefit in locomotor ataxia than in other syphilitic nervous affections. He usually employed small doses of arsenic and biniodide of mercury, which was the English treatment. In thirteen cases treated by suspension at the Vanderbilt Clinic, tabulated by Dr. Peterson, there were seven cases of locomotor ataxia. There had been distinct improvement in two cases only, and none at all in four, while in two the results had been bad, the suspension producing syncope, nausea, and vomiting, severe pain, and enuresis at different times. It might be stated, therefore, that a small proportion only of cases had been improved by suspension.

Dr. B. SACHS had observed in two cases the disappearance of the cardinal symptoms of locomotor ataxia without treatment. The first was as follows: B. L., a merchant, aged forty-eight, seen on August 18, 1886, complained of retching, with dizziness, a numbness of the left arm, and unsteadiness in walking. Both knee-jerks were absent, and could not be elicited with Jendrassik's method. There was slight swaying with the eyes closed, and the patient complained of a feeling as though his drawers were too tight around the waist. The speaker made the diagnosis of tabes incipiens, but with some hesitation, for the general condition of the patient was very good. After two months a slight knee-jerk returned on the right side, and a few months later the left was recovered. Three years had now elapsed since the observation of these symptoms, and the man was in perfect health at the present day. He believed it to have been a functional depression of the cord due to overwork. A second case had shown all the symptoms of tabes, except that the knee-jerk was absent on one side only. The patient had the Argyll-Robertson pupil and the Roinberg and girdle symptoms. He had seen him four months before, and all of the symptoms had diminished.

A simple syphilitic spinal meningitis might simulate a posterior sclerosis, and this should be borne in mind when cases improved under treatment. He mentioned another case, diagnosed as locomotor ataxia by Erb twelve years before, the patient now living in Utah, which had been stationary for five years. So far as actual curability was concerned, he could not speak of that unless a progressive form had been arrested. He would classify cases into optic and spinal types. As to suspension, he had found it unsatisfactory, and had been unfavorably impressed by it. It had seemed to him better in spastic cases, such as myelitis.

Dr. E. WAITZFELDER had been using suspension in a case of spastic paraplegia, and it had made the patient worse, as well as several others with myelitis, but he had noted considerable improvement in gait in several patients with locomotor ataxia who had been subjected to this method of treatment.

Dr. W. M. LESZYNSKY had observed a few favorable results in the employment of suspension in spinal cases. He had also used it in a case of paralysis agitans three or four times with good effect.

Dr. GRAY said that Fournier's and Rumpf's syphilitic patients had shown great improvement under treatment, but this had not been his own experience. He believed there were certain cases where there would be great difficulty in distinguishing peripheral from central symptoms. As to the matter of self-limitation mentioned by Dr. Starr, he saw no analogy between tabes and phthisis. In treatment he preferred to follow French authors and employ inunction in syphilitic cases rather than potassic iodide, for the results were much better.

#### NEW YORK ACADEMY OF MEDICINE.

##### SECTION IN SURGERY.

*Meeting of October 14, 1889.*

Dr. ROBERT ABBE in the Chair.

**Severed Tendons.**—Dr. B. F. CURTIS presented a patient who had received a transverse wound of the left forearm, severing all the flexor tendons. The accident had been caused by glass. The ends of the tendons had been united by sutures, with extension of the hand. Part of one of the tendons had sloughed, leaving a deep depression where the wound had healed by granulation. The patient had recovered considerable power. The speaker thought that further improvement might be effected

by an operation which would free the tendons from the cicatricial tissue which surrounded them.

The CHAIRMAN remarked that the question of further repair was one of interest. He did not see why the tendons should not be dissected out and grow up in new cellular tissue. They might then be sutured individually, and, if a new bed were formed, would then have an opportunity of surrounding themselves with loose cellular tissue.

Dr. R. H. SAYRE spoke of a case in which there had been a cross cut of the forearm through the annular ligament, followed by union of the tendons in one mass. An operation was performed in which the tendons were dissected out, resulting in restoration of separate movements, with great increase in the power of extension.

**Contraction of the Annular Ligament of the Wrist.**—The CHAIRMAN presented a patient upon whom he had operated for the relief of contraction of the annular ligament of the wrist joint due to extensive tuberculous deposits in the forearm. He had made a free incision through the ligament, on the limb, and on the flexor tendon of the first finger. He had also removed about two hundred rice seed bodies which had been found connected with the tuberculous deposit. His patient had now excellent play in the fingers, and would make a satisfactory recovery. These cases were now recognized as tubercular in their origin, and afforded an excellent field for clean antiseptic work.

**Fibrous Contraction of the Fingers.**—Dr. CURTIS reported a case occurring in a girl whose right finger had been bound down upon the palm of the hand as the result of cellulitis. After raising a flap and uncovering the tendon, he found that it and its sheath had become one mass of fibrous tissue. He dissected out the tendon from this fibrous mass until he succeeded in getting a freely movable finger; at least his patient had got perfect palmar flexion.

The CHAIRMAN remarked that in the case he had reported no passive motion had been made, but active motion had been allowed at the end of six days.

**Diseases of the Bones.**—Dr. A. M. PHELPS presented a child, three years and a half old, upon whose foot he had operated for disease of the tarsal bones. He had scraped out each of the bones except the cuneiform and os calcis, which last he had removed. In so doing he had left nothing but the periosteum. The Esmarch bandage was then removed. No ligatures were applied, the blood being allowed to find its way freely into the excavated portions. The wound was then closed and dressed. He had been told that at the end of three weeks it had healed by primary union throughout, and at the end of five weeks there had been reproduction of solid bone, and the child could walk well. No pus formation had followed the operation, and after a few days a thin dressing of plaster of Paris had been applied and the child allowed to walk about. Another case was that of an Italian girl who, since she was five years of age, had suffered from osteomyelitis involving the tibia and fibula, the leg being flexed at a right angle. The question as to amputation or exsection having been discussed, it was decided to exsect the knee joint. The operation showed the lower end of the femur also to be involved in an old tuberculous condition. The diseased portions were removed, as much of the periosteum being left as possible, and the ends of the tibia and femur were approximated. Bony union had resulted, though, of course, there had been want of general development in the bone after such extensive disease, the girl having been bedridden for five years.

**Knots, Ligatures, and Sutures.**—Dr. B. F. CURTIS read a paper on this subject. He gave an elaborate and minute description of the technique of tying, ligaturing, and suturing according to the best and most recognized methods.

Several forms of knots were used in surgery. The surgeon's knot and the square or reef knot were tied in pretty much the same way, the only difference being that in the surgeon's knot there was an extra twist on the first half, which prevented it from slipping while the second half was being tied. When the tension was extreme, and a slippery catgut was used, it was well to tie a third turn after the square knot was completed. This additional turn should always be employed in tying the surgeon's knot in catgut, for the double turn of the first twist did not correspond to the second turn made in the ordinary way. The greatest tension should always be exerted upon the first turn, for that was tied around tissues which were more or less elastic and yielding, and the encircling loop of thread helped to take up the extra strain, so that the material might safely be put to its fullest stretch. This was not the case with the second turn, which had no such safeguard, and might easily break if too much of a pull was put upon it. The "clove-hitch" knot was sometimes useful in surgical work. As it did not slip easily, it was employed in securing the catheter in the bladder, and in reducing dislocations and deformities. It was surprising to know that the now almost obsolete "granny knot" was still used by some surgeons. In ligating thick pedicles, where the tissues were very elastic, and a slippery catgut was used, a surgeon's knot might be employed, but, as a rule, it should not be used for ligatures. In tying a ligature, the points of the thumbs or fingers should be carried down the thread close to the knot, so as to make a direct pull upon the knot itself, thus avoiding displacement of the artery-forceps or tissues, or the dragging off of the inclosed mass. When there was difficulty in securing a bleeding point on account of the friable nature of the tissues, or because the latter were too dense to be pinched up by the forceps or ligature, the haemorrhage could be arrested by passing a suture deeply through the tissues beneath the bleeding vessel and tying the whole mass so as to include it. It was in this way that Horsley controlled haemorrhage in his extensive operations upon the delicate brain tissue. When an artery was to be tied in its continuity, catgut was now almost exclusively used. It was not necessary to draw the thread tight enough to divide the internal coat of the artery, as used to be the rule, for the lumen of the vessel would be obliterated by simple adhesion of the internal surfaces. If a permanent obliteration of the vessel was desired, it would be better to apply two ligatures, and divide the artery between them. If a vein had received a small wound, and the vessel could be picked up by forceps without entirely occluding its lumen, a ligature might be thrown around the forceps and the permeability of the vein retained. In treating the pedicles of tumors, especially those which were to be dropped into the abdominal cavity, it was not safe to depend upon a ligature simply tied around the pedicle or mass. It was necessary to transfix the pedicle with the ligature before tying, and to tie it in two or more places. It was in these cases that the interlacing ligature was of valuable service. Lawson Tait had introduced a very good method of applying ligatures to pedicles, which combined all the advantages of the various methods, and required less time to apply it; this was the "Staffordshire knot." The best material for ligatures for pedicles of any size was silk: catgut was too readily absorbed and too bulky when sufficiently thick to be strong. The silk became encapsulated and gave no trouble. Various forms of suture were used in the accurate coaptation of parts after operations or wounds. The interrupted suture was to be preferred where there was much tension, for if it yielded in any place the integrity of the other stitches would not be impaired. If the continuous suture was used in such a case and one of the stitches should break or cut out, the whole line would become slack. In exposed parts of the body where

close and smooth apposition was required, the interrupted suture was the best. The continuous suture was to be employed for almost all other wounds than those just noted, on account of the ease and rapidity with which it could be applied. A modification of the continuous suture was found in the chain-stitch or "glover's suture." Another form was the "quilt suture," designed to bring broad surfaces into apposition. This suture had a tendency to cause eversion of the edges of the wound, making it an excellent suture in operations on the skin, which had a natural tendency to inversion. The "cobbler's stitch" was another form of the continuous suture, and was very useful for covering in broad, oozing surfaces in pedicles where it was impossible to ligate *en masse*. In some cases where there was great tension of the skin, or where there was a tendency of the deeper parts to fall away from each other and leave a cavity, the lead-plate suture might be used; it acted as a support to the part. The hare-lip suture was useful in very much the same conditions as the preceding suture. The buried suture could be used to prevent the formation of cavities after wounds, and was frequently used in plastic operations, or after excision of anal fistulae. In cases where a strong supporting suture was required the wire suture was generally used. In suturing the tendons and nerves, much ingenious surgery was necessary to overcome mechanical difficulties. One of the obstacles to the suturing of nerves was the fact that degenerative changes were set up at once in the divided ends, so that, even with immediate restoration of physical continuity, functional restoration was delayed until the nervous tissue could be regenerated. The only available forms of suture for the intestine and stomach were those which brought the peritoneal surfaces together and prevented leakage of the contents. This requirement was most simply fulfilled by the Lembert stitch, whether applied as an interrupted or as a continuous suture. One of the greatest difficulties in circular suture of the intestine was the treatment of the mesenteric attachment at the wound. It required great care to cover the raw surfaces here with the ordinary Lembert suture, even when the two peritoneal layers of the mesentery had been fastened together by a stitch at the wound. A passage-way of non-serous surfaces was very apt to be left in the wound, communicating at one end with the interior of the bowel and at the other with the fatty cellular interspace between the two layers of the mesentery. This formed an easy route for infection, and was the point where the suture most frequently gave way. The old idea of protecting the line of sutures with a strip of the omentum stitched around outside had lately been revived by Dr. Senn. The best needles for use in intestinal work were the fine needles with long eyes, such as were used by ladies for working in crewels. Fine silk was the best material for the suture. More complicated methods of suture were in favor with some surgeons, such as those of Czerny, Wölfler, and others. A great advance in intestinal surgery had been made by Senn's proposition to employ perforated plates of decalcified bone when it was desired to make an anastomotic connection between two adjacent loops of bowel, instead of the tedious operation of uniting the edges of the openings in the two loops to each other by sutures. These plates had a large opening in the center to allow the contents of the intestine to flow through. This method insured a continuous patent intestinal canal. Dr. Abbe had suggested oval catgut rings. These were coils of catgut of about the thickness of a lead-pencil, and flattened by pressure between two plates of glass. Brokaw, of St. Louis, had experimented successfully on dogs with rings made of short pieces of rubber tubing threaded on catgut strands, to which the silk threads were attached. Perhaps the most important development in the use

of the rings was their adaptability to lateral anastomosis in the place of end-to-end suture of the intestine. A considerable number of cases were on record in which the rings had been used successfully for entero-enterostomy and gastro-enterostomy.

Greig Smith had introduced a very ingenious suture for securing the stomach to the abdominal wall for gastrostomy. It was also available for securing any cyst to the abdominal wall for drainage, and in the operation of lumbar colotomy. It would be a hard matter to say which was the best method of closing the abdominal wound in laparotomy. Everybody was agreed, however, upon the necessity of bringing the peritoneal surfaces into contact. Some surgeons used only a single row of sutures, which passed through all the layers of the abdominal wall, while others applied several series, uniting each layer independently. In suturing the bladder and in the treatment of the uterine wound after Cæsarean section, the Lembert stitch was to be preferred.

The author of the paper contrived to make his subject, which was of necessity one of detail and technicalities difficult to describe and to follow, thoroughly interesting. Many of his points were admirably elucidated by very cleverly executed diagrams.

The CHAIRMAN said it was remarkable that while the field of operative surgery was becoming enormously enlarged, the practical details of its performance were being cut down to smaller dimensions. The old authors, if writing on the subject of Dr. Curtis's paper, would have included very much more material and very many more styles of work. Now only the essentials had been given, and yet even here some things might with reason have been left out; for instance, the hare-lip pin seemed to him a device of the past. He advocated the use of sutures to secure secondary union. The sutures might be introduced at a primary operation, and then, when so desired, the wound could be kept open for forty-eight hours by stuffing. This could then be removed, and the sutures tied, when it would be found that union was secured as effectively as by primary coaptation. In the matter of suturing tendons he would like to allude to a form of injury of the finger known as Ségond's fracture. The end phalanx of the finger dropped, and there was no power of raising it. The injury was very easily incurred. A lady in slipping off a stocking had caused the accident; another had caught the end of her finger in a fold of her dress. A patient of the speaker's had had his finger struck by a base-ball, and the result had been produced, and another had stubbed his finger. In the case last mentioned he had operated by making a free incision over the parts, dissecting till he had reached the extremely attenuated attachment which had drawn back the phalanx. He had then divided the tendon and, after removing sufficient to reduce it to the required length, sutured the ends together with silk, making use of the second method described by Dr. Curtis. He had left the suture buried and it remained so at the present time. The patient could use his finger and had good motion in the joint.

Dr. SAYRE said that he would like to call attention to a use of the buried suture which had not been mentioned. By continuing the shoemaker's stitch and passing up to the edge of the skin the operator could avoid the needle punctures. This made a very beautiful cicatrix, which in plastic surgery was very desirable.

Dr. R. H. M. DAWBARN spoke in terms of approval of Dr. Abbe's catgut rings. He had used them in two cases on the living subject and had been struck with the ease and rapidity with which the anastomosis could be effected.

Dr. V. P. GIBNEY said that he had had some experience in the deformity alluded to by the chairman, but had never had an opportunity of operating for its relief. Some three or four years ago, however, two or three patients had presented themselves on

various occasions at his clinic with a condition of the phalanx such as had been described. He had resorted to various expedients in the way of splints, but only to find them perfectly useless. Finally he had superextended the fingers and put on a very light plaster-of-Paris bandage, which he had kept on for three or four weeks, and in one instance for as long as two months. These patients had recovered perfectly. In a case at present under his notice the patient had fitted a little splint into the finger of a glove, but was always removing it. Now there was a distinct area of inflammation and the finger looked gouty. Using the finger increased this inflammatory appearance.

The CHAIRMAN said that he had noticed this inflammatory zone of which Dr. Gibney had spoken. He thought the plan of superextension and immobilization with plaster was an excellent one, and he would certainly prefer it to that of suturing and leaving the silk *in situ*.

**A Case of Nephro-lithotomy followed by Nephrectomy.**—Dr. ANDREW J. McCOSH read a paper with this title. He said operations for the extraction of renal calculi were not of very common occurrence. On that account it was important that all cases of nephro-lithotomy should be reported in order that a definite conclusion might be reached as to the surgical position this operation was to occupy. Cases in which the result had not been satisfactory were even more important than those in which a cure had been accomplished.

W. H., aged forty-four, a canvasser, was admitted into the Presbyterian Hospital, July 15, 1889. Some five years previously he had begun to feel pain in his back, especially on the right side. This had continued, with intermissions, ever since. Lately it had increased. At the time of admission to the hospital he passed, in his urine, a large amount of blood. This continued for a few days, after which the urine appeared perfectly clear and natural. At times he suffered from frequent and painful micturition. He had tried all sorts of treatment without benefit. Exertion so aggravated his pain that he had been unable to attend to his business. He had been obliged to remain in bed on this account, his strength gradually failing. Within the preceding eighteen months he had lost twenty pounds in weight. When admitted, he was a large, athletic, robust-looking man with well-developed muscles. He was anaemic, however, and had a careworn expression. He complained of pain in his right loin, at times excessively severe, and never altogether absent. He described it as of a gnawing character. His right testicle had always been more or less retracted. The urine contained albumin and a few pus-corpuscles. No red blood-corpuscles or crystals of any kind were present. Daily examination of the urine for six days gave the same result. The amount of albumin was about a half of one per cent. The pus-corpuscles were sometimes entirely absent, and were never numerous. The diagnosis of renal calculus was made. As the patient had for years been subjected to various kinds of treatment without benefit, an exploration of the kidney was proposed. On July 20th the patient was anaesthetized with chloroform. A vertical incision at the outer edge of the right erector spinae muscle was made from the last rib to the crest of the ilium. The lumbar muscles were found to be enormously developed, and the circumrenal fat could not be reached until an unusually deep wound had been made. Tearing through this, a small portion of the kidney could be seen, but not until strong pressure by the hand of an assistant had been made through the abdominal wall could the kidney be brought well into view. To sight and touch it appeared to be healthy. The finger, passed around the kidney, soon discovered a hard body of about the size of a walnut in its pelvis. A needle thrust against it verified the diagnosis of renal calculus. The kidney was situated so deep and high under the ribs that a transverse

incision, at right angles to the vertical one, was made for two or three inches outward. This gave more room, but the pelvis of the kidney could not be brought into view. It was decided to extract the stone through the kidney structure proper. Accordingly, a cut about an inch and a half long was made through the external border. By cutting and tearing, this incision was extended down to the pelvis, whence the stone was easily extracted with a long forceps. The bleeding from the cut kidney was moderate and easily controlled by pressure. Not a drop of pus escaped from the kidney, which appeared but little diseased. The stone weighed one hundred and twenty-two grains and was covered by small, rough crystalline projections, apparently composed of oxalate of calcium. Bleeding having ceased, two cat-gut sutures were placed in the capsule, which drew the walls of the incision into apposition. The external wound was partly closed and packed with boro-salicylic gauze. At the end of the operation the patient was in good condition, and recovered rapidly from the anaesthetic. For the first few days the urine contained a considerable amount of blood, but at the end of a week this had disappeared. For a few days there was a purulent discharge from the urethra with pain on micturition. The original dressing was not changed until the fourth day. The discharge had not soaked through the dressings, and there had been no indication for interference. Twenty-four hours after the operation the patient said that he was more comfortable than he had been for years. The first week the temperature had varied between 99° and 100·5° F. On the tenth day there was severe pain in the wound with elevation of temperature. It was feared that the exit for pus was insufficient. The house surgeon then passed his finger deeply into the wound to break open any pockets which might have formed. This was followed by a discharge of urine from the wound, which lasted but a few hours. The result had been a decided improvement in the patient's condition. At the end of three weeks he was out of bed and feeling fairly well. A granulating sinus still existed in his loin, but, except on the one occasion, there had been no sign of urine in the wound. Improvement continued, and on the thirtieth day the patient was discharged apparently cured. On the afternoon of the same day, however, he experienced severe pain in his kidney, accompanied by vesical tenesmus and the passage of blood *per urethram*. His temperature rose to 102° F., and his pulse to 110. The next day the temperature remained elevated, the pain continued, and pus and blood were passed in the urine. The sinus in his loin was explored, and found to be an apparently healthy granulating channel leading toward the kidney without pouches or lateral branches. On the third day the patient's condition was much worse, and an accumulation in the pelvis of the kidney was suspected. An exploration by the finger was followed by a sharp gush of urine and blood. An effort was made to stop the haemorrhage by pressure of the finger, but it was found necessary to pack the wound with iodoform gauze to arrest it permanently. No improvement in the patient's condition followed; the temperature rose to 104° and the pulse to 120. Considerable blood was passed in the urine. At the end of twenty-four hours the dressing was removed, and this was followed by profuse bleeding, rendering repacking necessary. Although bleeding from the external wound had been prevented by the tampon, considerable blood appeared in the urine, which continued till the next day. The temperature remained the same, and the pain and restlessness increased. It was estimated that at least thirty-two ounces of blood had been lost during the three days, and it was evident that more energetic action would have to be adopted. On the 24th of August, thirty-five days after the first operation, chloroform was administered with the intention of freely exposing the kidney and, if necessary, of re-

moving it. The condition of the patient was decidedly unfavorable. Without disturbing the gauze in the sinns, incisions through the old cicatrices were rapidly carried down until the kidney was exposed. As soon as the gauze had been removed, free haemorrhage took place, but was controlled by pressure. It was expected, from the experience of the former operation, that removal of the kidney would be difficult on account of its depth, its high position, and the large development of the lumbar muscles. The space between the ribs and the iliac crest being short, the last rib was excised. This gave sufficient space to allow the kidney to be drawn well into the wound. The pedicle was secured by a ligature *en masse*, the kidney was cut away, the vessels and ureter were tied separately, and the wound was irrigated with boro-salicylic solution and packed with gauze. Toward the end of the operation the patient required rectal and hypodermic stimulation. The extirpated kidney was found unusually large. On its external border, where the original incision had been made, there was found an oval opening leading down to its pelvis. The kidney-substance forming the edges of this opening was softened and seemed to be breaking down or sloughing. The whole organ was congested, and a stone of the size of a pea had been found in one of the calices. The patient rallied slowly, and by the next day had decidedly improved. The urine, drawn a few hours after the operation, contained considerable blood. From this time onward there was complete suppression of urine. Toward afternoon, twenty-four hours after the operation, persistent vomiting began; the temperature rose to 105°. Vomiting continued and the pulse grew weaker, and the patient, from extreme restlessness, passed into a state of semi-coma, and died at 11 P. M., thirty-two hours after the operation. Death was due principally to uræmic poisoning, and partly to exhaustion from loss of blood. The remaining kidney, for there had been one, had failed to perform its function.

This case had been a very disappointing one. At the end of a month the patient had been apparently cured, when suddenly symptoms of pyelitis, or pyelo-nephritis, developed. These rapidly reached a point where a fatal termination was imminent. In an attempt to ward this off the kidney was reopened. The result was persistent haemorrhage without amelioration of the other symptoms. The bleeding took place from the parenchyma of the kidney, and its source appeared to have been the numerous blood-vessels which had been torn. The writer had never seen or heard of a case where moderate pressure for a few moments would not entirely control bleeding from lacerated kidney tissue. The question as to whether the haemorrhage had been due to the sloughing of the edge of the wound or to failure in contraction of the blood-vessels on account of the cicatricial tissue, he was unable to answer. He thought that, after unfavorable operations, it was always instructive to review the technique and consider how it might with advantage have been modified. In this case he could not see how the unfortunate complication could have been foreseen or avoided. He said that the secondary disease might possibly have been prevented if the stone had been extracted through an incision in the pelvis of the kidney instead of through the substance proper, although it had been considered preferable to incise the kidney itself. He thought it would have been wiser to extirpate the kidney twenty-four or thirty-six hours earlier, thereby saving the loss of blood. So far as the writer knew, no such complication had ever before arisen. This was his third case of nephro-lithotomy. In two cases recovery had been prompt and permanent. In one the stone was extracted by an incision in the pelvis; in the other, through the body of the kidney. In the case in which the pelvis was opened the escape of urine persisted for twelve days; in the other case it ceased in twenty-four hours.

## New Inventions, etc.

### NASAL INSTRUMENTS.

BY J. W. GLEITSMANN, M. D.

1. *A Nasal Bone Forceps.*—Although the writer feels some aversion to increasing the already large number of existing designs of nasal forceps, the instrument here described has, after repeated trials, proved so satisfactory that he deems it advisable to publish a description of it. The forceps has the usual angle of nasal instruments. The branches, which are slender but very strong, cross each other when the instrument is closed, thereby occupying very little space. They can be introduced through the narrowest nasal speculum to any desirable depth, and, on account of their smallness, do not obscure the field of vision. The chief point distinguishing it from other devices is the location of the joint near the distal end, by which arrangement great power can be exerted when the blades seize the part to be removed (Fig. 1).

The design had its origin in the desire to extract pieces of septal cartilage, or still oftener bones which had been operated upon either with the nasal trephine or the saw. Especially in using the saw the

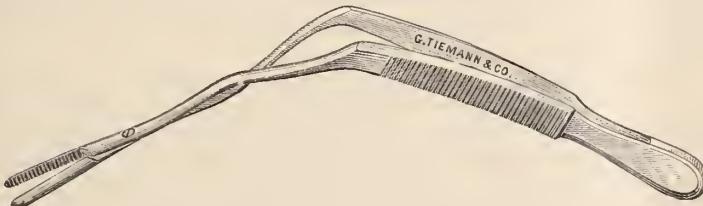

FIG. 1.

severed bone was often found to be difficult of removal on account of being firmly imbedded in the stenosed canal or still adherent to the septum by a shred of undivided mucous membrane. The failure to extract the bone with a slender forceps and the difficulty of overlooking the field when using a stronger straight forceps led to the construction of the instrument.

Although intended only for removal of bone which had been operated upon, quite recently a foreign body, a shoe-button, which yielded to no other instrument, was extracted from the nostril by the aid of the forceps, having blades with three prongs, as shown by the second drawing (Fig. 2).

FIG. 2.

2. *A New Nasal Dilator.*—The dilator here described is made from the wood of the *Nyssa aquatica*, or tupelo-tree of the Southern States, which was first introduced into medical practice by Dr. G. E. Sussdorf. In the May number of the "Richmond and Louisville Journal," 1879, he recommended its use for tents to dilate the os uteri, and subsequently Mundé corroborated his statements. The root is subjected to heavy hydraulic pressure, and, when exposed to moisture, offers the following advantages: It expands very rapidly and equably, and is therefore preferable to laminaria, which swells irregularly, and consequently exerts unequal pressure. Its surface is smooth and does not lacerate the tissue when introduced into a narrow opening. After removal the tissues do not appear dry, but even more moist and pliable than before. Tupelo has also to a certain degree antiseptic properties; it does not favor decomposition, and no smell is perceptible after it has been extracted. Its chief advantage for our purpose is the softness of its texture, which enables us to cut it into any desirable shape with an ordinary knife (Fig. 3).

The writer was for some time in search of an agent to produce sufficient dilatation of naturally narrow nostrils, which did not require active interference—viz., which did not present a turbinate hypertrophy or a septal exostosis. Further, cases often presented

themselves for treatment in which after such operations sufficient space could not be gained for satisfactory nasal drainage, or in

FIG. 3.

G.TIEMANN & CO.

which the danger of subsequent formation of adhesions was imminent. The soft rubber tubes and similar devices did not fulfill the requirements, and a more thorough and efficient method seemed highly desirable. Tupelo, to which the writer's attention for this purpose was first drawn by Messrs. Tiemann & Co., has proved to him so eminently satisfactory that he considers it his duty to lay the results of his experience before the profession. He has employed it now in about a dozen cases, and in no instance has it failed to meet his expectations. A single case may serve as an illustration: A patient with naturally very narrow nostrils and bilateral exostoses on the lower part of the septum suffered from almost complete obstruction of the nares, the lateral walls and the septum being in immediate contact with each other without the presence of true turbinate hypertrophy. On one side the septal exostosis had been removed by a physician, but the operation had not given the desired relief. The introduction of the tupelo dilator four times opened the nostril enough for all practical purposes, and no contact of the parts took place afterward. The other nostril was treated in precisely the same manner, tupelo being introduced after the wound from the nasal trephine had healed sufficiently, and the result was equally satisfactory.

The writer feels confident that he has materially shortened the time of treatment of suitable cases since applying the tupelo dilators, and he would feel loath to part with them.

↑ The manner of application is very simple. After the nostril is thoroughly cleansed with a disinfectant solution and anæsthetized with cocaine, a piece of tupelo is cut to correspond to the required size, seized with an ordinary forceps, and introduced to the desired depth. After remaining in the nose for fifteen to twenty minutes the expansion is accomplished and the piece, generally swollen to quadruple its size, removed. After another cleansing, the patient can be sent home, or, as it has been my custom lately, a piece of tinfoil, which also can easily be shaped according to the requirements of the case, is inserted, to prevent contact of the parts, if there should be such an indication. The tinfoil may remain with impunity till the patient pays his next visit. The smaller piece of tupelo in the drawing represents the size generally employed. It was put into water for ten minutes, and the second figure shows the appearance of the piece after that time. This is the usual expansion obtained in the nostril. It has been found most convenient to have the tupelo made up in pieces of six inches by an inch and a half

## Miscellany.

The Medical and Chirurgical Faculty of Maryland will hold a semi-annual meeting in Hagerstown, on Tuesday and Wednesday, the 12th and 13th inst., under the presidency of Dr. A. Friedenwald, of Baltimore. The programme includes the following titles: "Persistent Headaches and how to cure them," by Dr. J. J. Chisolm; "Practical

Remarks on Hernia," by Dr. Robert W. Johnson; "Report of a Case of Double Popliteal Aneurysm cured by Ligature," by Dr. J. Edwin Michael; "The Use of the Galvano-eautery in Skin Diseases," by Dr. George H. Rohé; "The Early Detection of Pulmonary Consumption," by Dr. William B. Canfield; "Typhoid Fever," by Dr. Joseph T. Smith; "Remarks on some Recent Cases of Abdominal Tumor," by Dr. Randolph Winslow; "The Origin and Treatment of Pus Accumulations in the Female Pelvis," by Dr. T. A. Ashby; "Remarks on the Principal Modes of treating Hemorrhoids," by Dr. S. T. Earle; "Rhachitis considered in Regard to some of its Special Symptoms," by Dr. William Lee; "Post-nasal Obstruction in Children," by Dr. J. N. Mackenzie; and "A Review of Hypnotism," by Dr. George J. Preston.

**The New York Academy of Medicine.**—At the next meeting of the Section in Surgery, on Monday evening, the 11th inst., Dr. F. R. Dennis will read a paper on "Fractures of the Base of the Skull," and Dr. F. Kamperer will report a case of "Operation on a Sarcoma of the Dura Mater and Ligature of the Longitudinal Sinus."

At the next meeting of the Section in Paediatrics, on Thursday evening, the 14th inst., Dr. M. Putnam Jacobi will make "Remarks on a Case of Empyema" (the discussion to be opened by Dr. F. Delafield); Dr. L. E. Holt will read a paper on "The Anatomical Characters and Nomenclature of the Diarrhoeal Diseases of Infancy"; and Dr. H. D. Chapin will read a paper entitled "Observations relating to the Summer Diarrhoea of Infants" (the discussion to be opened by Dr. W. P. Northrup).

At the next meeting of the Section in Orthopaedic Surgery, on Friday evening, the 15th inst., Dr. Henry Ling Taylor will read a paper on "The Treatment of Pes Equino-varus by Continuous Leverage."

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the abstract of sanitary reports received by him during the week ending November 1st:

CITIES.	Week ending—	Estimated population.	DEATHS FROM—										
			Total deaths from all causes.	Cholera.	Yellow fever.	Small-pox.	Varioloid.	Variola.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Malaria.

**Resolutions offered by the Board of Obstetric Surgeons of the Maternity Hospital on the Death of Dr. Isaac E. Taylor.**—Resolved, That in the death of their late president, Dr. Isaac E. Taylor, the members of this board have met with an irreparable loss—the loss not only of a faithful and efficient colleague, but of a warm personal friend.

*Resolved*, That in his beautiful and serene old age they recognized the noblest type of the good physician, who retired from the active practice of his profession in the fullness of his fame and with the universal love and respect of his associates.

*Resolved*, That they extend to the family of the deceased their heart-

felt sympathy and that they will unite with them in cherishing his memory.

*Resolved*, That copies of these resolutions be sent to the family and to the medical journals.

HENRY J. GARRIGUES, M. D.,

WALTER R. GILLETTE, M. D., ROBERT A. MURRAY, M. D.,

WILLIAM T. LUSK, M. D., EGERTH II. GRANDIN, M. D.,

MONTROSE A. PALLEN, M. D., HENRY C. COE, M. D.,

Consulting Surgeons.

Attending Surgeons.

HENRY C. COE, M. D., Secretary.

#### ANSWERS TO CORRESPONDENTS.

No. 295.—Thiersch's solution consists of 1 part of salicylic acid and 6 parts of boric acid, dissolved in 500 parts of hot water.

No. 296.—A five-per-cent. emulsion of creolin is probably germicidal, but not so "effective in a given time" as a 1-to-1,000 solution of corrosive sublimate. As to its being too strong to use on a surface where primary union is sought for, if the contact is prolonged, some of the creolin may cling to the surface and act as a foreign body; it will not interfere with healing in any other way.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

Original Communications.

THE CURABILITY OF LOCOMOTOR ATAXIA,  
WITH AN ACCOUNT OF OUR PRESENT KNOWLEDGE OF  
ITS PATHOLOGICAL ANATOMY.

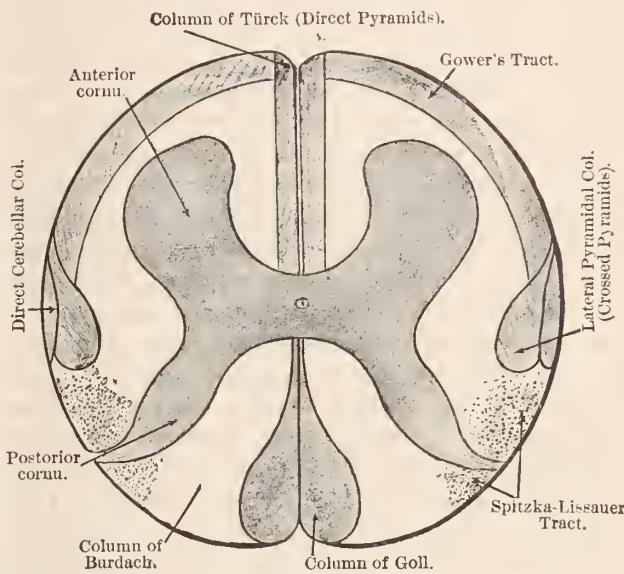

By LANDON CARTER GRAY, M. D.,  
PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE NEW YORK POLYCLINIC.

AT the very outset of this subject we are confronted with the query as to what we mean by the term locomotor ataxia. The truth is that this designation, originally of clinical derivation, is no longer in consonance with either our modern clinical or pathological knowledge, for the ataxia of this disease is often wanting, is generally a late symptom, and in some instances is static and not locomotor. Nor are the other synonyms—tabes dorsalis and posterior sclerosis—any more appropriate, since the pathological process is not a softening or tabes, is occasionally of cervical and not dorsal origin, and modern research, as I shall point out later on, has demonstrated that the lesions are by no means confined to the posterior columns. Yet usage has atoned for the manifest imperfections of these terms, and it would be rash to suggest anything in their place until our present knowledge of the exact textural alterations and their anatomical site has become precise, as I have no doubt that it will be in the very near future. But by the term locomotor ataxia or its synonyms the neurological world, if I may venture to correctly interpret its consensus of opinion, means a group of symptoms characterized by stabbing or lightning-like pains, which in their typical form are sudden, severe, and not fixed in location; loss of knee-jerk; pupils responding sluggishly or not at all to light, generally to accommodation, small in size (Argyll-Robertson pupil); optic-nerve atrophy; ataxia, manifested by a peculiar gait and an inability to perform movements requiring accurate muscular coaptation; swaying of the body with eyes closed (Romberg symptom); patches of anesthesia throughout the affected limbs; transient ptosis or strabismus; paroxysms of sudden and severe gastric, laryngeal, nephritic pains that are called crises; trophic joint lesions.

To these main pathognomonic symptoms may be added others of secondary importance, such as vesical paresis, various kinds of sensory impairments, muscular atrophies, paralyses, trophic lesions, etc.; but these occur in other spinal diseases, and their diagnostic value will therefore be made or unmade by the accompaniment of the main or pathognomonic symptoms.

Until within about a decade these symptoms were thought to be due to disease of the posterior columns of the cord and the adjacent gray matter of the posterior horns, and there was a difference of opinion as to whether these posterior columns and cornua were together or separately the paths of sensory conduction.\* Then Flechsig's embryological researches mapped out the direct cerebellar

columns in the posterior portion of the lateral columns. Then Worosehilloff demonstrated that section of both posterior columns and the posterior halves of both lateral col-

umns in the lower dorsal region of the rabbit did not prevent sensory impulses passing from the hinder limbs to the motor structures in the cervical cord and the brain. This was in 1874. Gowers, three years afterward, was the first one to confirm anatomically what Worosehilloff had observed physiologically by the discovery of the antero-lateral peripheral tract which has since come to be known as the Gowers column, although Westphal, Kahler, Pick, Strümpell, and Leyden had also partially figured this column before. That this is a sensory tract is proved by the fact that it is the site of an ascending degeneration, as is made patent by the cases of Haddon, Gowers, Westphal, and myself in cases of tabes dorsalis, and by Tooth in a case of compression myelitis. The objection of Déjérine, that the degeneration of this peripheral tract might be due to a meningitis, has been abundantly disproved, especially by Sherrington, who has found the column in the eighth month of intrauterine life, and who has also demonstrated that it takes on its medullary covering at a different time from other strands of the cord. Bechterew, in his turn, has subdivided the Gowers tract into an anterior and posterior portion, and has also been confirmed by Sherrington's embryological observations. In 1885 Dr. E. C. Spitzka called attention to a tract which he describes as being "an area bordering on the entry line of the posterior roots and the posterior gray horn on one side and on the periphery of the cord on the other," and to this he gives the name of the *analgesia tract*, as he had found it impaired in all cases of analgesia, and healthy in all cases without analgesia. Immediately adjoining the gelatinous head of the posterior horn, as described by Dr. Spitzka in the same paper, there is a column of vertical fibers which he believes to bear the same relation to the gelatinous substance that the ascending roots of the fifth pair bear to the gelatinous substance of the tuber cinereum of Rolando, and this analogy inclines him to believe that the

\* For the benefit of the non-neurological reader I have inserted a chart of the spinal cord, indicating the strands to which allusion is made in this paper.

tract may be possessed of trophic functions, although he can affirm nothing more positive than that it was healthy in those cases in which there were no trophic disturbances, as well as in that other class of cases with cutaneous lesions directly related to the fulminating pains. By one of those curious coincidences which have been so frequent in the history of medicine, in the same year Dr. Lissauer, in a long and minute description of the posterior horn in its relation to locomotor ataxia, also described these two tracts with great precision, calling the region in which they lie the *rim zone* (*Randzone*), and maintaining that it consisted mainly of fine fibers from the posterior roots, most of which passed into the gelatinous substance, while a smaller portion went to the inner part of the posterior columns. According to this author, the posterior horn receives posterior root fibers of two kinds—firstly, large ones that proceed directly into the spongy substance and then take another direction; secondly, small fibers (mixed with fibers from other columns) that branch immediately after entering the cornu and pass up as an ascending column in the *rim zone*. This *rim zone* was degenerated in twelve of thirteen cases examined by Lissauer, in three being a field of degeneration by itself. As a rule it was attacked early. In two of my own cases it was distinctly degenerated, although I do not know at what stage. Lissauer states that the large root fibers are affected at a late period relatively, disease of them proceeding slowly. In two cases they were normal. Lissauer also believes that the loss of the large root fibers of entry and the alterations in Clarke's column may be regarded as the first pathological phenomena in locomotor ataxia. The direct cerebellar column of Flechsig, the antero-lateral peripheral column of Gowers, and the Spitzka-Lissauer postero-lateral column, are therefore all outside of the posterior columns, and are yet sensory tracts which are affected in locomotor ataxia. The old subdivision of the posterior columns into the columns of Burdach and the columns of Goll remains unimpeached, except that the outlines of the latter in the different levels of the cord are being very considerably modified.

Until 1883 it was supposed that this symptom-group which we call locomotor ataxia was always due to affection of the sensory columns of the cord, but in that year Déjérine reported the following two cases of peripheral neuritis with these symptoms:

Male, aged forty. Symptoms of ataxia arrived at a marked stage of inco-ordination, loss of patellar reflex, very marked derangement of sensibility, anaesthesia, analgesia in the lower limbs, no myosis, slight diminution in volume of the pelvic muscles, Romberg symptom. *Post mortem* the spinal cord, the spinal ganglia, and the posterior roots normal macroscopically and microscopically, but the cutaneous nerves, taken from different regions of the calves and thighs and subjected to osmic acid and picro-carmine, showed very marked alterations of a parenchymatous neuritis.

Female, aged fifty, unable to walk. For several months she had felt pains in the lower extremities; shortly afterward she had difficulty in walking, and gradually she became unable to walk. Pains in the arms for several weeks. She was slightly cachectic, probably from alcoholism. The upright station was still possible, but only with the eyes open. No myosis. Emaciation of trunk muscles. Muscular strength still quite marked.

Slight diminution of faradaic contractility. Absolute incoordination of lower extremities, somewhat less in superior extremities. Anaesthesia and analgesia very marked, with retardation of several seconds in the transmission of painful impressions over the whole surface of the body, excepting the face. No thermo-anesthesia. Loss of patellar reflex. The sensory troubles were more marked in the inferior portions of the skin. *Post mortem* an interstitial hepatitis was found. The spinal cord and the nerve roots appeared healthy to the naked eye. Microscopical examination, while nerves were still fresh, revealed extreme parenchymatous neuritis of the cutaneous nerves of the calves, thighs, arms, abdomen, and thorax. There was not a healthy tubule after preparation in the cutaneous nerves of the calves and thighs; osmic acid had no action upon them. The same alterations were found in the skin of other regions, diminishing gradually in ascending to the upper portion of the body. Slight alterations were found in the intramuscular nerves, such as slight increase of the nuclei of the primitive fibers. There was absolute integrity of the posterior and anterior roots throughout the length of the cord. After hardening, the spinal cord and the spinal ganglia were found microscopically intact.

The well-known law of a secondary degeneration is that there must be an original focus of disturbance from which the nerve fibers secondarily degenerate, upward in the case of the sensory strands, downward in the case of the motor strands. The beautiful safranin stainings of Adamkiewicz have made it evident that the lesion of the nerve tubules in locomotor ataxia primarily affects the axis cylinder or its medullary layer, and that the changes in the neuroglia are secondary, the results that had previously been obtained by Schiefferdecker and Homén with aniline blue being thus confirmed and rendered more precise; and this, to my mind, increases the probability that some such focus, either of arterial origin or due to some cellular alteration in the lower dorsal or lumbar portion of the cord, is the starting point of locomotor ataxia.

Dr. E. C. Spitzka regards the middle area of Burdach's columns as the site of the primary disease, as the connective tissue is thickest here, there is a dense maze of overlapping ascending and descending fibers from the posterior roots, and the lymphatics are most sparse. In other cases a meningitis, such as has often but by no means invariably been found, would be quite capable of acting as the starting point; and when we consider the autopsies in Déjérine's cases, and couple them with the well-known clinical fact that locomotor ataxia can follow a peripheral trauma, we may very properly surmise that the original lesion may occasionally be a peripheral one. It is difficult, however, to understand how a peripheral neuritis can be started in both lower extremities except by some underlying diathetic cause, while a very small focus of disturbance in the spinal cord itself or its meninges might be ample enough to affect bilateral strands. In the syphilitic cases this probability is even stronger of a focus whence the secondary degenerations proceed, the more especially if we may pin our faith to the microscopical descriptions given by Rumpf in his classical work upon "Syphilis of the Nervous System." Nor, in this study of locomotor ataxia, must we forget that the characteristic symptoms have been produced by the poisons of ergotine, lead, and arsenic, and in many of these cases lesions have been found in the posterior columns of the cord,

and, finally—most startling of all—cases have been reported where the cord and peripheral nerves have been found unaltered.

From this review, necessarily cursory and imperfect in a paper of this kind, it is evident that the symptom-group to which the name of locomotor ataxia has been given may be of spinal or of peripheral nerve origin, possibly sometimes without any organic changes. But little advancee has been made, however, in the exact localization of the individual symptoms; indeed, the only results in this direction have been the *analgesia tract* described by Spitzka, and the opinion advanced by some authors that the ataxia is due to a loss of the muscular sense; but the former of these two lacks confirmation, while the latter is refuted by two cases of my own, whose history is herewith subjoined. Yet I can safely prophesy, I think, that we stand at the threshold of an era when the individual nerve fibers will be accurately delimited in the cord, when their functions will be thoroughly understood, when central or peripheral lesions of them will be diagnosticated by certain symptoms, and when the designation of locomotor ataxia or tabes dorsalis or posterior sclerosis will give way to the more scientific names that shall be based upon the central or peripheral localization—when, in a word, we shall map out the functions of areas in the cord as we have so brilliantly begun to do in the cortex of the cerebrum.

With this understanding of our present knowledge of the pathology and pathological anatomy of locomotor ataxia we may proceed to consider the question of the curability of cases presenting this symptom-group. It will be found that the patients who are alleged to have been cured, or whose symptoms have been seemingly arrested, are of the following kinds:

1. The syphilitic cases.
2. Cases associated with general paresis of the insane.
3. The non-syphilitic cases.

1. *The Syphilitic Cases.*—I do not need to remind you how the doctrine of the syphilitic causation of locomotor ataxia, first maintained by Fournier in 1875, in the face of the most furious opposition, has now come to be generally accepted, the percentage of some authors even running up to 90 per cent. The most remarkable confirmation of this view is to be found in the recent observation of Dr. L. Minor, of Moscow, showing the infrequency of locomotor ataxia among the Jews, who are singularly free from syphilitic affections. I may say in passing that this present belief in the frequent specific origin of tabes is a rare posthumous tribute to the clinical genius of Duchenne (of Boulogne), to whom we owe our first accurate description of the symptoms, and who specially remarked the occasional efficacy of iodide of potassium. These syphilitic cases may be subdivided into those in which the locomotor ataxia is developed after a specific infection, those in which the symptoms are associated with symptoms of intracranial syphilis, and those in which the lesion has been found to be a syphilitic spinal meningitis. The first group is illustrated by the following cases:

Dr. L. Lahmann ("Deutsche medicinische Wochenschrift"): Male, aged thirty-one, came under observation September 15,

1884. Twelve years before (1872) had had a hard chancre; was treated with inunction, and cured. He had never had any throat trouble, roseola, or any other symptom of constitutional disease. But somewhat later pains appeared in the shin bone, relieved by iodine. Patient is married, father of a healthy child. During summer of 1884 slight weariness of feet, worse in August, and gradually and steadily grew to the present degree of difficulty. Iodine was ordered in large doses up to fifty grammes, but the symptoms increased. The patient thought the cause of his trouble was the disappearance of the sweating of the feet, which had been present since taking cold in the summer of 1883. He complained of formication, numbness, feeling of stiffness and coldness in the feet and legs, weakness in walking, tottering gait, and uncertainty in walking, which was impossible in the dark. In urination, weakness, long tardiness, many interruptions.

Examination made evident great swaying with eyes closed; eyes and other sensory organs normal; no strabismus; no pupillary abnormality; vision normal; even with eyes open, standing was difficult, impossible upon one foot; the muscular bellies were everywhere strong, firm, and well nourished, possessed of normal strength while patient was sitting, but if the eyes were closed in sitting, the limbs were lifted above the point determined beforehand. When lying down with eyes closed the limb could not hit an object placed beforehand. Rising from a sitting position was done with the aid of the arms. Walking is uncertain to a high degree, swaying, ataxie; the legs are slung around; the gaze fixed upon the floor. Patient twice fell headlong in going out of the room. Painful going from house to house was forbidden and a rolling chair was recommended. The electro-muscular excitability to both currents was normal. Sensibility was faulty on the thorax anteriorly and posteriorly, on the abdomen and the os sacrum. Island-shaped areas of anaesthesia alternating with surfaces of greater sensibility. *Aesthesiometer* points at ten centimetres distance are not separately felt with certainty. The sense of location is also lessened in the legs. Sensation of pain with a needle lessened and retarded. The direction of the limbs is imperfectly felt when the eyes are closed. Passive movements of the toes imperfectly recognized when the eyes are closed. Sense of pressure and temperature are correctly appreciated to some degree when the differences are great. No painful points along the vertebral column on the outer surface of the iliae bone, or at the points of exit of the larger nerves. Patellar reflex gone on both sides. The movement of the fingers clumsy, as in counting money, the fingers clinging to one another. The treatment lasted a month, and consisted of warm baths, at 31.5° C., of twenty minutes' duration, and at irregular intervals; constant electrical current, from the angle of the lower jaw to the spinal cord, two minutes' duration, four to six milliampères; current to the spinal cord stable, descending, three to five minutes, eight to ten milliampères, determined by Hirschmann's galvanometer; internally, iodide of potassium, seven grammes and a half, divided into one hundred and twenty pills, three or four times daily. When patient left the hospital in the middle of October he was advised to continue the iodide, and after two months to use cold rubbing with water in the mornings. In May, 1885—that is, about eight months afterward—patient was heard from as being perfectly cured. Shortly afterward it was reported that the patient could descend a deep stairs backward, carrying a cradle with a child in it. On the 30th of July, 1885, Dr. Alfred Hoppe stated that the only abnormal symptom was the loss of the patellar reflex, and that the patient had done military service for twelve days in the beginning of June, at a time of great heat, without any ill consequences. In November, 1885, patient was still well, but the sweating of the feet had returned, while the patellar re-

flex was still absent, although a prickling is still left in the soles of the feet when he stands at work a whole day.

Danos ("L'Union médicale," September 29, 1883): Male, aged twenty-four, fatigued with intellectual work and sexual excesses. Had had syphilis several years before, according to his own statement and a letter of his physician. Had had mucous patches and a specific roscola. Entering the hospital in May, he complained of pains in the calf muscles, present in bed, but becoming of such intensity as to render him motionless when he attempted to rise or in walking only around the room. There were no cephalic symptoms. Pressure or the passage of a sponge wet with warm water along the vertebral column caused no pain. The sensibility of the skin in the inferior extremities was intact to the extent that it was present in its various degrees, but the patient felt frequent rapid shocks, very painful, instantaneous in the calves or the thighs, at the same time that he felt a very painful permanent constriction in the calves. In walking, the functional troubles became characteristic. He walked throwing forward the stiffened extremities, tapping the floor lightly with the toe, and, when deprived of the aid of sight, throwing his legs from one side to another, crossing them one on the other, walking titubatingly, and certainly falling unless care were taken to place a person at his side. In attempting to hold himself upright, in a stationary position with the eyes closed, he swayed, and it became immediately necessary to support him. He was gradually but rapidly subjected to a mixed treatment of five centigrammes of protiodide of mercury, four to five grammes of iodide of potassium, and an equal dose of bromide of potassium administered daily. This treatment was interrupted occasionally during several days, because of the diarrhoea provoked. It was several weeks before any favorable result was visible, but toward the 18th of June—that is, about six weeks after beginning treatment—the pains began to disappear while he was in bed, and he could walk somewhat longer without difficulty; the upright station in walking again became possible without the eyes being fixed on the lower extremities. On the 23d of June he suddenly declared that he had no more pain, and that he could close his eyes without experiencing the least obstacle to locomotion, which we found to be true. On the 28th he was completely cured, walked quite normally, and desired to go out. Since this time Dr. Danos has twice seen the patient, who stated that he remained quite well, could attend to his affairs, and could run without inconvenience. He often closed the eyes in walking to assure himself that so doing was no inconvenience.

Dr. G. M. Hammond ("New York Medical Journal," August 30, 1884): Male, age not stated; ten years ago he came under the observation of Dr. James Anderson, of this city, for syphilitic lesion of the glans penis. Dr. Anderson is unable to say at this date whether it was a chancre or a chancreoid. The secondary symptoms were never apparent. He has two perfectly healthy children. Not intemperate, but a steady drinker. In the winter of 1882 went on a spree, culminating in delirium tremens. Following this the prominent symptoms of ataxia appeared, though for the previous six months he had complained of sharp, shooting pains in the legs and slight difficulty in walking. He was now unable to stand without support. When assisted, his walk was characteristic of ataxia; there was a loss of the tendon reflex, a difficulty in retaining the urine, and anaesthesia of the lower limbs. The arms were somewhat affected, and there was partial loss of sight. Dr. Anderson prescribed iodide of potassium and bichloride of mercury, and referred him to Dr. Hammond for further treatment, who applied the actual cautery several times to the spine, together with dry cups, the ether spray, and static and galvanic electricity. From this time the patient began to improve, and a

year ago he was apparently perfectly well. He walked correctly, could stand with his eyes closed, could jump on and off a car while it was in motion. The tendon reflex returned. On this latter point he was tested by several members of the society. He has had no treatment whatever since then. He is stouter and seems to be in better condition now than he has been any time for several years. During the winter he frequently ran over the ice and snow drawing one of his children—a feat which any person afflicted with ataxia would find it impossible to accomplish.

Male, age not stated, consulted Dr. William A. Hammond about two years ago. He exhibited all the symptoms of locomotor ataxia, was unable to stand with the eyes closed, the tendon reflex was absent, he was unable to hold urine for any length of time, having to pass it as often as forty-five times a day, anaesthesia was present, and the passage of sensory impressions through the cord was considerably prolonged. A specific history was admitted. Dr. Hammond treated him with iodide of potassium and bichloride of mercury, alternating occasionally with nitrate of silver. The actual cautery was applied to the spine, together with dry cups, ether spray, and galvanism. Improvement in his symptoms was gradual but steady. The anaesthesia disappeared, he began to stand and walk better, and his urinary symptoms improved, but the tendon reflex did not return. Not having been seen for nearly a year, he was written to, and in reply stated that, as far as he was able to judge, he was completely cured of locomotor ataxia, having no difficulty in walking or standing in any position, and was free from vesical trouble.

Landsberg ("Berlin. klin. Woch.", 85, No. 33): Male, aged thirty-nine; nine years before had syphilis; was treated for six weeks with pills. Two and three years afterward cutaneous eruptions, bony growths and ulcerations, all treated successfully with iodide. Five years after, patient married; one child died in second year; no other children. Ten years after, paresis of left abducens, with a normal left pupil, while right one was myotic and reacted badly to light. Paresis disappeared. One year after this gastric crises appeared; later, lancinating pains in the extremities, creeping and furriness in the soles of the feet and the lower limbs. Impotence and then decrease of visual acuity. Objectively: Decrease of sensibility and retardation of pain sense in lower extremities; loss of patellar reflexes; ataxia; swaying marked in standing, increased with closed eyes; miosis and reflex pupillary immobility; optic-nerve atrophy; diminution of hearing. Inunctions of mercury, later iodide of potassium employed, and all symptoms disappeared, and for a year and a half patient has been perfectly well.

Rumpf, p. 437: Male, aged fifty-three. Chancre fifteen years before; secondary symptoms; treated with mercury. Patient then perfectly well till about two years before, when ulcers appeared on the arms and lower limbs; cured by inunction. Lancinating pains in the limbs and loins one year after; although patient had rheumatism for a long time, Rumpf thinks the pains in the lower extremities were too intense to be rheumatic. About a month later, furriness and numbness of the feet and toes and paresis of the lower limbs and trunk. Twenty-five inunctions, each of about three grammes, were used during four weeks, and the patient was so improved that standing and walking were again possible in a slight degree. With the administration of iodide of potassium the pains returned, gait became uncertain, and occasional diplopia appeared. Four weeks later, gait and all other movements were highly ataxic, but motor strength good; standing was possible with aid—without latter, marked swaying increased by closing eyes; cutaneous sensibility apparently not altered; point and head of a needle are well differentiated. Muscular sense apparently normal; patellar reflex

and Achilles reflex entirely wanting; ataxia present and tendon reflexes absent in the upper extremities; intense cincture feeling between the lower ribs and umbilicus; micturition difficult, with great effort. No sexual desire, headache, vertigo, or reflex pupillary immobility, although the left pupil is somewhat larger than the right. Treatment by inunction so improved the condition that, after eighty-five inunctions, the patient was discharged as entirely cured, and has for years been working as an engine-driver. Rumpf remarks of this case, as he had stated three years before, that the anti-syphilitic treatment had never given him another result like this.

Rumpf, Case IV, p. 379: Male, aged thirty-five. Four years before, chancre, cutaneous eruption, throat ulcer; four weeks and a half cure in Aix-la-Chapelle. Four months before, ulcers on rectum and cutaneous eruption on the scrotum and surrounding portion of the thigh. For one month and a half tickling and furress in the feet and hands. Difficult micturition and uncertainty of gait in the dark. Objectively: Can stand well; distinct swaying with eyes shut; gait and free movements distinctly ataxic; motor strength good. Tact normal; pain-sense diminished. Sense of location of limbs good; tendon reflexes absent. Arms slightly ataxic; sense of location diminished; tendon reflexes wanting. No myosis or reflex pupillary immobility. On the upper thigh and scrotum a syphilitic. No other cause of tabes. The patient is a merchant; had never had any particular hardship or fatiguing journeys. After two months' treatment with mercury and the faradaic brush all symptoms of the disease had disappeared, excepting that the tendon reflexes were still absent. Two years afterward the patient was reported to be well, but Rumpf does not know the condition of tendon reflexes.

Rumpf, Case XXXVIII, p. 397: Male, aged forty. Chancre twenty years before; cutaneous eruption; internal mercurial treatment. No symptoms since. For years lancinating pains in lower limbs; for one year itching and formication. Diminution of sensation in the limbs and unsteadiness of gait. Writing difficult, micturition also. Impotence. Iodide without effect. Objectively: Stands well; distinct swaying with closed eyes. Gait and fine movements distinctly ataxic, although strength well preserved. Tact diminished; pain-sense retarded. Sense of position of legs diminished. Tendon reflexes quite strong. In the arms slight ataxia, with retardation of pain-sense and tendon reflexes preserved. Rumpf states that this patient was treated with mercury and with the faradaic brush and that the pains disappeared, sensation became normal, the vesical functions re-established, and the ataxia disappeared; only the impotence remained. The patient resumed his usual occupation, and five years and a half afterward the cure had been maintained.

Rumpf, Case XXXIV, p. 444: Male, aged forty-six. Eighteen years before, chancre and cutaneous eruption; cure in one month. Married in thirty-first year; healthy children. Onset seven years before, with lancinating pains in lower limbs and difficult micturition. Then cincture feeling around the lower abdomen, and formication in limbs and back. For one year impotence. Objectively: Standing somewhat unsteady; marked swaying with closed eyes. Gait and fine movements distinctly ataxic; excellent motor strength. Tact not perceptibly disturbed. Pain-sense absent. Sense of location of lower limbs very much diminished; tendon reflexes absent. Arms normal; tendon reflexes lacking. Myosis and reflex pupillary immobility. After administration of twenty-eight inunctions of mercury, application of faradaic brush and galvanism, the abnormal sensations and the cincture feeling disappeared and the pain-sense returned. Then the sense of location of lower limbs became better. In the middle of February the treatment was interrupted, and re-

newed in April. After six weeks further the ataxia had disappeared, and the patient could walk for hours. He was then discharged. Three months afterward he reported that the impotence had also disappeared, and again, a year and a half afterward, abnormal symptoms are said to have disappeared, with the exception that the tendon reflexes are still absent.

Rumpf, Case XXVIII, page 393: Male, aged forty-six. Twenty-one years before, chancre; cutaneous eruption; internal administration of mercury; no syphilitic phenomena since. Since the thirty sixth year occasional lancinating pains in the lower limbs that became very intense at one time. Since the forty-first year pains in the arms and uncertainty in writing; itching and formication in the limbs and arms; difficult micturition. Since the forty-fourth year uncertainty of gait, greatly increased in the last few weeks; walking alone impossible. Objectively: Standing with feet approximated or closed eyes impossible. Gait and all movements highly ataxic, although motor strength well preserved. Walking alone possible with aid of another man. Tact diminished; pain-sense absent. Sense of location greatly diminished; tendon reflexes wanting. Arms distinctly ataxic; pain-sense and tendon reflexes wanting. Atrophy of the right optic nerve. The patient knows no cause for the trouble. He has not been exposed to catching cold or to any hardship, and has been a very temperate man. After two months' treatment with mercury and the faradaic brush the patient could walk with a cane through the room. After three months he could walk in the garden, and after six months he was dismissed, as his gait was normal and all other symptoms had disappeared, except a slight occasional urinary incontinence and slight tremor of the hand, which latter, however, was of long standing. After six months further, which was spent by the patient in the country, he resumed his occupation, and for two years has been employed in a counting-house, complaining only of a certain weakness of the sphincter vesicae.

Rumpf refers to three further cases—Cases V, IX, and XXXV—in all of which the lancinating pains had either disappeared or were reduced to a minimum, the ataxia has entirely disappeared or only observable with great tension, the myosis and reflex pupillary mobility had disappeared, but the sensibility, especially the pain sense, had remained diminished. Of these, one has for a year acted as a railroad secretary, the other as a teacher in a high school for two years. Both had come under treatment, as they were not capable of attending to their business, to which they were thus enabled to return.

Rumpf's treatment (page 451) consisted first of an inunction for four or five weeks, followed by iodide of potassium for some length of time. If the patient remained long enough under treatment, inunction was again used, again to be followed by the iodide, the latter being employed in doses of two to two grammes and a half daily. Gingivitis was very seldom observed by this method. Chlorate of potassium was also employed as a gargle, and a trouble of the gums was very seldom observed. The anti-syphilitic treatment was continued for a year or a year and a half. Lately he had employed a new mercurial preparation for subcutaneous injection of Dr. Schnetz.

Erb ("Arch. f. klin. Medicin," 1879, Bd. 24) speaks of quite a severe case, without giving the details, that had resisted the ordinary therapeutic methods, such as galvanism, hydrotherapy, Nanheim baths, nitrate of silver, but

was made to improve so much by mercurial inunction that the patient has for years been able to ply his affairs.

Erb also narrates this case: Male, aged fifty-seven, syphilis fourteen years before. For eight years has had gastric catarrh. Duration of tabes three years. Initial symptoms began with lancinating pains of great intensity; slight anaesthesia of the lower limbs; later, uncertainty of the lower limbs. Present condition: Slight ataxia, easily fatigued, general strength good. Slight anaesthesia of the lower limbs; distinct swaying with closed eyes. Skin reflexes very lively. Tendon reflexes wanting. Some vesical weakness. High degree of spinal myosis. Cranial nerves, arms, vertebral column normal. Impairment of memory and intelligence; drowsiness. Signs of syphilis still visible upon the skin and tongue. Erb simply says that this case was as greatly improved as the preceding one, without giving details. In two other cases mercurial treatment was without any effect.

The following cases are those in which the locomotor ataxia was associated with symptoms of intracranial syphilis:

Berger ("Dentsch. med. Woch.", 1885 No. 2): Male, aged thirty, chancre six years before, probably hard, healing under entirely local treatment in about six weeks; no secondary symptoms. Four years after, being chilled, lancinating pains in both lower extremities, then paresthesia and formication in lower extremities, and especially on soles of feet, formication in different fingers, painful tension in the neck, diplopia, and cephalgia. After several months of lassitude and inability for exertion, uncertainty of gait began, especially in the dark. Frequent vesical tenesmus, obstructions. Loss of sexual desire and potency. Objectively: Great ataxia, swaying with closed eyes, great diminution of tact in the lower extremities, in lesser degree of cutaneous general sensibility. Especially remarkable is disturbance of pressure sense, greatest in the left leg, so that a weight of twenty pounds is not at all perceived when placed on anterior surface of left thigh. Muscular sense and perception of passive movements are highly disturbed, especially in the foot joints and toe joints of the left foot. Frequent pollutions, ischuria, obstructions. Reduced visual acuity of both eyes. Lower inner quadrant of visual field of right eye entirely impaired, also upper inner corresponding portion is not entirely intact; but externally his eye is normal. In left eye the lower outer quadrant is impaired. Optic nerve is somewhat reddish in color, veins somewhat more swollen than normal. After eight weeks of galvanic treatment (back and peripheral nerve trunks of the upper and lower extremity) and use of iodide of potassium, there was improvement of the incoordination and the anaesthesia, but cure only after inunction and further use of the iodide. Later there were intense, especially nocturnal, cephalic pains, disappearing after short administration of iodide. Patient remained perfectly able to perform his duties as infantry officer, and after fifteen years no sign was present of the former spinal lesion.

But Berger could detail no other cures.

The following case of Oppenheim's is one of syphilitic spinal meningitis:

Dr. Hermann Oppenheim ("Berlin. klin. Woch.", December 31, 1888): Female, aged thirty-one, syphilitically infected; first seen in May, 1885; former keratitis parenchymatosa and iridochorioiditis syphilitica dating back to 1881. In February, 1885, pains in limbs began, weakness of them, tendon reflex lost, treatment by inunction begun, and decided improvement attained, so that patient was dismissed "cured" in short time. In May same symptoms began again with greater intensity.

And the following: Tearing pains, especially in the right arm; hoarseness; spasmotic attacks of coughing (of the character of laryngeal crises); difficulty of deglutition; double ptosis; almost complete paralysis of right motor oculi, a paresis of the left in certain of its branches; double pupillary immobility (iritic synechiae); paresis of one soft palate; attacks of vomiting; paralysis of the right vocal cord; galvanic reaction lost in right recurrent laryngeal, while that of the left was normal; paresis of the right trapezius and sterno-cleido-mastoid, with partial reaction of degeneration; constant increase in pulse frequency; patellar tendon reflex on both sides; sensory impairment in legs; vesical difficulties; Romberg symptom. Decided improvement with inunction. In September, 1885, the mobility of both ocular bulbs had been restored, the reaction of the left pupil to light was again present, the pulse had a normal beat, while the attacks of vomiting and difficulty of deglutition and the disturbances of distribution of the right vago-accessorius had been reduced to the paralysis of the vocal cord. Patient left the hospital, but entered again in January, 1886, when she had a paralysis of the left motor oculi and paresis of the right internal rectus, paresis of the legs, patellar tendon reflex lost, sensory impairment, especially a feeling of felt under the soles of the feet, swaying with closed eyes, vesical difficulty, attacks of vomiting, laryngeal crises, etc.

At this time, however, while knee-jerk was gone, tremor of the foot was present. Further treatment by inunction was without effect, although nearly five hundred grammes of nnguentum hydrarg. cinereum were used, and in February, 1887, case was regarded as incurable. In July of the same year patient was again examined, when, to the narrator's great astonishment, there was great exaggeration of the tendon reflex, with foot clonus and general spastic paresis of the lower extremities. For these reasons the diagnosis of tabes was abandoned, and no definite one made in its stead. In April, 1888, patient died of carcinoma uteri. Autopsy made by Dr. Ewald. Macroscopically there was found a focus of softening in the left corpus striatum, but pathologically in the vessels and membranes of the brain and in the middle and lower cervical and upper and lower lumbar regions the membranes were greatly thickened, adherent to one another and to the cord, and imbedded in them was a grayish fatty tissue, here and there fibrous, developed in varying degree in the different localities. These now embraced the nerve roots. Where these alterations were the greatest the spinal outlines were entirely obliterated and the substance soft. The pathological process was an internal pachymeningitis and a chronic arachnitis. On the inner surface of the dura was a deposit of fibrous tissue of many layers. The arachnoid and the pia were infiltrated with a strongly developed granular tissue, very cellular, and containing numerous newly formed vessels. These also embraced the nerve-roots and sent prolongations into them both toward the periphery and the spinal substance. There was secondary degeneration of the cord upward and backward in some places; in others the peripheral portions of the cord were alone affected. The spinal vessels, and also the larger arteries, present the lesions of endarteritis, and especially of chronic peri-arteritis. A slight degree of arachnitis also existed in the upper spinal regions, together with a moderate ependymitis on the floor of the fourth ventricle. Lesions were also found in the medulla oblongata, pons, corpora quadrigemina, mainly about the region of the vagus, accessorius, glosso-pharyngeal, and the nuclei of the ocular muscles. There was marked atrophy of the right solitary bundle, very complete throughout the whole length, and evident macroscopically. Two small foci of softening were found in the region of the tegmentum and the crus cerebri. The cerebral arteries, seemingly normal to the naked eye, were found

microscopically markedly altered, with specially great proliferation of the intima.

The connection of general paresis and locomotor ataxia is too well known to be disputed, and the following case of my own illustrates this connection:

Male, age forty, had chancre thirteen years ago, secondary sequelæ, treated by a well-known syphilitographer. Has been suffering for several years with stabbing pains, severe, sudden, and wandering, about lower limbs, with difficulty of micturition and with difficulty of walking, which had been first noticed at night. First examined in May, 1886. Loss of both patellar reflexes. Optic-nerve atrophy. Swaying with the feet closely approximated and almost unable to stand with eyes closed, doing it imperfectly with eyes open; upper extremities also slightly ataxic. Argyll-Robertson pupil. Tactile sense greatly impaired in the feet; muscular sense imperfect; great retardation of pain sense. Considerable distress and difficulty in micturition. Gastric crises of great intensity every few months. This patient improved greatly under treatment with the iodide in large doses, mercurial inunctions, and galvanism, so that at the end of four months, when he discontinued the treatment, he was suffering but very little from his pains, his ataxia was considerably improved, his vesical symptoms had almost entirely disappeared, but the sensory impairments and the patellar reflexes were essentially unaltered. This patient was able to undertake a most fatiguing journey in the winter time into the mountains of Oregon, where he was snow-bound for several weeks in a mountain camp, and yet claims to have grown no worse. Two years afterward he returned to New York, maintaining that he was much better. A careful examination showed that the optic-nerve atrophy was still unaltered, the patellar reflex was still absent; the tactile anaesthesia and the conduction of pain were seemingly much improved. His bladder symptoms and his lancinating pains were said to have disappeared. But, observing him at different times through a period of several weeks, I found that there was an occasional inequality of the pupil, that his ataxia was still very evident, that there was a marked fibrillary tremor of the tongue present every time I examined him, an occasional fibrillary tremor of the facial muscles, and occasional difficulty of articulation. His friends and business associates also confirmed what was evident to me in my short interviews with him in my office—viz., that he was absent-minded, undecided, and confused about business matters, and occasionally so apathetic as to excite remark from those with whom he was doing business. I have since had this patient under observation through the last winter, and it is very evident that his mental symptoms are slowly and steadily progressing.

The so-called cures have been almost entirely confined to the syphilitic cases, while non-syphilitic cases have ordinarily been improved by treatment. The famous case of Schultze and Erb belongs to this category.

Friedrich Schultze ("Arch. f. Psychiatrie," 1882, p. 232): The patient came under Erb's observation in April, 1871. He was then forty three years old, had had for two or three years continuous lancinating pains in the lower extremities, and for one year unsteadiness of the legs, concurring vesical symptoms, and a feeling of numbness in the left ulna. These phenomena increased, and a feeling of uncertainty in walking in the dark became stronger; nocturnal enuresis appeared, and even by day it became difficult to retain the urine. With nitrate of silver the condition was improved, so that the patient did not sway so much in standing with closed eyes, and the irregular move-

ments of the limbs almost disappeared. The patient was treated from April, 1871, with the galvanic current. At this time there was only a slight uncertainty in walking, barely perceptible to the eye. There were no sensory disturbances in the lower extremities. On the ulnar side of the left hand and in the fourth and fifth finger there was a feeling of numbness. Sexual desire greatly diminished. Nocturnal enuresis. In the middle of May this nocturnal enuresis disappeared for the first time, and the patient could take long tramps in the mountains without especial weariness. The lancinating pains present at the beginning of the electrical treatment had entirely disappeared, but the vesical weakness still remained in slight degree, as well as the feeling of numbness in the left ulnar region. In February, 1872, the improvement had persisted, the lancinating pains were almost entirely gone, the numbness in the left ulna much less, but the feeling of fatigue in the lower extremities is still abnormally great, and after an hour's walk the patient feels himself fatigued till the next day. Vesical difficulty unaltered. During the summer of 1872 and 1873 the patient was treated several times weekly with galvanism. In 1873 and later there were no more lancinating pains, the abnormal feeling in the left ulnar region had almost disappeared, the general health was good, no ataxic walk, occasionally only nocturnal enuresis and urinary dribbling. In this condition the patient remained to the end of January, 1880—i.e., about twelve years after the beginning of the first phenomena. At this time Dr. Schultze saw and examined him. His walk was perfectly normal. Upper eyelids sunken, although a paralytic ptosis could not be assumed, as the patient had had this peculiarity in youth, and the mobility of the lids had not been re-established. No demonstrable sensory disturbances. Patellar reflex gone on both sides. Vesical paralysis of moderate degree, with nocturnal enuresis and urinary dribbling by day, vesical catarrh, urine with non-alkaline reaction. Pupils small, reacting feebly to light. In the electric treatment the bladder was especially treated, without any particular effect after twelve sittings. The patient was strong, and took daily walks of an hour without finding himself unusually fatigued. Death resulted from poisoning, and the autopsy was made nine hours after death. Spinal cord was found abnormally thin and soft, the lumbar enlargement being ill-defined. Dura and pia were normal. Posterior columns were somewhat shrunken in the lumbar portion, and in the upper portion of the lumbar enlargement showed a distinctly gray-colored portion about in the middle of the area of the posterior columns, and not touching either the posterior commissure or the posterior periphery. This focus was smaller below. In the lumbar and cervical cord there was nothing abnormal macroscopically. The cerebral pia was thickened on the anterior half of the convexity, but the convolutions were normal. The ependyma was not granular, and the large arteries not atheromatous. There were also pyelitis and cystitis. The hardened preparation showed microscopically that the cord was of abnormally small volume in the dorsal and lumbar portions, less so in the cervical. With glycerin preparations the degeneration of the posterior columns could be seen extending in the lower third of the lumbar enlargement over almost the whole surface between both posterior horns in the one direction, and between the posterior commissure and posterior periphery in the other. The portions bordering immediately upon the posterior commissure were richer in nerve tubules, the other portions being equally diseased to a high degree. In the middle and upper portion of the lumbar enlargement the posterior columns immediately adjoining the posterior horns were somewhat richer in nerve tubules. Microscopically, in the greatest portion of the posterior column there was a rarefaction of the nerve fibers. There was a degeneration of the posterior column adjoining the posterior

horns, which was indistinct in the lowest third of the dorsal region and distinct in the upper portions, representing the entry of the inner nerve roots and reaching to the point of the posterior horns, while the anterior third of the posterior horns was bounded on the inner side by intact nerve fibers. In the cervical region the columns of Goll were intact. But the boundary line between the columns of Goll and the columns of Burdach was marked by a very small zone of degenerated substance, club-shaped anteriorly in the upper portion of the cervical region, near the posterior commissure, in such a manner that the larger portion of the anterior region of the Burdach column was most degenerated. In the upper two thirds of the cervical enlargement this zone is widened toward the pia mater, so that a complete triangle of degenerated substance resulted, with the basis to the gray substance of the Burdach column, the apex toward the aforesaid small zone. Throughout the cervical enlargement the region of the inner nerve roots was degenerated, as has been described in the dorsal region, more so upon the left side, so that here, in places, half of the substance of the Burdach column was implicated. Farther toward the medulla the degeneration limited itself to the boundary between the columns of Burdach and the columns of Goll, decreasing in extent and intensity. The other white strands, especially the lateral columns and the gray substance, were normal. With carmine preparations the abnormal areas described in the posterior columns were found to be in a condition of reduction and atrophy of the nerve fibers and an increase of connective-tissue substance. Granular cells were lacking, even in fresh glycerin preparation; but corpora amylacea were present in small number. The anterior ganglion cells were intact. There was, therefore, in general, a diffuse degeneration of moderate intensity of the posterior columns in the lumbar region; a degeneration of the outer portions of the column of Burdach in the dorsal region, least marked in the lower fourth of the same; partial degeneration of the columns of Burdach, especially in the outer portions, but more extended in the cervical than in the lumbar region; moderate implication of the columns of Goll.

This case demonstrates the almost incredible fact that almost all the symptoms of the disease may disappear while the spinal lesion persists unabated.

There can be no question whatsoever but that the improvement in many of the syphilitic cases has been such as would have warranted the term "cure," did we not know of this remarkable case of Schultze's; even in the face of it we are perfectly justified in saying that these syphilitic cases have been practically cured. The best results seem to have been attained by the use of mercury, usually in the form of inunction, in conjunction with large doses of the iodide of potassium. I have not been able to obtain such brilliant results in these syphilitic cases as have been described by such reliable authors as those whom I have quoted, and especially by such men as Fournier and Rumpf, for the best that I have been able to effect in my cases has been an improvement in some such symptoms as the pains and other sensory affections, less often in the ataxia, and never in such phenomena as the Argyll-Robertson pupil and the lost patellar reflex. A great many cases of so-called cures will not bear rigid analysis, and are very often cases of ordinary myelitis of subacute or chronic nature, recovering readily under proper treatment, as such cases often do, and as they generally do when they are of specific causation. In my experience the non-syphilitic cases of ataxia have been very intract-

able. I have found, to be sure, that galvanism, rest, iodide of potassium, nitrate of silver, and the faradaic brush would effect a certain amount of improvement in some of these cases, but only in certain symptoms. The ataxia has been a singularly obstinate symptom in this class of cases. The lancinating pains have been best treated by absolute rest for several weeks at the onset of treatment, and great attention to this point for a varying time afterward; indeed, so well known was this fact in my hospital wards that it became the routine treatment for those cases in which the pains were severe. I was somewhat chagrined, as I had flattered myself that this treatment was original with me, to learn from Dr. Weir Mitchell, in a casual conversation with him last year, that he had advocated this treatment as far back as 1873, in a contribution to the "American Journal of the Medical Sciences," and had frequently mentioned it to M. Charcot without being able to overcome the incredulity of the latter gentleman. It is impossible to ascertain how many of the older cases of the so-called cures or improvement were without specific infection, and this casts the more confusion into our estimate of the results, as it is undoubtedly true that many of the syphilitic cases are absolutely unimprovable, as any one may satisfy himself by reading the histories given by Fournier and Rumpf and as all of us have probably seen in our own experience. Nerve stretching has not, as a rule, been successful, although Benedikt has reported some great successes, but the fact remains that several patients have died after the operation. The results of the latest neurological fad, suspension—first really introduced, I am sorry to say, into this country by the sensationalism of the New York "Herald"—have been gathered and sifted very completely by Dr. C. Eugene Riggs, of St. Paul, in a recent article in which he points out that "the most brilliant successes have been obtained by French and American experimenters, while the Germans are lacking at the same time in enthusiasm and results." Certain it is that these startlingly brilliant effects that have been described by the French and German physicians are not exaggerated, if I may infer from my own limited experience in a few cases, and my own results were the more surprising to me as I was greatly prejudiced against the method at the start, although my patients have been treated too recently to permit of a report as yet. Dr. Motchoutkouski, of Moscow, to whose publication in 1883 we owe our first suggestion of the method, speaks of one patient whose only remaining symptoms at the end of five years were myosis and absence of patellar reflex. One great advantage of the suspension treatment, should it prove to be permanent in its effect, is the marked improvement that it effects in the ataxia, a singularly intractable symptom except in certain of the syphilitic cases. Rumpf speaks with great positiveness of the beneficial effects of the faradaic brush in diminishing the anesthesia, and I can bear him out in this assertion.

As Schultze's patient lost most of his characteristic symptoms during a period of some twelve years, notwithstanding that the posterior columns were found to be in the usual diseased condition, the question inevitably arises as to whether this may not also have been the case in the so-called cures. We are therefore forced to the conclusion

that there is no record of a really authentic cure of locomotor ataxia. We may furthermore affirm that the cases of syphilitic locomotor ataxia have yielded the best results, and that they have done best the earlier the treatment has been begun; while many of the non-syphilitic cases have been improved by the various methods of treatment that have been enumerated, although there is a doubt as to what proportion of this improvement may have been due to the inhibitory effects of a supervening general paresis.

But this scientific doubt should not blind us to the immense practical advantage of such improvement as has been described in so terrible a disease as locomotor ataxia, and it would be a great boon to us to be able to differentiate the cases of favorable prognosis from the hopeless ones. In this regard it should be borne in mind that many of the cases which I have narrated have been associated with an intracranial syphilis, and that others have been in the early stage of locomotor ataxia. Fournier expressly states that the prognosis is much better in what he calls the pre-ataxic stage. If the spinal lesion of this disease be a secondary degeneration starting from a primary focus of inflammation or cellular alteration in the lower dorsal or lumbar cord, it would seem reasonable to assume that this primary focus would be the lesion that could be treated best, especially in the syphilitic cases, and that the secondary degenerations resulting therefrom would be as hopeless as they are in other portions of the cord. We should therefore vigorously treat our syphilitic cases of locomotor ataxia, at as early a stage as possible, with large doses of mercury and the iodide of potassium. Nor should this treatment be any the less vigorous when an accompanying intracranial syphilis can be diagnosticated. As I pointed out some two years and a half ago, the pathognomonic symptoms of some forms of intracranial syphilis are these:

1. A quasi-periodical cephalgia, generally nocturnal, but occurring at certain other times of the day—especially in the afternoon.
2. A hemiplegia under forty years of age, with or without preceding cephalgia of the foregoing type.
3. Cephalgia followed by hemiplegia, which bear a singular relationship to one another in that the cephalgia ceases immediately upon the supervention of the hemiplegia and seldom recurs.
4. Convulsions in the adult, which have not been preceded by convulsions in infancy, and are not of traumatic or nephritic origin, or due to pregnancy, or in an individual subject to migraine.
5. Symptoms indicative of a lesion at the base of the brain.

6. A comatose condition extending over days or weeks, not traumatic, diabetic, meningitic, nephritic, or from typhoid fever.

As I said at that time, these symptoms may be regarded as proof of the kind to which lawyers give the name of "prima facie"—*i. e.*, proof amounting to a presumption, which may, however, be rebutted by adequate testimony to the contrary. I should be extremely suspicious of any case of locomotor ataxia in which these symptoms were present in larger or smaller combination, even though I could not ob-

tain a certain history of syphilitic infection. I know of no certain signs by which we can recognize the cases of peripheral origin or the pseudo-tubes.

#### *Appendix.*

*Developing of Symptoms of Locomotor Ataxia Twelve Years after Chancre; Rapid Loss of Sight; no Loss of Muscular Sense; Abatement of General Symptoms.*—Age fifty, merchant. Soldier during the war, 1861 to 1865. Had dysentery. About twelve years ago had chancre; does not think it was followed by any secondary symptoms. Was never treated. Always been healthy. About four years ago had sudden attacks of dizziness and sharp pains through the temples. Six months after, noticed he did not walk as firmly as before. "While I did not exactly stagger, I always felt when these spells were on as if I swayed." About this time, every few weeks, would have sharp piercing pains in legs and back. About a year after the onset of these symptoms he fell off a stoop (at night) and struck the back of his head and spine. The parts were sore for a few days, when all symptoms passed away. Five months after, noticed his sight was not so good; consulted oculists, who did not remark any ophthalmoscopic changes. Eight months later had pronounced atrophy (white) of both optic nerves, with bare perception of light.

Examined May 6, 1889. Well-nourished man with fixed expression and dilated pupils. No loss of power, but he complains of being easily fatigued and then he staggers. Has attacks of dizziness and paroxysms of pains in buttocks and back. So sudden and sharp are the attacks that he can not sleep. These pains are decidedly vagabond. Never had any evidences of visceral crises. No rectal or vesical impairment. No plantar anaesthesia. Muscular sense not impaired. Sexual power about as usual. Knee-jerks absent. His loss of vision prevents many tests. Has typical motor ataxia in the lower limbs.

Treatment by massage, galvanism, nitrate of silver, pilocarpine, and strychnine. All symptoms have disappeared, and, as he remarks, "If it were not for my blindness I would be a well man."

Male, aged thirty-five, car-driver, twelve years ago had chancre; was followed by full secondaries; did not undergo treatment. Says he was perfectly well until two years ago, when he noticed a feeling of tightness about his body and a sense of numbness over left side. These symptoms continued until five months ago, when he became constipated; had difficulty in making water; left hand and forearm became numb (ulnar distribution). Began to be uncertain in walking and staggered badly in the dark. His feet became so numb that he could not tell where they were. About that time he suffered greatly from "neuralgic pains" of sudden onset. Two months ago total paresis of left third nerve came on. Loss of sexual power for past two years. Is markedly ataxic, static and locomotor. Walks heavily, heels well down, feet well apart. Tactile sense over toes impaired, diminished on outer side of both legs, on right of outer thigh, on left of inner thigh. Muscular sense not impaired in feet, not impaired in right hand. Left over ulnar distribution absent. Reflexes—plantar, patellar, cremasteric, epigastric—absent. Left ptosis. Paresis of iris and recti (recovering). Some weakness of left facial muscles. No electrical changes. No facial anesthesia. No ophthalmoscopic changes.

THE TREATMENT OF ACUTE GASTRO-ENTERITIS  
OCCURRING AMONG INFANTS AND CHILDREN,  
WITH SOME REMARKS ON  
THE USE OF PEROXIDE OF HYDROGEN.

BY ROBERT H. GREENE, A. M., M. D.

My apology for writing at this season concerning a disease which is confined so closely to the hottest days of summer is a desire to arouse what interest I can, before hot weather comes again, in the search for some more effective methods of home treatment, or for some better combination of remedial measures that we already have, than are at present in use. And it is fair to suppose that the same treatment which would be most effective in this would be of use in diseases closely allied to it. During the summers of 1887 and 1888, as attending physician to the Floating

Hospital of St. John's Guild, I had an opportunity to examine the effects of air from the open sea on this disease in many thousand cases. That the air from the open sea is of great benefit to children suffering from this and diseases resembling it is a fact generally known to the profession. That it is an almost absolute specific can be vouched for by the large number of physicians who have visited this institution since its commencement, myself included. Would it, therefore, not be wise to try and analyze the methods which Nature teaches us, and might we not expect good results from imitating her methods as far as practicable? We find as positive factors that Nature uses in her treatment of this disease—

First. A generally lowered temperature.

Second. The sodium chloride present in the atmosphere.

Third. The destructive action of the oxidizing constituents of the atmosphere on the products of decomposition. And, as a negative factor, the absence from the atmosphere of any infective material.

1. That the air from the open sea must be of great purity would seem evident to every one, and the absence of microbes has also been demonstrated, according to von Ziemssen, by the experiments of Mireau and Miquel.

2. It is not easy to understand definitely how the beneficial results derived from the lower temperature are obtained. We may, however, conceive that by stimulating the nerve centers it slows the action of the heart, that by increasing the absorption of heat from the body it reduces the fever, and that some benefit is derived from a preventive action exercised upon the further continuance of decomposition.

3. It is probable that the ultimate effect of the salt in the atmosphere is similar to its effect when taken in solution. It is generally conceded that part of the action of chloride of sodium is its stimulating effect upon all the properties of secretion and excretion. Professor A. Jacobi says, speaking of the action of salt in solution: "It is chiefly chloride of sodium, other solutions not excepted, which renders the generation and disintegration of tissue possible." Although late experiments would seem to show that the action of a solution of sodium chloride in itself is not destructive to bacilli, we may presume that, entering as it does into the formation of hydrochloric acid in the stomach, and also as sodium salts are among the constituents of the bile, through assisting in the formation of these, it exerts an antiseptic influence on the results of fermentation in the stomach and intestines. 4. It is evident that, owing to the absence of microbes and decomposing material from the air, nature has the opportunity through the oxidizing constituents—such as ozone, etc.—to more rapidly and thoroughly destroy any morbid products present. How, then, can we most closely imitate Nature in her successful treatment of this and allied diseases when we are unable to place our patients in the best hygienic atmosphere?

First. By insisting on as thorough ventilation as possible, we can, to a certain extent, dilute the poisonous material present in the air.

Second. When practicable, "we may succeed, to some

extent, in cooling the air of the sick-room artificially by the use of large pieces of ice." By frequent sponging with cool water, and by its application with cloths to various parts of the body, through its evaporation, aided probably "by some stimulant action on the central nervous system," we may reduce the fever. Bearing in mind the extreme sensibility of the nerve centers in children, and remembering that Nature does nothing violent in her treatment of this disease, it would seem well to refrain from the shock of powerful douches, or the abstraction of heat from the body by conduction through immersion in the cold bath itself.

Third. We should be able to get the physiological effects of the sodium chloride by the addition of salt to the cold applications and by giving small quantities internally in solution, taking care that the solution is so well diluted as not to have too irritating an effect on the intestinal canal.

Fourth. We must increase the oxidizing power of the atmosphere by the use—either through the mouth, by rectal injections, or possibly by inhalations—of some substance which would assist in the more rapid oxidation of the various products of fermentation present. What clinical reports we have had of the use of oxygen gas itself offer us little encouragement to look there confidently for means of relief. But, from the use of peroxide of hydrogen,\* from the decomposition of which ozone is formed, or the discovery of some remedy chemically resembling it, I think we may find useful aid to the other methods stated. In fact, peroxide of hydrogen has been shown to be present as a constituent of the atmosphere, according to Fox,† by the experiments of Frémy, Schönbain, Meissner, and Corup Besançez. I have been able to obtain reports from one source only where this remedy has been used for this disease. I am informed by Dr. J. Mount Bleyer that in 1886, at the Eastern Dispensary and in private practice, he used this remedy in forty cases of acute gastro-enteritis, his practice being to give first some alkaline solution, such as one of sodium bicarbonate, to remove excess of mucus, etc., and then give a teaspoonful, three times a day, of glycerine, the glycerine being a twenty-five-per-cent. solution of peroxide of hydrogen in glycerine (the glycerine being used to prevent the formation of gas, which, when a solution of peroxide of hydrogen in water is swallowed, it is liable to give rise to too rapidly), ordering the rectal injection twice daily of a solution consisting of one ounce of Ch. Marchand's solution of peroxide of hydrogen and nine ounces of water, at the temperature of 70° F. He reports "very gratifying results in about ninety per cent. of the cases treated."‡ It is generally considered to be harmless, when free from impurities, when taken internally in solution of such strength

as to be of great antiseptic value. It would certainly seem that, through close observation and careful experimentation, aided, perhaps, by the discovery of better methods in its manufacture, we may be able to prescribe this remedy intelligently and with gratifying results in some intestinal diseases, especially among children, where the products of fermentation are so abundant and complex, as well as in many other diseases to its action in which our attention has been more generally called.

## A CASE OF ADENITIS CALCULOSA.

BY W. C. KLOMAN, M. D.,  
BALTIMORE.

F. D., a boy of thirteen years, had scarlet fever in February, 1889. As far as I could ascertain (not having been the attendant physician), it was a case of the anginose variety, and of moderate severity. After convalescence, an enlargement of one of the left submaxillary glands began, which gradually increased until the mass was of the size of a hen's egg. I first saw him in the beginning of April, 1889. The tumor was then of the size mentioned, smooth to the touch, having no lobulations or irregularities of the surface. It was dense and firm, feeling very much like a subcutaneous fibroid; it was not painful, but firm pressure elicited sensibility. The boy was somewhat anaemic, but there were no other evidences of serofulness about him. I put him upon cod-liver oil with fifteen drops of syrup iodide of iron after each meal. Locally I applied compound iodine ointment made with lanolin. Under this treatment, after some weeks there was a slight diminution in the size of the tumor and the general condition of the patient was considerably improved. The hardness of the tumor remained the same. I then injected into the substance of the gland five drops of compound tincture of iodine on two separate occasions at the interval of a week, but without any apparent effect upon the size or hardness of the tumor. I administered internally two grains of iodoform three times daily for several weeks, locally also using oleate of mercury, ten per cent., but without any result. I then injected the gland with three drops of Clemén's solution of bromide of arsenic. This caused some pain, which, however, soon ceased, and in about ten days I found evidences of suppuration, as in a cold abscess, without pain, redness, or swelling. I then carefully made a small puncture with a tenotomy knife and discharged about three drachms of healthy-looking pus, after which the cavity was injected with a solution of iodoform in oil until it was thoroughly distended, when what would was allowed to flow out. No poultices were applied; only a piece of absorbent cotton. The next day the opening was found closed, and, as there was some fluctuation, it was opened with the point of the hypodermic needle and a small amount of pus pressed out; the cavity was then again injected with the iodoform oil. This was done daily until the part finally healed, the discharge of pus becoming less day by day. On the third day of dressing in this manner, together with the pus, small granules of a calcareous nature were discharged. There were thirty to forty; these continued to be discharged in decreasing numbers for six or seven days, when they ceased. By this time the tumor was well-nigh gone, and there was only a slight discharge of pus. The injection of iodoform in oil was continued as long as there was a cavity to receive it, and in about three weeks from the time of opening the abscess it was healed.

The calcareous particles discharged were of various sizes and

† "Ozone and Autozone," by Cornelius B. Fox, M. D., London.

‡ Dr. Bleyer did not publish his reports, from the fact of having been more particularly interested in observing the effects of this remedial agent in diseases of the respiratory organs.

irregular forms. The largest measured about one sixteenth of an inch in length; some of them would stick in the opening, requiring some little effort to disengage them. The greater number did not exceed one half this size. I have preserved a number of them in a phial. Several of them were thrown into dilute hydrochloric acid to dissolve out the lime, and the residue, now soft but of undiminished size, was examined under the microscope with a lens of one fifth, but no formed elements were distinguished; only an aggregation of granules, possibly the *débris* of lymph-cells, etc. There was nothing like a stroma. Neither could I discover any bacilli. After soaking in hydrochloric acid and removing the lime, I threw the specimen into a solution of carbonate of sodium to saturate the free acid; then into a solution of picrocarmine. I regret not having examined with the microscope the pus discharged in the first place for the presence of bacilli.

I would call attention to the gradual formation of the abscess, unattended with any signs of inflammation, after the arsenical injection, and to the small opening made to discharge the pus. In consequence there is scarcely any cicatrix to be observed. The daily discharge of the pus and the injection with iodoform in oil prevented the long-continued suppuration which so generally attends these cases. I had seen an ethereal solution of iodoform recommended for this purpose by French authorities, but preferred using the oil, as being less painful.

1519 JOHN STREET.

### A USEFUL GALACTAGOGUE; "NUTROLACTIS."

BY ROBERT J. MILLBANK, M. D.,  
VISITING PHYSICIAN TO THE NEW YORK INFANT ASYLUM.

A LITTLE over a year ago my attention was called to a combination of drugs said to be *Galega officinalis*, *Galega apolinea*, *Tephrosia virginica*, and sold under the name of "nutrolactis." The recommendations from some of those who had used it gave ground for believing that, notwithstanding my skepticism on the subject, it ought to have a fair trial. I offered to give it such a test during my service at the New York Infant Asylum, provided a sufficient quantity should be sent to the asylum at the expense of the makers, to settle the question as to its practical use.

Having had occasion to try about every galactagogue used by the profession, and having often been disappointed in the results, as many of my friends have been disappointed, I am glad to report that after more than a year's use it has been more satisfactory than any galactagogue I have hitherto employed.

I have thought it might be of interest to quote from the history books of the asylum a few cases taken in order without selection.

Lottie G., aged one year, gained half a pound in eight weeks, during which the mother took nutrolactis. The child had previously been losing weight.

Bernard R., aged eight months, wet-nursed. Nurse has been taking nutrolactis; no gain.

Edward E., aged eight months. Mother took nutrolactis for eight weeks; gain, four ounces. Has had in the mean time a severe attack of enterocolitis.

Josephine C., aged five months. Mother on nutrolactis six weeks, during which time the child gained one pound twelve ounces.

Edith C., aged five months. Mother on nutrolactis eight weeks; gain, one pound.

The following women are recorded among others as nursing two children:

Mary McM., on nutrolactis six weeks. Francis McM., aged eight months, her own child, during the above time gained twelve ounces. John S. (nurse child), aged eight months, gained two pounds twelve ounces.

Mary D., on nutrolactis eight weeks. John D., aged ten months, her own child, gained one pound eight ounces. Howard B., aged six months (nurse child), gained one pound and a half.

We have had several women whose supply of milk was insufficient, but after taking nutrolactis they have been able to nurse two children.

The women who take it all say that it positively adds to their flow of milk. As it is not particularly agreeable to take, containing little alcohol, I believe that their praise of it is not due to bias on account of palatability, and, as the facts in our tests seem to bear them out, I believe their statements. The class of mothers and children which come under our care is one to which such a medicine is peculiarly valuable, and after a year's use I am much pleased with the results.

We are now using about a dozen bottles a week. The dose is a tablespoonful two or three times daily. I hope that its use will be of benefit in the hands of some of my brethren who may be tempted to try it from what I have said about it.

154 WEST FORTY-EIGHTH STREET.

**Uterine Tuberculosis.**—"An interesting case of primary tubercular disease of the Fallopian tubes has occurred in Professor Lebedeff's wards. The patient, who was the widow of a man who had died of phthisis, was of a cachectic appearance and suffered from amenorrhœa. On examination, a firm, nodulated, intra-abdominal tumor was made out, situate in the space of Douglas. An attempt was made to remove the tumor, but had to be given up, as disseminated miliary tubercle was found affecting the peritoneum. The intestines and the uterine appendages, too, were all matted together. Six weeks after the attempted operation the patient died with symptoms of general tuberculosis. At the post-mortem examination miliary tuberculosis was found affecting the peritoneum, the lungs, the pleuræ, the colon, and the mucous membrane of the uterus. Both the Fallopian tubes were dilated and filled with pus, the epithelium in parts being absent. The intensity of the destructive process was greatest in the tubes, and became less marked toward the periphery. In sections, tubercle bacilli were found; there was no tuberculosis, however, in the ovaries, and only the mucous membrane of the uterus was affected."—*Lancet*.

**The Ill Effects of Mouth-Breathing.**—S. C. G. Watkins, in the "Ohio Journal of Dental Science," says: "I know the case of a child that has been under my care from birth. At birth and up to the third year the child had a perfectly formed and normal arch; but it acquired the habit of breathing through its mouth. The result has been that the muscles, in the effort of holding the mouth open in that way, are drawn down over the teeth, and the arch is decreasing in width and becoming narrow—so much so that you can not do more than place your finger in the center of the arch; the child is now nine years of age. There has been a radical change in the shape of the mouth, and from no other reasons than mouth-breathing and the force of these muscles on the side of the mouth."

Published by  
D. APPLETON & CO.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, NOVEMBER 16, 1889.

THE ANATOMY OF THE FUTURE.

SOME years ago an elderly professor of anatomy expressed his thankfulness that in the branch he taught there was no harassing progress. Physiology and chemistry, he said, were undergoing changes from one day to another, but anatomy was always anatomy, a bone was always a bone, and there was no wearisome struggle to keep up with the rushing progress of the times. And such is the view of anatomy entertained by many of the profession. Not a few of us think, when we look back over a number of years spent in active practice, that we started on our journey with much more baggage than was necessary in the way of memorized anatomical truths, that we could have done with a smaller quantity, but that that smaller quantity should have been better selected. We question whether the anatomy taught in our colleges to-day is the anatomy of the future. Is it not rather a result of the labor of successive generations of book-writers, each showing more eagerness to add new facts to the mass than to examine into and verify the old ones?

The anatomy of the future will not resemble that taught now. The scope of the subject requires enlarging, and for the narrowing memory work done to-day a broad view of the whole must be substituted. In other words, the student should first acquire a knowledge of general and comparative anatomy, and subsequently study its application to the human body. To begin work with the descriptive anatomy of man is working backward. Such a course has been likened to the study of an ultimate twig of a tree by a person who is ignorant of the character of the larger branches, of the trunk, and of the soil on which the tree grew.

Embryology urgently demands attention as a necessary introduction to the study of the parts of the body and as a subject the knowledge of which is of direct practical advantage in daily professional life. Observe how important has become the anatomy of the embryo in connection with the study of disease. The disposition of the layers of the embryo must be clearly understood to enable one to understand the structures of the body and the diseases developing in those structures. Studies such as these lighten the student's task. Take, for instance, the arrangement of the great vessels in the root of the neck. The disposition of these structures is learned commonly by the study of a scheme or diagram, perhaps by the friendly aid of a cunningly devised "tip." The relations of these vessels could, by the study of development, be so impressed upon the student's mind as never to be forgotten. Can any of our readers forget what a bugbear the peritoneum was? Can you put your hands on your hearts and say that you thoroughly under-

stand all about it now? And yet when the peritoneum is studied from its early and simple state there will be no longer any difficulty either in comprehending or in remembering the arrangements of its folds.

The very great advance made of late years in the study of nervous disease renders a change in anatomical teaching very necessary. In our day the anatomy of the arteries was paramount, and the nervous system occupied a position of secondary importance. Yet the nerves, their cutaneous distribution, their communications with central ganglia and with one another, are matters of daily, almost hourly, consideration in the round of a doctor's visits, while of the arteries, over which we spent such time and such labor, there is rarely occasion to think. The practitioner is constantly meeting with nervous manifestations the correct interpretation of which renders a clear knowledge of nerve distribution necessary, while it is possible for him to practise for the whole course of his natural existence without ever being called upon to tie an artery. Should such a demand be made, he will seize the bleeding point in the wound, secure it, save his patient, and then go home to study the vascular system afterward. The statement has been made, we think by the late Dr. Fothergill, that the chances of an ordinary practitioner being called upon to tie the subclavian are almost equal to those of his meeting his death by lightning stroke.

To render the study of anatomy attractive and at the same time thoroughly useful, a complete change in our present system is called for, and teachers will soon have to consider the importance of comparative anatomy and of embryology as introductory studies, and the necessity of putting the nervous system in its proper place as the most important department of the human body, and not waste their energies in teaching the relations of arteries with which the student is unlikely ever to have anything to do.

ACUTE ABSCESS OF THE TONGUE.

This affection is quite infrequent, yet it is worthy of consideration on account of the occasional rapidity of its progress and the need of prompt and intelligent treatment. In the "University Medical Magazine" for July Dr. Wharton relates the history of a case that occurred in his own practice, and appends a short account of the complaint.

A patient who had been smoking to excess asked advice concerning a painful and somewhat rigid condition of the tongue, which had come on a few days before. The organ was of normal size, covered with a whitish-yellow fur, and a little indurated, especially on the right side near the median line. He was advised to quit smoking, and a mild wash was ordered. Three days later he was suffering great pain, the tongue being swollen so that it nearly filled the mouth. Its tissues were greatly thickened, and it projected beyond the line of the teeth. There was profuse salivation, and the patient could hardly make himself understood. The sudden increase in size of the tongue had begun twenty-four hours before. Salivation was increased and difficulty of breathing occurred when he lay

down. Finding upon the indurated dorsum a spot to the right of the median line at which he thought he could feel deep fluctuation, Dr. Wharton made an incision an inch and a half long, and, thrusting in a director, struck an abscess cavity containing several drachms of thick pus. There was little bleeding, and the pain, difficulty in breathing, and obstruction to deglutition diminished at once. The slight discharge of pus ceased in a day, the induration quickly vanished, and only a little denseness about the incision remained.

Acute abscess of the tongue generally results from acute glossitis, which is said to be caused by exposure to damp and cold, to injury, and to septic inoculation, by bites or stings, by the undue use of mercury or iodine, by caustics, by eruptive diseases and fevers, by excessive smoking, and by abuse of alcoholic drinks. Dr. Wharton has himself seen it occur in delirium tremens. In one case fatal acute abscess resulted from penetration of the lower surface of the tongue by a beard of barley, which was found post mortem in a pus cavity of the size of a turkey's egg, at the root of the tongue. Acute abscess is accompanied by symptoms such as occurred in the case above described. There may be also swelling of the salivary and lymphatic glands. The abscess may open of itself or there may be sloughing of the adjacent tissues. A number of fatal cases have been reported, death coming on from dyspnoea, septicaemia, or pneumonia.

The treatment is like that for acute glossitis, consisting in free incisions into the organ to let out the pus. It may probably be prevented by incisions, when inflammation has set in and before suppuration has begun. If incision fails to relieve the dyspnoea, tracheotomy may be required, or, in very urgent cases, laryngotomy, as the easier and more rapid operation, may be done instead of tracheotomy. Bryant recommends the application of leeches to the organ when it is swollen so as to project from the mouth. He agrees that, when the swelling becomes dangerous by pressure, the oedema may be dispersed by puncture or incision, but the surgeon need not be in haste to incise unless he detects an abscess, as such incisions may lead to dangerous haemorrhage. In case the abscess presses dangerously upon the glottis, producing suffocation, Druitt recommends an incision into it beneath the chin through the mylohyoid muscle.

### MINOR PARAGRAPHS.

#### THE ANTHROPOLOGY OF THE GYPSIES.

In a recent number of the "Wiener klinische Wochenschrift" Dr. Hinterstoisser gives a brief notice of a monograph entitled "Die Zigeuner," by Dr. A. Weisbach, of the medical corps of the Austrian army. Dr. Weisbach has made a careful study of the peculiarities of the bodily development of fifty-two Gypsies, all soldiers in a Hungarian regiment. He refers in the beginning to the great resemblance of the Gypsies to the ancient Egyptians (from whom they profess to be descended), although their cranial formation places them closer to the very dolichocephalous Hindu. The bodily formation of these fifty-two men had been prematurely developed and exercised, as demonstrated by the employment of the measurement system. They were of the average weight and height that appertain to

the pure dark type of the Indo-European stem. The mesocephalic projection of the head was small, diminishing moderately toward the base; of the 52 men, 11 were dolichocephalous, 28 mesocephalous, and 13 brachycephalous. They had low foreheads, moderately high cheek-bones, and projecting jaws; the nose was of considerable length, well formed, with a straight dorsum, the upper portion being very small; the neck was short and thick; the thorax was of moderate depth, of slight circumference, and slightly flat; the pelvis was small, especially between the anterior superior spines of the ilia. The arms were very short. The legs were longer than the arms. The feet were broad and high, with moderate length and thickness. The precise results of the measurements are recorded in tables in the monograph.

#### DEATH FROM SULPHONAL.

A DEATH has been reported following the use of two fifteen-grain doses of sulphonal, the doses being given an hour and a quarter apart. The fatal result occurred forty hours after the first dose. The patient was a woman with melancholia, aged twenty-eight years. The mode of death was by apnoea. Artificial respiration was resorted to for several hours, the pulse having been good for some time after extreme cyanosis had set in. As antidotes there were used the faradai current, atropine, strychnine, ammonia, and alcohol. The case is reported in the "Medical News" for August 10th, by Dr. R. R. Pettit, of Dayton, Ohio.

#### THE ABERDEEN CHAIR OF ANATOMY.

THE "British Medical Journal" states that the generous action of Professor Struthers at the Aberdeen University on the opening day of the anatomical course, in offering to continue his lectures until his successor should appear, was a fortunate concession to the school, for otherwise "chaos must have reigned." The delay since the resignation of Professor Struthers, on the part of the governors of the corporation, to name his successor has not been on account of any lack of candidates for the position, but rather by reason of a difficulty in deciding between many of nearly equal eligibility.

#### ANTIPYRINE IN WHOOPING-COUGH.

THE efficacy of antipyrine in whooping-cough has been denied of late by a number of observers. Its use has even been found to be attended with more or less danger. The "Montreal Medical Journal" sums up a careful review of a number of articles with the conclusion that the drug is practically inoperative and even injurious in this affection; and that it should always be given with caution, especially to children, when a continuous action is desired. In twenty-eight cases treated by physicians of Vienna, the duration averaged fifty days, the drug being given in doses ranging from five to thirty grains per diem.

#### SPECTACLES AND EYE-GLASSES.

DR. CHARLES GEORGE BULL, formerly a practitioner of New York, but now one of the faculty of the McGill Medical College, Montreal, has quite recently taken a supplementary degree at Paris. His inaugural thesis has been published in book form, with an introduction by Dr. Javal. His subject was the choice of means for the correction of visual errors, and the title of his book is "Spectacles and Eye-glasses." The Paris correspondent of the "Lancet" speaks of Dr. Bull as having been an especially favored pupil of Javal's at the Sorbonne. Myopia, according to Dr. Bull, is seldom congenital, but is developed dur-

ing early life because of an uncorrected astigmatism which leads to the habit of reading and writing at too short a distance.

#### A SUIT BY A PHYSICIAN AGAINST A BOARD OF HEALTH.

DR. DUNCAN, of Brooklyn, formerly surgeon to the steamship Colon, has brought suit against that city for an alleged causeless removal from his home to the Quarantine Hospital by order of the Health Commissioner. He demands \$60,000 damages. He accuses the health officials of incompetency, harshness, and cruelty in affecting his removal when he was sick with remittent fever, whereas the disease was reported by the said officials to be yellow fever.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending November 12, 1889:

DISEASES.	Week ending Nov. 4.		Week ending Nov. 12.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	32	9	40	6
Scarlet fever.....	35	1	60	2
Cerebro-spinal meningitis....	2	2	3	3
Measles.....	13	1	46	6
Diphtheria.....	74	16	89	26

**Leprosy in Kings County.**—A leprous Chinaman, who has for some time been an inmate of the Kings County Hospital, has been discharged in order that he may be returned to China.

**A Grant to the International Medical Congress of 1890.**—The Imperial Ministry of Germany has made a grant of 80,000 marks (\$20,000) in aid of the Tenth International Medical Congress, to be held in Berlin next year.

**A New Brooklyn Dispensary.**—A new dispensary was opened in Brooklyn on November 11th, at the corner of Prospect and Sixth Avenues.

**The Johns Hopkins Hospital "Bulletin."**—The Trustees of the Johns Hopkins Hospital have authorized the issue of a monthly publication to be known as the "Hospital Bulletin." The first number will be dated November of this year. Nine numbers will appear each year.

**The New York Academy of Medicine.**—At the annual meeting, to be held on the 21st inst., the annual address will be read by Dr. William M. Polk, on "The Relation of Medicine to Some of the Questions of the Day." The meeting will be open to the general public.

**The College of Physicians and Surgeons.**—We learn that Dr. T. Gaillard Thomas has resigned his clinical chair, and that he will be succeeded by Dr. George M. Tuttle. It is stated that Dr. Thomas will give six didactic lectures a year. A chair of nervous diseases has been established, with Dr. M. Allen Starr as the incumbent.

**Changes of Address.**—Mr. Reginald Harrison (London, England), to No. 6 Lower Berkeley Street, West; Dr. Charles A. Powers, to No. 35 West Thirty-fifth Street.

**The late Dr. Isaac E. Taylor.**—The faculty of the Bellevue Hospital Medical College has taken action expressed as follows:

"The faculty of the Bellevue Hospital Medical College have the peculiarly painful duty of directing a record in their minutes of the death of their first and only president, the late Dr.

Isaac E. Taylor. His invaluable services in the organization of the college and his unflagging interest in its progress and success need not be recorded here. The same may be said of his contributions to medical science and of his labors in the various medical organizations of this city and State. His refined, gentle, and kindly nature endeared him to all, and especially to those associated with him in the Bellevue Hospital Medical College; while his lovable personal qualities protected him from the enmities which too often attend professional success."

[Signed.]

AUSTIN FLINT, *Secretary.*

At a meeting of the New York Obstetrical Society, held November 5th, the following was unanimously adopted:

"Resolved, That the members of this society have learned with deep regret of the death of Dr. Isaac E. Taylor, one of its most distinguished fellows. It is their wish to express here their high appreciation of his purity of character, his enthusiasm in promoting obstetric science, his lofty ideals, the kindness of his nature, his self-sacrificing disposition, and his warm-hearted benevolence. In recalling his life and character, it is pleasant to remember that the deeds of good men live after them."

[Signed.]

FORDYCE BARKER, M. D.,  
WILLIAM T. LUSK, M. D.,  
WILLIAM M. POLK, M. D., } Committee.

The Council of the New York State Medical Association sadly records its unfeigned sorrow for the loss of a valued founder, fellow, and late president, endeared by his personal qualities as he was admired for his scientific attainments.

An illustrious name is transferred from the active list to the roll of honor of those who have bravely borne themselves in the foremost rank, and fallen triumphant.

Untiring in industry, wise in counsel, affectionate in friendship, steadfast in religious faith, beloved by his associates, and revered by the profession which acknowledged him as one of its leaders, Isaac E. Taylor lived an example for emulation by his survivors and successors, and rests from his labor, leaving a reputation unassailed by envy and beyond the reach of jealousy.

By the Council, { JOHN G. ORTON, M. D., *President,*  
{ E. D. FERGUSON, M. D., *Secretary.*

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 3 to November 9, 1889:*

O'REILLY, ROBERT M., Major and Surgeon, will, by direction of the Secretary of War, at the expiration of his present leave of absence, proceed to Fort Logan, Colorado, and report in person to the commanding officer of that post for duty.

Par. 6, S. O. 256, A. G. O., November 2, 1889.

MERRILL, JAMES C., Captain and Assistant Surgeon, is relieved from duty at Frankford Arsenal, Pa., and ordered to duty at Fort Reno, Indian Territory. Par. 6, S. O. 256, A. G. O., November 2, 1889.

BLACK, CHARLES S., Captain and Assistant Surgeon, is relieved from duty at Fort Sidney, Nebraska, to take effect upon the expiration of his present leave of absence, and will report in person to the commanding officer, Fort Dn Chesne, Utah. Par. 6, S. O. 256, A. G. O., Washington, November 2, 1889.

JOHNSON, R. W., Captain and Assistant Surgeon, is granted leave of absence for one month, to take effect on or about November 10th proximo. Par. 4, S. O. 110, Department of Arizona, Los Angeles, Cal., October 29, 1889.

POWELL, JUNIUS L., Captain and Assistant Surgeon, is granted leave of absence for two months on account of sickness, by direction of the Secretary of War, with permission to leave the Division of the Missouri. Par. 2, S. O. 258, A. G. O., Washington, November 5, 1889.

IVES, F. J., First Lieutenant and Assistant Surgeon, is granted two months' leave of absence. Par. 3, S. O. 256, A. G. O., November 2, 1889.

By direction of the Secretary of War, the following assignments of officers of the Medical Department (recently appointed) are ordered:

WILCOX, CHARLES, First Lieutenant and Assistant Surgeon, will report to the commanding officer at Fort Columbus, N. Y., for duty at that station.

MOVAY, HARLAN E., First Lieutenant and Assistant Surgeon, now at Fort Mackinaw, Michigan, will report in person to the commanding officer of that post for duty.

FRICK, EUOLID B., First Lieutenant and Assistant Surgeon, will proceed from Philadelphia, Pa., to Fort Keogh, Montana, for duty at that station.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending November 9, 1889:*

MACKIE, B. F., Surgeon, and PICKRELL, GEORGE MoC., Assistant Surgeon. Detached from the U. S. Steamer Ossipee, and placed on waiting orders.

**Marine-Hospital Service.**—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the three weeks ending November 9, 1889:*

PURVIANCE, GEORGE, Surgeon. Granted leave of absence for twenty-one days. November 8, 1889.

AUSTIN, H. W., Surgeon. To inspect unserviceable property at St. Louis Marine Hospital. November 4, 1889.

GASSAWAY, J. M., Surgeon. Relieved from duty at New Orleans, La.; to rejoin station at Cairo, Ill. October 23, 1889.

BANKS, C. E., Passed Assistant Surgeon. Granted leave of absence for thirty days. October 28, 1889.

STONER, J. B., Assistant Surgeon. Ordered to Vineyard Haven, Mass., for temporary duty. November 6, 1889.

CONDYOT, A. W., Assistant Surgeon. Ordered to Cairo, Ill., for temporary duty. November 4, 1889.

GUITÉRAS, G. M., Assistant Surgeon. Ordered to Washington, D. C., for temporary duty. November 8, 1889.

GROENEVELT, J. F., Assistant Surgeon. Ordered to New York, N. Y., for temporary duty. November 5, 1889.

#### Society Meetings for the Coming Week:

MONDAY, November 18th: New York Academy of Medicine (Section in Ophthalmology and Otology); New York County Medical Association; Hartford, Conn., City Medical Association; Chicago Medical Society.

TUESDAY, November 19th: New York Academy of Medicine (Section in Theory and Practice of Medicine); New York Obstetrical Society (private); Medical Association of Central New York (semi-annual, Syracuse); Medical Societies of the Counties of Kings and Westchester, N. Y.; Ogdensburg, N. Y., Medical Association; Baltimore Academy of Medicine.

WEDNESDAY, November 20th: Harlem Medical Association of the City of New York; Northwestern Medical and Surgical Society of New York (private); New Jersey Academy of Medicine (Newark).

THURSDAY, November 21st: New York Academy of Medicine (annual); Brooklyn Surgical Society; New Bedford, Mass., Society for Medical Improvement (private).

FRIDAY, November 22d: Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

SATURDAY, November 23d: New York Medical and Surgical Society (private).

## Letters to the Editor.

### VAGUE CAUSES OF INFANT MORTALITY.

NEW YORK, November 4, 1889.

To the Editor of the *New York Medical Journal*:

SIR: In the Journal of November 2d you seem to be a little severe toward the physicians of this city as regards the certification of causes of death in children. It is often impossible to state, even after a careful autopsy, why a child should have wasted away and died. In many cases there are probably congenital defects of a very obscure kind, not at present discernible by us, which render it impossible for the infant to maintain life independently, for children will simply waste away, notwithstanding the best of care and food, including mother's milk. In some cases the wasting may be due to tuberculosis, but I have been informed that in the New York Foundling Asylum, where 500 babies die every year, and autopsies are frequent, the cases of so-called marasmus seldom show any evident cause of death other than the lack of nutrition, which was just as plain before the autopsy as after. What better cause can be given in such cases than marasmus, atrophy, or inanition?

It seems to me that to return a certificate of an infant's death, when the cause has been given as marasmus, would only exasperate the doctor, and procure no additional information. If such a course were persisted in, marasmus, atrophy, etc., would undoubtedly disappear from our mortality reports, but the causes given in place of them would be mere guesswork, and would vitiate the figures of other diseases to which they were referred. It is much better, if the doctor does not know the cause of death, to have him say so plainly, using terms that other doctors understand. To a statistician, a precise mortality report, in which there were no ill-defined causes of death, would be, on its face, suspicious.

To show that our physicians are not more liable than others to report causes of this kind, I subjoin corresponding figures from other large cities. In Berlin all physicians are presumed (by us here) to be thoroughly educated and competent to make a diagnosis in any case.

In Berlin, in 1885, (the latest full report at hand), out of 16,828 deaths of children under five years of age, there were due to *Lebensschwäche* (lack of vitality), 1,688; *Kinderschwind-sucht* (marasmus), 181; *Erschöpfung* (debility), 894; and to *unbestimmte Todesursachen* (ill-defined causes of death), 133. Total, 2,896, or 17·21 per cent. of the whole number.

In Paris, in 1888, out of 14,909 deaths of children under five years of age, there were due to *débilité congénitale, ictere\* et selérème\** (congenital debility, icterus, and sclerema), 1,303; to *mort subite* (sudden death), 14; to *épuisement, eachezie* (exhaustion, cachexia), 3; and to *causes inconnues ou non-spécifiées* (unknown or not specified causes), 80. Total, 1,400, or 9·39 per cent. of the whole.

In London, out of 34,426 deaths of children under five years of age, there were due to premature birth, 2,025; to debility, atrophy, inanition, 2,809; and to other ill-defined and not specified causes, 45. Total, 4,879, or 14·17 per cent. of total.

In New York, in 1888, out of 17,358 deaths of children under five years of age, there were due to premature birth, 670; to debility, 114; and to inanition, marasmus, atrophy, 1,134. Total, 1,918, or 11·05 per cent. of the whole.

If deaths from *Lebensschwäche* and premature birth are omitted from the totals, we have for Berlin, London, and New

\* Generally a very small number.

York, respectively, 1,208, 2,854, and 1,248 deaths from indeterminate causes, or 7·18, 8·29, and 7·19 per cent. of the respective totals. Very respectfully,

ROGER S. TRACY, M. D.

#### ARSENIC IN WAR-PAINT.

NEW YORK, November 4, 1889.

To the Editor of the New York Medical Journal:

SIR: As an illustration of the manner in which some of our old wheel-horses will sometimes kick over the traces, permit me to cite the case of a patient with chronic eczema that came to my office September 14, 1889. I prescribed—

R. Acidi arseniosi.....	gr. j;
Ferri redacti, {	.....āā gr. xij.
Mangani oxidi, {	

Misce et fiat massa in pilulas dnodecem dividenda et sig.: One pill after each meal.

This treatment was continued with most happy results for four weeks, at the end of which time my patient was practically cured. He had a few pills left, and I advised him to finish them, and dismissed the case. The next evening, at ten, I was hurriedly sent for, and, hastening to the house, found my patient suffering from severe gastric spasms, without any other concomitant symptoms of arsenical poisoning. On the plea of stomach derangement I prescribed again, and ordered a discontinuance of the pills for two days, at the end of which time another one was taken with precisely similar results. I was surprised, not daring to impeach the compounder, who was an exceptionally careful pharmacist, and, abstracting a few of the pills, took one myself without any subjective symptom. In an hour I took two of the pills, without any apparent result, and, in the light of this experience as well as others before, have come to conclude that arsenic in each case of exhibition makes its own clinical therapeutic history.

J. R. PARKE, M. D.

#### Proceedings of Societies.

##### AMERICAN DERMATOLOGICAL ASSOCIATION.

Thirteenth Annual Meeting, held at Boston, on Tuesday, Wednesday, and Thursday, September 17, 18, and 19, 1889.

The President, Dr. I. E. GRAHAM, of Toronto, in the Chair.

(Concluded from page 502.)

**Dermatitis Papillaris.**—Dr. L. HEITZMAN, of New York, read a paper on this subject in which he said that benign tumors would not recur after extirpation; but there were many cases where tumors which were proved both clinically and microscopically to be non-malignant began to recur after their removal, sometimes assuming a larger size than the original. Such tumors were known to the surgeon as recurrent fibroids. A simple fibroma might gradually change into sarcoma during the course of a series of operations for its removal. Sometimes the growths commonly called moles would recur after their removal in the shape of scars, which were generally called spurious keloid. In a patient of Dr. Nicolai's, the application of green soap had caused the growth of large, branching hard scars over the chest. On some people every wound of the skin would be followed by such a growth. Such a condition might follow an eruption of acne pustules; and such growths had been termed by Kaposi dermatitis papillaris. A negro, who had slept on a pillow filled with horse-hair, had developed such growths upon

the neck and occiput. In another case, that of a Hebrew gentleman, constant picking of a few acne pustules had been the starting point of the disease. Kaposi considered the disease a primary one, but the author thought it secondary to the irritation arising either from an acne or from a syphilis. This view agreed with the opinion of Hebra, who had called it syphilis framboesiformis.

What the cause was we did not know. Von Recklinghausen thought it followed the distribution of the nerves. In the experience of the author this had not been true. It seemed to depend on a peculiar activity of the skin which enabled it to respond to moderate irritation. It was most common in negroes, in whom pricking of the lobes of the ears might be followed by such a growth. The Hebrew race was also prone to the formation of this recurrent fibroma. It was composed of interlacing bundles of fibrous tissue, with a large amount of protoplasm or medullary corpuscles between the bundles. Sometimes the latter became so great that it was called myxo-fibroma. The larger the amount of this free substance, the more rapid the growth of the tumor. We also met with indifferent corpuscles or medullary corpuscles, which pointed to rapid growth of tissue. From a pathological standpoint the recurrent fibromata were allied to keloid and dermatitis papillaris. The papillary character was of secondary importance, depending on the regular distribution of the blood-vessels in the superficial layers of the cutis. Treatment was tedious. Caustics, cutting, and the hot iron were forbidden; they would aggravate the disease. Nitric acid might be applied cautiously. The history of one case, in which an operation had been done in Vienna, was related; the result had been a great increase in the size and number of the growths. A three-per-cent. solution of salicylic acid seemed to promise as well as anything.

Dr. FOX had seen one of the cases of which Dr. Heitzman had spoken. The patient had refused operation, and electrolysis had been tried, great care being taken not to produce ulceration. Progress had been very slow, but a portion of the growth had been reduced to a level with the skin. Then the patient had disappeared until last spring, when he had appeared with the story that he had been operated upon in Vienna, and at that time he presented tumors considerably larger than when he had been under treatment before. Since that time the speaker had treated an almost identical case occurring in a colored man. A study of this case had led him to believe that, with the exception of its occurrence in the follicles, its occurrence in this particular locality, and perhaps its greater vascularity and tendency to suppuration, there was no difference clinically between this disease and keloid. It had occurred to him that the occurrence of keloid on the sternum might have had something to do with the hair-follicles there. He would question the exactness of making a distinction between true and false keloid; the history of the presence or absence of injury could not always be depended upon. In cases of spurious keloid the speaker had seen excellent results from scarification and the application of acetic acid.

Dr. ZEISLER protested against the view that the disease as described by Kaposi was not a distinct affection. In the case mentioned, even though there had been a resemblance to keloid, which he would not admit, there had been such prominent clinical features, such as the occurrence upon the occiput and the peculiar growths of the tufts of hair, that we had no right to throw over the diagnosis of Kaposi. Pure nitric acid in one case of keloid upon the cheek had caused its entire disappearance without disfigurement.

Dr. GREENOUGH mentioned a case where a number of keloidal growths had appeared upon the sternum after the application of croton-oil in the treatment of a cough.

Dr. KLOTZ would use salicylic acid in strength as high as ten per cent.; with it he had caused the disappearance of keloid in one case.

Dr. JACKSON, in a case of keloid upon the cheek, had tried salicylic acid, hydronaphthol plaster, mercurial plaster, and finally scraping. The hypertrophic scar which followed had not been removed by the use of scarification and acetic acid.

Dr. DENSLAW had tried electrolysis for a period of several months in one of these cases, but without result.

The PRESIDENT had watched with much interest for several years a case where he had observed from time to time keloidal growths appear upon the face, following a sycosis. The same patient had had a keloidal growth upon the leg, at the scar of an old bullet wound. He had not dared to operate in the face of the emphatic advice of Kaposi.

Dr. HEITZMAN said that pathologically there was not much difference between the lesions of dermatitis papillaris and those of keloid, although clinically they might differ.

Dr. FOX protested against the great multiplication of names in dermatology. It seemed to him that the term keloid of the occiput answered the purpose perfectly well.

**Clinical Notes on Sycosis Capillitii.**—Dr. ZEISLER read a paper on this subject. He had found very little said about the disease in the different text-books. In a case reported by Hebra, in the "Vierteljahrsschrift" in 1876, it had been said that the skin had been somewhat elevated and sclerotic, so that a fold of it could not be pinched up. There were small nodules and pustules, perforated by hairs, generally in bunches of ten or twenty, and the epilation of these hairs was almost impossible. Two cases that he had seen were of especial interest in relation to the last paper read on dermatitis papillaris. In one of the cases there had been abscesses on the scalp for six months. The sores left after the healing of these abscesses, which had been opened, had not been linear, but raised and thickened on each side. Tufts of hair had been very prominent, and at these points the patient had complained of an itching sensation. Depilation, with shaving of the head and anti-septic lotions, had been used, and the scalp had been entirely free in about three months, although there had been slight recurrences. A second case presented similar features. In each one of these patients he had noticed that the hair upon the scalp had been very thick. This recalled Wirtheim's explanation of the cause of sycosis—viz., that it was a disproportion between the diameter of the hair and the follicle, resulting in pressure. Although this might be a predisposing cause, yet the reader believed that it was the entrance of the *Staphylococcus aureus* and *albus* which caused the affection. It was therefore a local disease, and constitutional remedies were not indicated.

Dr. ROBINSON explained the meager literature that had been found by the reader by the fact that the name had been stricken from the list at the first meeting of the association and had not been put back until three or four years ago. He did not agree at all with Wirtheim's view. When we had pustules form they were, of course, due to organisms, but many lesions occurred which were not pustules. In the pustules of acne you got the same organisms. In every case there was a predisposing cause. The best treatment was to render the soil uncomfortable for the organisms by the use of constitutional remedies.

Dr. BULKLEY had seen cases in young men which he had put down as folliculitis of the scalp, where papules or pustules were formed. In these cases a permanent baldness of the spot affected had remained. One case had been cured finally; in a second case the treatment had been neglected, and the patient seemed to be growing worse. In both these cases he was sure there was a constitutional cause.

Dr. FOX referred to the case that he had published in the

first edition of his photographic illustrations, where the hair grew in large tufts upon the surface of a keloid in a colored man.

Dr. DENSLAW reported a case where small nodules had appeared deep in the scalp very much like those which were seen in deep-seated acne, and accompanied with burning and itching; they had been opened, a small sore had been formed, and the hair had been lost. As a young man this patient had had a very severe attack of acne, especially upon the shoulders. In this patient it was noticed that the mouths of the follicles upon the face were patent. It was discovered afterward that he had a stricture at the meatus, and the urethra was in a highly sensitive condition. Under the combined treatment there had been no recurrence.

Dr. HEITZMAN thought the diseases which had been mentioned could all be classed together, and he preferred the name folliculitis, as used by Dr. Bulkley. In some of the cases we had atrophy and sometimes we had hypertrophy.

Dr. ROBINSON thought the names were used according to the location, and the fact that the cause was the same had nothing to do with it. The case was comparable to that of bronchio-pneumonia and bronchitis, which were separate diseases, although the cause was undoubtedly the same. In sycosis, or eczema, or acne the cause was the same, but the seat was different and the clinical history was different.

The PRESIDENT had had an experience in one case which had led him to believe that the disease was not local simply. The case had been one of sycosis. A typhoid fever had come on, and during its run the sycosis had disappeared, only to return again after the fever had abated.

Dr. ZEISLER replied that it had long since been established by Hebra that during fevers many local diseases were arrested temporarily.

**Relapse of Pemphigus Foliaceus after Eleven Years' Quiescence.**—Dr. SHERWELL reported an instance of this sort. The case had been reported in the "Archives of Dermatology" for 1877, and also in 1878 before the American Dermatological Association. The treatment in the first instance and in the relapse had been mildly protective. The patient had recovered, and had been entirely well until March of the present year. She was now twenty years of age and healthy. At the beginning of the attack there had been general febrile disturbance, anorexia, chill, and irregularity of the bowels. The eruption had commenced as an erythema over the front of the chest and arms, followed by the appearance of vesicles with the peculiar sour-milk-like contents. The temperature had been 102.7°; pulse, 115. The eruption had spread rapidly over the entire body. She had recovered entirely within three weeks. Dr. Fox, who had seen the case at one stage, had remarked that it looked like a case of pityriasis rubra.

**Impetigo Herpetiformis.**—Dr. SHERWELL also reported the history of a case of this disease. The patient was Miss K., aged thirty-two, under the care of Dr. Risch, of Brooklyn. She had had five living children and several miscarriages. In 1884 she had had a slight eruption, consisting of small bullæ, which had become puriform. In the summer of 1888, when three months pregnant, she had suffered with gastric disturbances, and about October 1st she had first noticed an eruption similar to the one she had had before. At that time it had resembled scabies very much, but did not get well under treatment. Crusts, looking like impetiginous eczema, had formed, and the nervous system had become a good deal affected, there being a constant tremor of the limbs. Dilute hydrocyanic acid had been used as a dressing with benefit, but in November another relapse had occurred. When seen on November 23d she was in a pitiable condition, moving the limbs with uncertainty

and difficulty. Pulse weak; temperature elevated. The eruption was of the small impetiginous variety, apparently spreading in somewhat of a wavy line, and the diagnosis of impetigo herpetiformis was made upon that observation. Arsenic was administered. On December 23d she gave birth to a non-viable child. After this numerous relapses of the eruption occurred until the middle of June, at which time she was free, and had remained so ever since. The writer believed that all these cases were due to absorption of suppurating and effete matter. One case had occurred during an attack of diphtheria, and, if it had been chronic, would have been considered a case of this kind. It had been reported that Dr. Duhring had given up his idea that this disease belonged to the group of dermatitis herpetiformis, and if it were so the reader was sorry, for he believed that that view was the correct one.

Dr. HEITZMAN said that Kaposi had criticised him for reporting a case of this disease because the woman in whom it had occurred had not been pregnant; but it happened afterward that a man came to the clinic in whom Kaposi himself had been obliged to make the same diagnosis.

Dr. BULKLEY, referring to a remark made by the speaker, said that this disease was not at all like the cases which he had reported under the name of herpes gestationis, differing in the character of the lesions, in the absence of lines or gyri, and in the fact that it was never fatal. It seemed to him that this was a disease *sui generis*.

Dr. ROBINSON preferred the term hydroa for this class of diseases.

Dr. HARDAWAY reported a case of pemphigus foliaceus in a gentleman sixty years of age, beginning on the chest, making slow progress for the first few months, and then progressing rapidly until the whole cutaneous surface was invaded. The speaker had had at the same time under observation a case of pityriasis rubra, and there had been a period in the history of the two cases when they had looked absolutely alike—a fact which, to his mind, gave a good deal of color to the idea that they were one and the same disease, representing different processes of the same trouble.

**A Rare Form of Skin Disease.**—Dr. BRONSON, of New York, read an account of a case. The patient was a boy of fourteen, seen at Charity Hospital. He had had a swelling of the forehead, eyes, and mouth, with the formation of scales and crusts over the cheeks. There had been papules, tubercles, pustules, and incrusted ulcerations over the face, and also rounded or irregular cicatrices on various portions of the face, the scalp being free. The cervical glands had been slightly enlarged. Scattered over the trunk and extremities had been lesions similar to those upon the face, while between the patches the skin had remained for the most part normal. Considerable pus could be obtained from the ulcers. The primary lesion had seemed to be a pustule or papule, the disease first affecting the hair-follicles. This might undergo ulceration, leaving a slight papule, or a pustule might form. A year and a half ago a sore had come upon the right ear, and about the same time an abscess had come upon the neck, resulting from a suppurating lymph-gland. He had been working at that time in a paper manufactory. General health good; urine negative. After two months the ulcers had been healed, and the swelling of the face had been less. He had been discharged from the hospital, but a little later had been looked up, and had been found to be in St. Francis Hospital in Jersey City. At this time the eyelids had been enormously swollen, forming a fold above the eyebrows. Primarily the disease seemed to have been an acne, and the only diagnosis that the reader could make was acne cachecticum. It had been at first thought that there might have been arsenic in the paper in which he had been working, but on investiga-

tion that view had to be given up. But, even if it had been so, we would suppose that the eruption would have disappeared after the removal of the exciting cause. There was no appearance or history of syphilis. The edema of the face was hard to account for, but probably there was a local cause, perhaps the presence of confined pus in the deeper parts of the skin.

Dr. SHERWELL thought that dermatitis necrogenica would be a good title, on account of the absorption of necrobiotic elements, which were having an action upon the nervous system.

Dr. MORROW had seen the case, and thought it resembled most nearly cases of arsenic poisoning that he had seen. While not entirely satisfied with Dr. Bronson's diagnosis, he could not suggest a better one.

Dr. BRONSON was willing to accept the diagnosis of dermatitis herpetiformis if there was such a disease. One of the important features was the distribution of the eruption, which was similar to that of dermatitis herpetiformis, showing that the same pathological motive was present, and yet the clinical disease ran a very different course from that of Duhring. It seemed to him that the fact of the relapse occurring was sufficient to indicate that it was not arsenical.

**A Case of Urticaria Pigmentosa.**—The secretary read a paper by Dr. H. W. STELWAGON, of Philadelphia, on this subject. The objective symptoms were almost always the same in the cases classed under this head, and midway cases between this type and the ordinary urticaria were rarely seen. It would almost appear that this was a peculiar disease by itself. The case reported had occurred in a boy of six, who had had a good personal and family history. The disease had begun at eight months, after two unsuccessful attempts at vaccination. The eruptions had been most abundant upon the covered portions of the body at first, but later there had been a disposition for them to appear upon the face. The disease had been present constantly since its first appearance, the older lesions disappearing without leaving a trace. The eruption had consisted of rounded, elongated, reddish papules, sometimes surmounted by a small vesicle, varying from the size of a pin-head to that of a large pea: there had been also small, flattened, yellowish lesions, of the size of a pea, and of a salmon-color, and other spots, where recovery had seemed to be taking place, with nearly normal skin, slightly atrophied and pigmented. The first appearance of the lesion had been not unlike that of the wheal of urticaria, but smaller and less inflamed. The itching had been slight. No other lesions than these had been found at any time. The changes from the beginning of the eruption until the disappearance of the lesion would require weeks or months. The treatment had been without influence.

Dr. FOX had an impression that the disease was not correctly named, although he could not suggest a suitable term for it at the present time. It seemed to him that the pigmented lesions were the essential features of the disease, and that the urticarial element was secondary. It would be interesting in these cases to note the condition of the skin after a series of years, in adult life.

Dr. HEITZMAN did not agree with the last speaker. He thought we should not lay too much stress upon the presence of pigment. He would admit that there was a trophic neurosis leading to the edema, which went deep down to the subcutaneous tissue. In the ordinary cases there was edematous infiltration, without extravasation, and then we had the whitish color. But if there was stagnation, with exudation of blood, then we had blood-corpuscles mixed with the edematous liquids. It seemed to be the same as ordinary urticaria, plus haemorrhage into the wheals.

Dr. FOX did not mean that the pigment was characteristic, but that the lesions were not of the nature of an urticaria. The

pigment was a fact of minor importance. There was simply an urticarial element associated with the lesions.

Dr. TAYLOR had seen a child, twelve years of age, who had suffered with this disease until the sixth year. At the time of the observation she had had the appearance as though she had an intense erythematous syphilitide.

**Dermatological Hints.**—Dr. HARDAWAY, of St. Louis, read a paper thus entitled.

1. *Spontaneous Involution of Sarcoma.*—He had reported the case in 1882; it had been an alveolar pigmented sarcoma of the skin. The face, hands, and feet had been affected, and there had been swelling of the lymphatic glands. At that time the disease had existed eight or ten years. In 1884 a number of deposits had occurred on the hands and feet. A recent inspection, fifteen years after the beginning of the process, had shown that the disease was arrested. The tumors had all gone, leaving an atrophic condition of the skin. The patient had never received treatment. At about the same time another case of fibro-sarcoma had been reported, the patient had been put upon arsenic, and had died within six months, having been sick two years.

2. *Disappearance of an Extensive Eruption of Xanthoma.*—A paper had been read in relation to the case in 1884. All parts of the body had been affected. Since that time there had been a gradual involution of the disorder. In four years from the time of the observation the lesions had undergone complete involution, though the bronzed hue still remained. The patient had received no treatment whatever.

3. *Case of Bullous Eruption in a Child.*—The patient, eleven years old, had had measles four years before, and the present eruption had come on a month after recovery from that disease. The skin had been elevated and reddened. Often whole areas of sound skin would be surrounded by the bullæ. Under the use of arsenic the intervals between the attacks had been materially increased, and such lesions as made their appearance had been more or less aborted.

Dr. HEITZMAN remembered the case of sarcoma. He recollects that he had predicted that the course of the disease would be a slow one, on the ground that the pigment had been diffused and not granular. He had read of one case of sarcoma in the tonsil of a child where recovery had taken place spontaneously.

Dr. GREENOUGH asked how Dr. Hardaway would exclude chronic relapsing urticaria.

Dr. HARDAWAY replied that there had been no pruritus in the case.

Dr. TAYLOR spoke of a case where bullæ had appeared in large numbers and in the shape of most perfect rhombs and parallelograms. At first it had been thought the patient must have caused them herself, but that source had been excluded.

Dr. BRONSON called attention to the instances of intense neuralgic pain sometimes accompanying sarcoma of the skin. In one case the lesions had been upon the face and extremities especially, and had occurred in the form of very superficial, somewhat tough lesions, the largest having an area of an inch and varying in color from reddish to deep purple. The pain had been the most prominent feature. There had been no evidence of the growth of tumors in the inside of the body. The patient had finally died, apparently of exhaustion. No autopsy had been permitted. The observation had been made that these cases of pigmented sarcoma of the skin were most common in Hebrews. It would be an interesting point to settle.

Dr. BULKLEY thought this would be a proper subject for one of the regular meetings of the association. He thought, with Dr. Greenough, that a good name for these cases of hydroa and dermatitis herpetiformis would be chronic urticaria, with tendency to vesication.

The PRESIDENT here read the histological report of the case of herpes zoster that he had reported on the first day of the meeting, and exhibited specimens under the microscope. It was found that the ganglia were extensively invaded by leucocytes, some of the latter having taken the place of the destroyed nerve-cells. In this case it seemed as if the diplococcus was the irritant element. No inflammatory processes were found in the pons, medulla, or cerebellum from the same subject.

Dr. HEITZMAN said that the fact that the ganglion cells were affected in this disease had been known for twenty-five years, but now it was interesting to find micrococci in the ganglia, and perhaps that meant that we should find the real cause of the disease. It seemed to him that the bacteria shown were a new variety. He hoped the next opportunity for such study would be improved, and, if possible, cultivations made from the tissues.

**On the Alleged Tolerance of the Iodides in Syphilis.**—A paper with this title was read by the secretary, in the absence of the author, Dr. STELWAGON. The author would deny the statement made by Dr. H. C. Wood, that there was a tolerance of the iodides in the case of patients who were affected with syphilitic lesions. Perhaps there might be a certain ground for the belief in the case of those who had cerebral syphilis, but if it were so it was not on account of the specific effect of the disease, but because the central nervous system was the part affected, and a similar lesion from any other cause would have a similar result. The writer gave briefly the history of five cases of syphilitic skin disease, in which the assertion was certainly not true. Moreover, in investigating the influence of the iodides in psoriasis he had found cases that had borne the remedy quite as well as any cases of syphilis could have done.

Dr. TAYLOR thought the statement of Dr. Wood had been thoroughly disproved by Dr. White. There was no difference in this respect between the syphilites and non-syphilites. The speaker thought that we were inclined often to weaken in giving the drug in the cutaneous cases, whereas we pushed it more strongly in the nervous cases, under the view that the case was a desperate one. Sometimes there would be a toxic effect at one time, and none at all at another. It seemed to him that many of the cases that Dr. Wood had treated had gone through the stage of acclimatization, so to speak.

Dr. GREENOUGH referred to the fact that sometimes patients who could not take small doses would bear larger ones perfectly well.

Dr. TAYLOR, in reference to this point, recalled the case that he had reported a year ago, and said that the eruption had been brought on at the very beginning of the treatment, but the iodide had had to be continued, on account of the patient's general condition, and after a time he could take two or three drachms without any influence upon his eruption, or any inconvenience.

Dr. DENSLOW mentioned the case of a man who had had undoubted syphilis, and who had been laid up sick in bed every time the smallest amount of iodide had been given him.

Dr. BULKLEY spoke of the value of giving arsenic in connection with the iodide. He had reached as high as ten drops of Fowler's solution.

Dr. TAYLOR did not believe the arsenic did any good where the iodide caused coryza; but where there was a disturbance in the skin, with a tendency to form dermal lesions, the arsenic, he thought, would hold the inflammatory condition in check. And yet it would fail utterly in some cases.

Dr. Fox asked the effect upon the action of the bromides.

Dr. HARDAWAY had seen it tried in a good many cases, and had never seen good effects.

Dr. Fox believed that the bromine and iodine might produce lesions one week and be taken without trouble the next,

so that he was coming to believe that all supposed effects of arsenic, at least in the case of bromine, were simple cases of coincidence.

Dr. BRONSON spoke of the fact that the acne in bromism was more aggravated than in iodism, as perhaps having a bearing in the case.

Dr. TILDEN exhibited a boy, of whom mention had been made in reference to prurigo, and he was examined by the members of the association.

Dr. BRONSON was fully convinced of the diagnosis. In his mind the essential feature was the neurosis affecting the particular portions of the skin.

Dr. FOX agreed to the diagnosis. In his mind there was a doubt as to the propriety of separating the disease prurigo from chronic papular eczema. The history of the case, however, separated it from eczeua, since the latter tended to get well sooner or later without treatment.

Dr. ALLEN remarked that the diagnosis might almost be made from the peculiar pallor of the face which was present in this case. In a patient that he had under observation the body had been covered with molluscum tumors, which seemed to have developed upon the prurigo base from the scratching.

Dr. BULKLEY was ready to admit that perhaps American dermatologists had been too prone to place some of these cases under the head of eczeina. It would be better, perhaps, to call some of them by this name.

Dr. TAYLOR thought the cases had sometimes been presented to the society in the evening, and the light had interfered with correct ideas of the lesions.

Dr. ZEISLER considered the case a typical case. The cases in Vienna were not so very frequent. They were brought into the clinics again and again. The difference between the papular eczema and this case was striking. The joints, hands, and face would be most affected, and in this disease were free. Even though we had too many terms in dermatology, don't let us throw away distinct pictures of disease. If we called this a papular eczema we produced a terrible confusion.

Dr. FOX would base his opinion as to the entity of the disease on its occurrence in early life, its neurotic origin, and its duration, but not upon the fact that certain parts of the body were affected, or upon the deep-seated character of the lesions.

**Resolutions of Thanks.**—Dr. TAYLOR returned the thanks of the members for the hospitality that had been accorded them at the hands of the Boston members. A fitting response was made by Dr. GREENOUGH in behalf of the Boston members.

On a motion of Dr. FOX, the association voted to extend the thanks of the association for the use of their rooms to the Boston Medical Library Association.

#### NEW YORK ACADEMY OF MEDICINE.

SECTION IN OPHTHALMOLOGY AND OTOTOLOGY.

Meeting of October 21, 1889.

Dr. OREN D. POMEROY in the Chair.

**Cataract Extraction.**—Dr. HERMAN KNAPP said that he had hoped to present to the meeting a case of cataract extraction. One of the patient's eyes had been operated upon about three years ago by the ordinary method. Upon the other eye the operation had lately been done without iridectomy. He wanted to show a peripherie opening. Unfortunately, the patient had disappointed him and he would have to defer his remarks.

The CHAIRMAN said that several cases of cataract extraction recently operated on at the Manhattan Hospital had resulted in loss of the vitreous. This had been evidently caused by the use of the spring speculum. The operations had been performed

under cocaine and upon patients known to be of the unreliable class, and therefore every precaution had been taken to avoid accidents. After the lens had been removed the patients had in several instances given a spasmodic contraction of the orbicularis, and, though the assistant had at once depressed the speculum, still, in spite of this, a large portion of the vitreous had been extrnded. He had decided that it was better to operate without a speculum or forceps, and simply use either a lid elevator or the fingers.

**Opening the Auditory Meatus.**—The CHAIRMAN then introduced a patient upon whom the operation of opening the auditory meatus had been done, resulting in improved hearing. He felt a little uncertain about the case as yet, because a positive cure had not been effected. But he had made up his mind to succeed. It would be seen that the patient showed deformity of both auricles. The hearing distance was one inch, by the watch. After opening the canal the hearing distance had become two inches. He inferred that there was a tolerably normal drum membrane. There appeared to be an accumulation of superfluous tissue occupying the position of the normal canal. He had made an incision, thrusting the scalpel through about a quarter of an inch of sound tissue, when the knife had seemed to enter a cavity just where he had supposed the meatus should be. He had then made another incision, forming a V-shaped flap which he had cut off. He had then been able to pass a probe in three quarters of an inch. A rubber catheter had then been introduced which had been cut off to a suitable length for drainage. A good deal of suppuration resulted. The drainage-tube was removed and the cavity stuffed with boric acid, which would have been very good if it could have been kept dry. Then packing with iodoform gauze was suggested and tried. This was not satisfactory, for when removed it was a long, purulent, stringy mass. It had been next decided to let the cavity alone, simply syringing it with water. At the present time the discharge had almost ceased, but the canal was somewhat narrowed. He had ordered a silver tube made which he proposed to use until a permanent opening was secured. So far the hearing power had doubled. Whether there was anything like a reasonably good drum-membrane or not, he could not say. He had tried to use a rubber tube, but it would not stay in place. He intended to keep the canal open somehow.

Dr. KNAPP said it was exceedingly rare for such cases to be cured. Out of twenty-four or thirty such operations only one had been successful.

Dr. T. R. POOLEY thought the attempt to keep the canal patent by probes, plugs, and so on, was a procedure of very doubtful utility. He remembered a case which had come under his notice last winter of an exostosis of the auditory canal which had been removed by the electro-osteotome. This part of the operation had been successful enough, but the difficulty had been in keeping the canal from entirely closing. As long as he had kept using pieces of catheter or tubes and perforated plugs, he had not succeeded. But, after abandoning all these and treating the case as one of ordinary inflammation, syringing with hot water, and otherwise letting things alone, the patient had begun to improve, and now had a medium-sized canal large enough to admit of a view of the drum-head. The hearing also was very good. It must be admitted, however, that all these cases were attended with a great deal of difficulty.

The CHAIRMAN said that he had got far enough along to appreciate the uselessness of all tubes in such cases; at least, he would leave them out as much as possible. Still he felt that they had their analogue in the instruments used for piercing the ears for pendants.

Dr. H. S. OPPENHEIMER stated that his experience was limited to one case with very indifferent result. He suggested the

possible utility of a mild constant current of electricity kept up by means of an arrangement similar to that in use in hospitals for the healing of ulcers.

**Coloboma of the Choroid.**—Dr. WEEKS reported a case which he said had had conditions making it somewhat rare. The case was one of microphthalmia with nystagmus. The cornea in the left eye had measured 8 mm., and in the right eye 9 $\frac{1}{2}$  mm. The pupils had been 3 mm. in diameter by medium illumination. Irides normal. R. V. =  $\frac{2}{20}$ ; hyperopia 3 D.; L. V. =  $\frac{8}{20}$ ; myopia; at the bottom of the disc hypermetropia in the normal parts, 16 D. The defects in the field of vision had been rather peculiar. The speaker had found a marked coloboma in the choroid of the left eye taking in the optic nerve sheath. The defect in the field of vision had a little more than corresponded with the coloboma. In the right eye there had been a coloboma of the sheath extending upward and outward about a disc and a half in diameter. In the right eye the defect in the field of vision had corresponded with that of the left eye, although no corresponding coloboma had existed. The defect in the field for white had been much greater than that for light. The patient could distinguish the flame of the candle in a portion of the field encroaching considerably on that part of the field corresponding to the coloboma in the left eye. A similar condition existed in the right eye with no visible coloboma. For white the defect was very excessive. It was interesting, as Manz had shown by sections from cases of coloboma, to observe that the rods and cones disappeared at the margin of the defect. In two cases reported where the coloboma had been small, and had not reached the optic nerve, perception of light had been present over the whole field corresponding to the coloboma. If the perception of light were present in these cases where the rods and cones were absent, it went to show that their integrity was not necessary to the perception of light. The peculiar defect in the field of vision in the right eye, where no coloboma could be discovered with the ophthalmoscope, was unique.

**A Perimeter.**—Dr. KNAPP exhibited a perimeter which he had been using and which for ingenious simplicity he considered the best he had seen. On account of the intricate construction and complication connected with their manipulations, these instruments were not used so often as they should be. This instrument had the advantage of always being ready for use. The speaker thought that the present method of examining and recording astigmatic cases was a faulty one and might be improved.

**The Treatment of Obstinate Deafness.**—Dr. N. J. HEPBURN made some suggestions as to the treatment of obstinate deafness. He was instigated by the unsatisfactory nature of the results attending treatment of this condition. The class of cases to which he referred, or at least one of the varieties of it, was that of people who heard better in a noise. These answered all the tests for middle-ear deafness, but did not improve under treatment. The chairman had suggested multiple paracentesis, and the speaker had found that some of the cases behaved well under this treatment, but that others did not improve; indeed, that in some the hearing got worse. And in some it had even developed otitis. The use of the syringe would not infrequently cause vertigo. The idea had occurred to him that if he could inject through the small nozzle of a Davidson's syringe he could so regulate the flow as to limit the pressure on the labyrinth. By adopting this plan he had found that he got rid of much of the suppuration, and hearing was improved and the drum-membrane became somewhat more transparent. A case had come for treatment in which the patient, who had been the rounds, was so deaf that the speaker had thought that his hearing could not very well be made worse. He therefore

made a large perforation in the drum-membrane and fastened a Davidson's syringe to a Eustachian catheter, washing out the ear through the tube. The fluid escaped through the auditory meatus. The patient improved after three repetitions of this treatment so that from only hearing a watch at contact, he could hear it at eight inches distance. This maximum hearing had not been maintained, though hearing was still good at four inches. He had since pursued this plan in eighteen cases. When he found the end of the Eustachian catheter thoroughly engaged he allowed the other end of the syringe to fall into a weak solution of chloride of sodium, with a temperature of from 60° to 90° F. If it was found that the fluid was not flowing, an incision must be made in the posterior inferior quadrant. He found that the solution would come through very readily without any special leakage into the throat.

Dr. POOLEY said that the method used by Dr. Hepburn was not new. The Eustachian catheter had been used by Schwartze for the purpose of removing purulent secretions in acute processes, but whether with puncture of the drum-head or not he could not say; but he thought that the method had considerable merit in it. These cases always presented an accumulation in the cavity of the middle ear, and if this could be washed out the hearing would improve, and this was probably the explanation of the benefit obtained.

**Cataract Extraction.**—Dr. KNAPP then made some remarks on cataract extraction. He did not think simple extraction offered any better results than extraction with iridectomy. Whenever the capsule was left behind, it was sure to wrinkle and become clouded and probably agglutinated to the iris. The instrument he used was a specially made captotome, with a very delicate fine point. In operating he made his section follow the line of the transparent cornea as nearly as possible, as with this flap prolapse of the iris and inflammation were less likely to follow. He then endeavored to dislodge the lens by passing the instrument carefully under the iris and rupturing the capsule at its periphery. This method he considered better than to incise in the center, which left a scar which was detrimental to good vision. Patients for operation were fully cocaineized, which caused slight dilatation of the pupil. After the operation he used a one-per-cent. solution of eserine. Before bandaging the eye a one-per-cent. ointment of eserine was put into the conjunctival sac. He considered eserine the main factor in preventing prolapse of the iris.

Dr. POOLEY asked if adhesion of the capsule to the iris took place without inflammation.

Dr. KNAPP said it did; where the iris had been bruised or abraded, adhesion took place by first intention. He had seen an uneven notched iris heal perfectly round. He did not think a clean cut in the iris had so much chance of reacting as those which were only bruised. The speaker was not satisfied with vision of  $\frac{2}{10}$  after cataract extraction; he wanted to get  $\frac{2}{5}$ . This was his aim in doing capsulotomy. He never attempted an operation without good light, and used an artificial light if necessary.

The CHAIRMAN said that he had seen posterior synechiae take place where there had been no apparent iritis and where the symptoms had been slight.

#### NEW YORK ACADEMY OF MEDICINE.

##### SECTION IN OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.

Meeting of October 24, 1889.

Dr. J. E. JANVRIN in the Chair.

**The Management of Abortion.**—Dr. R. A. MURRAY read a paper with this title. He deplored the fact that no fixed prin-

ciples guided the general practitioner in the management of abortion cases. The result was often disastrous to the woman, for an abortion too frequently ushered in a whole series of uterine troubles—haemorrhage, salpingitis, barrenness, subinvolution, and so forth. Abortion was always a pathological process. The muscular coats of the uterus were still undeveloped and contractions were inefficient. The cervix did not relax readily and involution was but slowly accomplished. Goodell had likened abortion to the plucking of immature fruit. Two symptoms were always present—pain and haemorrhage. The speaker then went on to describe the symptoms of threatened abortion, in the treatment of which he advocated opium for the pain; extract of viburnum prunifolium would be of benefit, and chloral hydrate or the bromides, given by the mouth, seemed to contribute to the cessation of uterine action. Careful examination should be made to ascertain the exact condition of things, and whether the symptoms were really referred to threatened abortion or to some other cause. The appearance of regular menstruation was possible up to the second month, though not thereafter. If an escape of waters or membrane had taken place, then efforts at prevention should give way to others in the direction of hastening the process of abortion. Thorough and persistent antiseptic precautions should be maintained. The vaginal canal should be tamponed with gauze, well applied around the cervix by means of an applicator, the patient being placed in Sims's posture. If the bleeding was very profuse, alum might be used on the first tampon. Tampons were to be preferred to the coopeurynter. If the os was found dilatable, but not dilated, ergot might be given in small doses. When the tampon was removed the os was generally found to be sufficiently dilated to admit of the ovum being reached by the forefinger. It was better to empty the uterus. Examination of the endometrium should be carefully made, and if the membranes were found detachable they should be removed with a placenta forceps. If portions still adhered, the blunt curette of Thomas should be used to remove these fragments.

The operator should not be satisfied until the whole endometrium was freed from projections. The cavity should then be washed out with carbolic-acid solution of the strength of 1 to 100, a reflux catheter being used. The haemorrhage would cease entirely as soon as the uterus was clear. If the uterus had been depressed during the examination it was most important that it should be raised again. In cases of neglected or of incomplete abortions, great care should be exercised. It was important that everything which had been preserved should be examined. If the membranes had not been made away with they should be approximated to determine their entirety. Examination should be made of the cervix and the endometrium should be explored. When the speaker was able to see what had been passed and it seemed complete, he simply ordered antiseptic vaginal washes with antiseptic dressings to the vulva, and made careful inspection of the cloths removed each day, watching also for any local abdominal tenderness or rise of temperature. In neglected cases where the patient showed evidences of septic trouble, all authorities agreed that the cervical canal, if closed, should be dilated, the cavity thoroughly washed out, and the curette used. The general septic symptoms should be combated by the administration of alcohol, quinine, and generous food. It was said that the galvanic and faradaic currents possessed a certain antiseptic action, but the speaker had had no experience with the method. He did not favor the use of the brush as advocated by certain French obstetricians, but thought the blunt curette would be found to answer all requirements. Subinvolution might be averted by the judicious use of ergot. Abortion and miscarriage were fertile sources of a train of supervening uterine troubles, and the proportion dying

from septic complications after miscarriages was greater than that of the deaths by sepsis after labor at term.

Dr. A. F. CURRIER thought that the method of treatment in abortion cases was one which had reached something like exactness. This was largely due to the advances made in the use of antiseptics. He was glad that such stress had been laid on the value of the blunt curette in diagnosticating the condition of the endometrium after the expulsion of the foetus. It was much more reliable and more easily used than the forefinger. It was his rule to apply pure carbolic acid over the entire mucous membrane of the uterine canal, so that anything missed by the curette might be reached by the acid. He obtained good results from this method. There might be conditions, as, for instance, after prolonged and profuse haemorrhage, when interference at the time would be contra-indicated, in proof of which he cited a case from his own practice. Dr. Murray had spoken of tamponing the vagina but had not mentioned including the uterus. The speaker, however, advocated this plan and believed it facilitated the expulsion of the foetus.

Dr. PAUL F. MUNDÉ said that in 1883 he had written a paper advocating the immediate removal of the secundines after abortion. This article had elicited a great deal of criticism because of the very positive views which it contained. Whenever he had to deal with a case in which abortion was imminent and unavoidable he would endeavor to save the woman loss of blood and at the same time would hasten dilatation of the os by tamponing the vagina with iodoform gauze. This might be removed in twenty-four hours and replaced if required. Sometimes it might be necessary to dilate the external os. For this purpose tupelo tents could be used, two or three of which might be introduced, though it was now easy to get them large enough to allow of the introduction of one or two fingers after dilatation. When the canal was sufficiently wide to admit of the procedure he would introduce his finger and remove the contents of the uterine cavity as thoroughly as practicable. He would endeavor to keep the ovum intact if the membranes had not already ruptured. He much preferred to empty the uterine cavity at one sitting whenever this was at all practicable. The class of cases for which he was usually called in consultation was that in which haemorrhage, chill, and high temperature had already occurred. He generally found the canal sufficiently widely dilated to allow of the introduction of a finger, and even if this were not the case it was not difficult to open it. The finger once passed into the uterine cavity, the rest was easy, requiring only care and persistence in clearing it of its contents. He had always advocated this course, and it was still his firm conviction that a woman who retained within her uterine cavity any portion of a ruptured ovum was in danger of two accidents: first, haemorrhage, severe and sometimes fatal; and, second, septæmia. To those who urged the most extensive experience of cases in which the retained portions of the ovum or secundines had been allowed to take care of themselves he would say that, in spite of this experience, those gentlemen would surely some day come to grief. Nature would do a great deal, but it was not wise to let nature handle these cases too long. He differed with the last speaker, who thought that the curette was better than the finger. With an instrument it was impossible to determine that the cavity was really empty. He preferred to give the patient a little chloroform, and then, passing the exploring finger up to the fundus uteri and compressing the abdominal wall with the disengaged hand, he could determine accurately the condition of the cavity. Then a curette might be introduced and everything cleared away, when the finger should again be introduced. If it was ascertained that the work had been thoroughly done, then the patient might be deemed practically safe. He had yet to meet with a case in which he could regret having

conscientiously followed out this plan. He would never use more force than was justifiable, and would always be careful not to subject his patient to an injury more severe than that of leaving the uterus alone. The steps he had indicated were such as he always followed, unless the contra-indications were urgent and obvious—for instance, when the woman was very low and where temporizing was the only safe thing to do until she could bear interference. The speaker then described the various curettes and placental forceps which he found most useful, and went on to say that as soon as the uterine cavity was thoroughly clear he introduced a double-current catheter and passed in a stream of hot two-per-cent. carbolized water. He never introduced corrosive sublimate within the uterine cavity. He had always feared toxic absorption from its use. After the cavity was washed out the uterus invariably contracted, and there would be no further occasion for any local treatment, except perhaps in a few cases an intra-uterine injection for a few days. He wished to be understood as saying that he was not at all afraid of criticism on this subject. He was constantly reading in the journals about letting nature take care of these cases. He deemed it far wiser to give nature all the assistance possible in this particular. It had been urged that the procedure was unsafe at the hands of inexperienced men. If the practice was admitted to be sound in theory, then it was imperative that the inexperienced men should acquaint themselves with the requirements, and it was for such purposes that post-graduate schools were instituted. When it was necessary to induce abortion, as in cases of uncontrollable vomiting or fibroid in the pelvis, he found it best to introduce tupelo tents frequently, until the os would allow the finger to pass, and then, when the uterine canal was thoroughly dilated, the ovum might be gently detached by sweeping around the fundus uteri with a blunt curette, when it could generally be removed almost entire.

Dr. FRY, of Washington, was then asked to speak in reference to the use of electricity in the class of cases under consideration. He said that its use was not indicated in imminent abortion, but rather in neglected cases where the fragments of placental tissue remained in the uterus and produced haemorrhage or septic symptoms. The faradaic current was to be used only during contractions with a view to increasing them. He did not think this current capable of inducing them. He had used the galvanic current for its coagulating effect. The positive pole was considered antiseptic as it eliminated oxygen and chlorine. The latter was frequently given off in such quantities that it might be detected by its odor. He had been conducting some experiments as to the chemical effects of the electric current upon micro-organisms, but at present he was not able to give any results, as there had been some inaccuracy in the technique incident to the initial observations.

Dr. H. J. BOLDT thought the subject of abortion was very well understood theoretically but not practically. It was his experience to be called to cases where the first principles of antiseptic precautions had generally been entirely ignored or neglected. He thought a three-per-cent. solution of carbolic acid hardly strong enough to use as an antiseptic, and the solution itself not so good as the bichloride. He never failed to make use of the finger for purposes of examination, and he urged it as a plan to be adopted in every instance. He, however, deprecated the employment of too much force where portions of the uterine contents still remained closely adherent. So long as they were not disintegrated and remained attached, he thought it unnecessary to interfere with them, as they would be dislodged in the course of time.

The discussion then became general and was closed by some brief comments by the author of the paper.

**A Successful Case of Laparotomy and Supravaginal Amputation of the Uterus for Rupture.**—Dr. HENRY C. COE read a paper with this title. On September 8th, at 1 p. m., he had been called to a desperate case of labor to perform Cæsarean section. The patient was a healthy Irishwoman twenty-three years of age, with a rapid, feeble pulse, and evidently in a state of collapse. The gentlemen in attendance had feared that rupture of the uterus had taken place two hours before. Examination of the abdomen revealed two tumors—a larger one filling the right side of the abdomen and extending as high as the ensiform cartilage, and a smaller one occupying the left iliac fossa—both firm and unyielding. It was evident that the former was the body of the uterus tilted over to the right and in a state of tetanic contraction, and the latter the head of the child. Palpation of the abdomen above the latter gave an ominous gurgling sound, suggestive of free fluid in the peritoneal cavity. Prolonged attempts had been made to extract the child by forceps and version. With the introduction of the hand into the vagina the discovery of laceration of the anterior lip of the cervix antero posteriorly and a laceration through the vaginal junction on the left side was made. The finger passed through the rent entered the abdominal cavity. The child, which was unusually large, was dead, presented in the left dorso-anterior position with the right hand and foot prolapsed, and was firmly impacted, the head seeming to be partly outside of the uterus. Believing that a further attempt at version would only extend the tear, he at once decided that laparotomy offered the best chance of saving the woman. The patient's condition was desperate, and the surroundings were such that any approach to antisepsis would be impossible. She had lost a large amount of blood, and her pulse was so feeble that hypodermic stimulation with brandy and ether was resorted to. A free incision eight inches in length was made through a very fat abdominal wall and into the peritoneal cavity, which contained a quantity of fluid blood and clots. A rent was found extending upward from the cervix through the left broad ligament half way to the fundus. The head of the child lay in the left iliac fossa outside of the uterus, being grasped by the edges of the tear. It was at once seen that this would not be a case for suturing the uterus, as arterial hemorrhage was going on from the vessels of the lacerated broad ligament. As no time could be lost, the uterus was turned out of the cavity, the cervix constricted by a piece of rubber tubing cut from a fountain syringe, the écraseur having been forgotten in the haste, and the child extracted through the tear. Without waiting to remove the placenta, the tubing being secured with an artery forceps, the uterus was excised, together with the ovaries and tubes, and all bleeding vessels were tied. This part of the operation was completed in twelve minutes. The utero-sacral ligament on the right side had been also badly lacerated. After securing the vessels and sewing the torn peritoneum with a continuous catgut suture, the peritoneal cavity was thoroughly irrigated with hot water and the stump secured in the wound with knitting-needles. No drainage-tube was used. The bladder was examined and found apparently uninjured. The cervix had been so badly torn that it subsequently sloughed out. The patient rallied well, but had a pulse of 140 to 150, and no hopes had been entertained of her recovery. From the outset she was free from nausea and able to take stimulants. On the second day her temperature had risen to 102° to 103° F., and there were general abdominal tenderness and distension, but, by maintaining free catharsis and using the ice-bag, peritonitis was aborted. The urine was drawn for the first four or five days. The stump quickly necrosed; and on the fourth day the tubing was replaced by a Kœberlé's serre-nœud. The entire mass was removed by the end of a week, and the cavity packed with iodoform gauze. The patient had taken

nourishment and stimulants freely, but her pulse had remained at 120, and her temperature had risen every evening to 101° to 102° F. At one time an exhausting diarrhoea had threatened her life. She complained of no pain, but suppuration of the haematocele which had formed in the left broad ligament was feared. Early in the second week the urine began to escape *per vaginam*, although the patient could retain it to some extent. A careful examination with the finger and speculum showed that a cervico-vesico-vaginal fistula had been established, and that there was considerable sloughing of the upper portion of the vagina. All the necrosed tissue at the bottom of the abdominal wound was picked away, until nothing remained of the cervix but the portio vaginalis. The wound granulated satisfactorily, but there was a free communication with the vagina through which urine and the douche water sometimes welled up. She was allowed to get up at the end of the fourth week. The fistula was still patent, as the urine still dribbled away, but not so freely as at first. At the end of the fifth week the abdominal wound had entirely closed. It was hardly necessary to add that the after-treatment of such a serious case in a dirty tenement-house had required constant vigilance or the patient would certainly have succumbed to the operation or the subsequent complications. Before commenting on the case it was important to classify it. Dr. Robert Harris, of Philadelphia, had clearly pointed out that it was neither a Porro nor a Cæsarean section proper, but an operation *sui generis*. Prevôt, of Moscow, had reported the first case, an unsuccessful one, in which the ruptured uterus had been excised after removal of the child through the rent without previously incising the organ. There had been ten true Porro-Cæsarean sections for rupture of the uterus in this country, four of the women having been saved. Dr. M. Price had reported a case in which an operation very similar to the speaker's had been performed last April, but with a fatal result. In conclusion, the speaker said that, given the same conditions, he would adopt precisely the same method of procedure in another case of rupture of the uterus, because he believed that it offered the best chance of saving the patient, for the following reasons: 1. That this operation could be performed in the shortest possible time. 2. That it was impossible to properly suture such an extensive rent, with contused edges, as the one described. There was also imminent risk of haemorrhage after removal of the temporary constriction. 3. Where prolonged use of instruments without antiseptic precautions had occurred, the interior of the uterus was sure to be so badly contused that subsequent danger of sepsis was great. The additional shock to the patient from removal of the lacerated uterus was preferable to the exposure of septicaemia, which would certainly follow by leaving it. 4. The objection made by Dr. Harris that a cervix split by laceration could not be very well fitted for constriction, as the part below the wire might discharge septic matter into the abdominal cavity through the rent, was a good one. But the writer thought, if the tear in the peritonæum was carefully closed and the stump properly constricted and shut off from the peritoneal cavity, that there was less danger than in trusting to the suture alone without constriction. Finally, with due respect for the opinion of such a weighty authority as Dr. Harris, who believed that it "would hardly be admissible" to subject a woman with a normal pelvis to "the unsexing operation of removing the lacerated uterus with the ovaries, as was done by Prevôt," it should be borne in mind that the surgeon was sometimes called upon to do, and to do at once, what he believed was the best thing for the patient without regard to established precedent or even to the ordinary rules of surgery.

**Carcinoma of the Uterus and Ovary.**—Dr. A. PALMER DUDLEY read a paper with this title, and presented some patho-

logical specimens. He said the growth had been removed from a patient fifty-one years of age, of Irish birth, whose occupation had been that of a domestic servant. Her family history was good. She had been married twenty-eight years, and was now a widow. She had borne two children and had suffered one miscarriage since, due, she had said, to lifting a heavy weight. She had been operated upon several years before for some form of uterine trouble; just what it had been could not be learned. From that operation up to within three years she had been perfectly well. The patient had said that within the last three years, the exact time she could not remember, some sort of tumor had broken in the pelvis, and that a large amount of blood had come away. This had been followed by repeated floodings which generally had yielded to treatment. She was admitted to Randall's Island Hospital on November 13, 1888, into the service of Dr. McLean. Digital examination showed the uteruses to be large and the os patulous. Quite a large tumor of firm consistence, probably fibroid, was found to lie above and to the right of the uterus; the growth moved with the uterus. A curette was used and a large amount of villous tissue removed, which had the appearance of a cast of the uterine mucous membrane. The speaker could not learn whether there had been a microscopical examination of this tissue. The possibility of malignancy had been noted and recorded in the history book. The hospital service had changed and she had come under the speaker's care on February 1, 1889. He proposed to operate for removal of the growth, but the patient would not entertain the idea, and left the hospital February 3d. She had not been seen again until September 23d, when she reappeared at the hospital and begged for the operation for her relief. During her absence she had suffered from repeated haemorrhage. Further examination revealed an increase in the growth to the right of the uterus, but the latter seemed to have remained of about the same size. The passage of the finger through the external os revealed a growth presenting, which had the feel of a submucous fibroid. There was no odor about the parts that was unnatural. Pain was absent, there was no cachexia, and, in fact, there were no objective symptoms of malignant disease. The speaker made a diagnosis of subperitoneal and submucous fibroid, and proposed suprapubic hysterectomy, as the growth was too large to remove *per vaginam*. On October 4, 1889, he performed a modification of Schroeder and Bantock's operation, which he had designated previously as the intrapelvic, but extraperitoneal, method of treating the stump in hysterectomy. After the uterus and such of the structures as had been involved by the morbid growth, including the veriform appendix, had been removed, the mass was submitted to a pathologist for microscopical examination, and a diagnosis returned of epithelioma of both uterus and ovary.

Dr. COE, by means of a black-board illustration, depicted the steps of the operation he had performed, demonstrating thereby the all-important factor that the completed closure of the various incisions left no ligatures in the pelvic cavity, that if pus formed it would be outside the cavity of the pelvis, and that perfect drainage could be effected through the os uteri externum.

#### NEW YORK CLINICAL SOCIETY.

*Meeting of October 25, 1889.*

Dr. W. H. FLINT in the Chair.

**Operation for Tubercular Peritonitis.**—Dr. F. H. MARKOE presented a patient upon whom he had operated for tubercular peritonitis. The diagnosis in the case had been by no means clear, but when the peritoneal cavity was opened it had been

found to be occupied by a large tumor, comprised of agglutinated intestines and thickened omentum. The fact that the morbid material contained quantities of tubercle bacilli had settled the question of diagnosis. The patient had made a good recovery.

#### **Removal of a Kidney for Pyelo-nephritis with Calculus.**

—Dr. MARKOE then presented another patient from whom he had removed a kidney a few weeks before. The diagnosis in this case had been that of pyelo-nephritis with calculus. The kidney was also shown to the meeting. It was greatly enlarged, and contained a calculus of about the size of a walnut in its pelvis.

**A Laryngeal Illuminator.**—Dr. D. B. DELAVAN exhibited an arrangement by which illumination of the interior of the throat could be effected by means of a strong light, preferably electric, transmitted through a glass rod suitably curved, and fitted with an opaque disc, to prevent the distribution of the rays, and applied externally to the patient's neck.

**A Large Intubation Instrument.**—Dr. DELAVAN then showed a large intubation instrument, the use of which he urged for treating certain conditions of the upper air-passages in the adult. Its applicability was manifest in acute as well as chronic cases, such as acute œdema involving the larynx or any condition of stenosis of the larynx. It had been maintained that, in order to successfully deal with chronic stenosis of the larynx, it was necessary to rupture the bands which caused the stenosis, and that by inserting one of these intubation tubes no good was done. He thought that if the bands were divided by incision and then dilated by the instrument the desired result would be obtained, as the cut surfaces would be kept apart till they healed, while the tube was worn. He wished that surgeons would give the instrument a thorough trial.

Dr. L. E. HOLT inquired whether these instruments had ever been employed for hysterical spasm, in which women frequently suffered with marked and alarming dyspnoea.

Dr. DELAVAN replied that he had never heard of its use in that condition. He thought that a little galvanism in those cases would be more effective.

**A Pulmonary Click due, possibly, to Separation of the Costo-sternal Articulation produced by Vomiting.**—The CHAIRMAN reported the history of a case of a man, twenty-three years of age, in such perfect health that he could only be designated as a patient by a considerable stretch of courtesy and enthusiasm. Yet he had presented a physical sign which was susceptible of diverse interpretations, and which the writer had neither heard described nor encountered until this case had come under his observation. The patient's father had died with pulmonary tuberculosis in 1883, but there had been no other cases in the immediate family of the patient except in a cousin of remote degree. The physical sign in question had consisted of a distinct clicking sound, such as was often heard in incipient phthisis; this had been heard with maximum intensity at the junction of the fourth rib with its corresponding costal cartilage on the right side. It had been occasionally so loud as to be heard at a distance of some feet from the patient. The click had been generally noticed at the end of inspiration, but frequently during expiration or forced abduction and eversion of the arms. The click, when first heard by the patient in September, 1887, had been preceded the previous year by a depreciation of his general health without evident cause. There had been lancinating thoracic pains, which, in view of the recent death of his father from tuberculosis, had caused the patient considerable concern. These pains had been bilateral and chiefly confined to the supra-clavicular and infra-clavicular regions. In the summer of 1887 the pains had ceased in all other parts of the chest, and had become strictly localized at the junction of the fourth rib with its costal

cartilage, in the exact position where the click had subsequently appeared. At the time when the lancinating pains had become localized at this point, and indeed up to September, 1887, repeated physical examinations made by the writer had failed to detect any other thoracic sounds. In the autumn of 1887 the pains at the fourth costal cartilage had disappeared and had never returned. Shooting pains at the apices of the lungs had still recurred at long intervals. About this time the patient had sailed for Europe. During the voyage he had vomited profusely several times. The acts of emesis had been devoid of pain. Toward the end of the voyage the click had made its appearance. At first the sound had been so faint as to be almost imperceptible and of inconstant occurrence. It had gradually grown more frequent and more intense. The sound at that time had appeared only at the end of inspiration and had not been produced by any motions or changes of posture other than those incident to the act of respiration. After the patient's arrival in Europe the click had recurred with diminishing frequency, and in a few weeks had entirely disappeared. In May, 1888, during the patient's homeward voyage, the click had reappeared under precisely the same circumstances which had attended its first development. This time, however, the sound had not disappeared, but had remained up to the present date. After its reappearance it had at first occurred only at the end of inspiration, and had been independent of movements other than those of the respiratory muscles. A few months later, however, the patient had noticed that it was also caused by forced abduction and external rotation of the humerus, the pectoral muscles being thus put upon the stretch. A few months ago it had been noted that the sound was occasionally reduplicated, occurring both with inspiration and expiration. Quite recently a single expiratory click had been heard by the patient. There had been no cough at any time. A remarkable immunity from so called "colds" had existed for the last three years. A reliable spirometer had shown the patient's breathing capacity to be 310 cubic inches. There had been no tenderness over the seat of the click, either on percussion or on firm pressure. There had been no abnormal mobility of the rib or of the cartilage. The writer was inclined to the belief that the click proceeded from the fourth costo-sternal articulation, or from that of the fourth rib with the fourth costal cartilage. He had submitted the case to the meeting in the hope that some of its members might have met with analogous cases which would throw some light on the subject. He thought he was justified in calling attention to the case because of the difficulty which, in similar ones, might attend the exclusion of pulmonary tuberculosis.

The reading of this history was followed by a few remarks, the substance of which went to show that the condition described was probably the result of the exertion of vomiting, which might have produced separation of the ligaments of the costo-sternal articulation.

## Miscellany.

**Ectopic Gestation.**—At a meeting of the Philadelphia County Medical Society, held on October 23d, Dr. Mordecai Price read the following paper:

In bringing to the notice of this society the much-discussed subject of ectopic gestation, my hope is not so much to advance anything new as to make plain our duty and manner of procedure in these desperate conditions. Bermutz and Goupil, of France, and Parry, of our own country, did much to advance our knowledge on this subject, but it remained for Mr. Hallwright to bring it forcibly to Mr. Tait's notice in

one of his patients, in whom he had diagnosed ectopic gestation, and urged operation. "The suggestion staggered me," says Mr. Tait, "and I am ashamed to have to say I did not receive it favorably." A second hemorrhage killed the patient. A post-mortem examination revealed the fact to this great leader in abdominal surgery that Mr. Hallwright was correct in his conclusion, and that the patient could have been saved. An opportunity was soon offered in Dr. Dolan's case, of Halifax. Dr. Dolan had also diagnosed ectopic gestation, and given as his opinion to the husband that nothing but an operation would save the patient's life. He telegraphed for Mr. Tait, who not only agreed with him, but had the requisite daring to operate, save the patient, and revolutionize the whole treatment of extra-uterine pregnancy. I leave it to you, gentlemen, to judge to whom the greater amount of credit is due—to the practitioner who urged it, or to the illustrious surgeon who performed it.

A pregnancy, as we all know, should be within the uterine cavity, and the only other place is primarily in the tube. That this condition may be possible, the tube must be diseased, its lining membrane removed, its ciliated epithelium no longer urging the product of conception onward to its natural abiding place nor retarding in the least the spermatozoa from intruding on dangerous and forbidden ground. This condition is brought about, I believe, in fifty per cent. of the cases by gonorrhœa, and in the remainder by cold, septic conditions following childbed, and catarrhal affections from other causes. That the pregnancy in the beginning is always tubal, I think is well proved, from the fact that the tube is the only portion outside the uterine cavity offering the conditions favorable for impregnation. The product of conception thrown into the peritoneal cavity either at the time of impregnation or during the first few weeks of gestation would undoubtedly be digested. We have the best proof of this in the fact that in early ruptures into the peritonæum of only a few weeks no fetus can be found; only the blood clot, the diseased tube, and membrane remaining. Those cases that have advanced to maturity in the peritoneal cavity have, without doubt, been those first developed in the tube, and then ruptured into the broad ligament, and, when able to resist the digestive fluids of the peritonæum, the secondary rupture has taken place.

We may pass over the other forms of so-called ectopic gestation, for, if they ever occur, it is so rarely that they do not deserve our consideration. Tubal pregnancy would be of but little moment to us if it were not for the fact that most patients are not aware there is anything wrong. If they suspect pregnancy at all, they have no reason to doubt that it is of the usual old-fashioned kind, and the first warning, alike to patient and doctor, is rupture of the tube, with symptoms of internal hemorrhage—often so serious that the patient lives but a few hours. These cases are far more numerous than you would suppose—in our city alone, from all sources, about twenty-five a year; and when you remember that five years ago the mortality was one hundred per cent., and now at least ninety per cent. are saved, we have much to be thankful for to Mr. Tait and his adviser, Mr. Hallwright.

The symptoms of ectopic gestation before rupture are of a vague and uncertain character. Those best qualified to properly interpret them, whose experience in such conditions has been greater than any other investigators', have yet to see one and recognize it before rupture. The only reported cases said to have been recognized and treated before rupture have been in the hands of our electrical friends and enthusiastically dwelt upon, and the man who would treat them with a knife has been given a back seat and denounced in unmeasured terms for his mutilation of the poor woman when it was so easy to get rid of the product of conception by so safe a plan as the electrical current. But we find by investigation that in many of these reported cases there was little foundation for the belief that the women were pregnant. Some of them have fallen into the hands of other men and been operated on, and no pregnancy existed. And I can not but think the others could not bear investigation requisite to a proper diagnosis.

The symptoms after rupture are sufficiently plain and urgent to warn any earnest medical man of the patient's condition. They are as plain as any other surgical affection and more imperative than most. In a woman who has been sterile for a length of time, it may be for years, whose period has been delayed for two or three weeks or longer, after slight exertion or lifting some heavy object, there occur agonizing

pelvic pain and collapse, followed by all the symptoms of loss of blood. If the patient reacts, this is followed by recurring pain and collapse, constant uterine hemorrhage, it may be with small loss of blood, discharges loaded with shreds of decidua, leaving the impression in the patient's mind that she has had a miscarriage. There are pain and fullness on the side of rupture, with a mass of a hoggy, fluctuating consistence in the pelvis. No one case being a repetition of any other, there is nothing fixed and unchangeable, save the termination—death, almost without exception, unless prompt surgical aid is given. I know no better place than just here to call your attention to the terrible mortality of the past. All of Bernutz's reported cases ended fatally. Dr. Formad, the coroner's physician, in a letter to my brother, reports nineteen cases of death from hemorrhage from rupture of tubal gestation sacs. All ended fatally in six hours but one. How differently this list compares with that of many operators! All have recovered, save a very small percentage, from the surgical treatment in the hands of these operators.

There are many conditions that may be confounded with extra-uterine pregnancy. In fact, any mass in the pelvis, such as tubal trouble, a small ovarian or dermoid tumor, haematocele from traumatism, an abscess of the tube or ovary, gonorrhœal pyosalpinx, all have been mistaken for extra-uterine pregnancy. Even our electrical friends have mistaken tubal trouble for extra-uterine pregnancy, and wasted many valuable sittings to kill the fetus, where none existed, and, strange to say, they did not cure the diseased tube. How, then, Mr. President, can we ordinary mortals come to a positive diagnosis? But these mistakes of diagnosis are of small moment, as the conditions which could be mistaken for extra-uterine pregnancy should all be removed by the knife. I have seen the abdomen opened several times when a positive diagnosis had been made, where no pregnancy existed, and a small pus tube or dermoid tumor instead. I am sure the operator was not greatly disconcerted by the conditions found. No one need give himself anxiety; he should feel sure before operating that whatever the mass is, it must come away. In most cases of ectopic gestation in our own hands the diagnosis was made before operation. Rupture had taken place in every case. Diagnosis of tubal pregnancy before rupture would simply be a happy guess. Haematoceles, that have given our predecessors so much trouble, I think can be credited in great measure to ectopic gestation, and the remaining small number to traumatism.

We have come to that period where experimental treatment of ectopic gestation is a disgrace to our profession. Electricity, with all its barbarous instruments and murderous delays, will, I hope, ere long be forever thrown aside as a means of treatment for this condition. Its history certainly does not offer to any thinking mind any proof of its value, while, on the contrary, its record of death is truly appalling. Puncture, or injections into the sac of morphine or any substance, with the hope of killing the fetus, is attended with greater risk to the mother than an immediate operation for its removal. I can find no language strong enough to express my condemnation of these experimental methods.

*Operation.*—Where there is time, the room should be thoroughly cleaned, and all needless articles of furniture removed. A most efficient cleansing of the body with soap and water and brush is necessary, and the bowels should be thoroughly evacuated. No antiseptic should be used. If possible, a trained nurse should be obtained—one who is accustomed to the work of the operator, able to cleanse and take care of a drainage-tube and encourage the patient to bear patiently with the discomforts necessarily following an operation of this kind. Opium must be positively forbidden in all abdominal work; it interferes with the secretions, sickens the patient, makes her irritable and hard to manage, and conceals the symptoms of danger and otherwise complicates the recovery. A good light is needed. Every instrument and ligature and suture should be carefully sealed and placed in trays of warm water, handy to the operator or his assistant, so that in case of any emergency there will be no delay, for time is a material factor in these operations. The shorter the operation the less the shock. It should be minimized in every detail; short incision, careful enucleation, perfect tying, most thorough irrigation with warm distilled water. No antiseptic whatever has any place or purpose in this operation. Antiseptics

have done bad work for good operators. We see this admission in the journals almost daily: "Perhaps the antiseptic was too strong." Chemical antiseptics of any kind in the peritonaeum do murderous work, and should be abolished by law, if our surgeons have not sense enough to disband them in this department of surgery. The after-treatment in these cases is of great importance. The drainage-tube should be cleared every half-hour for the first day or two, until the discharge becomes small in quantity and serous in character, when it should be removed. The contents of the bowel should be kept in a soluble condition; and it should be purged with Epsom salts upon the slightest indication of peritonitis, when the symptoms will disappear like magic. The patient should be kept in bed from three to four weeks in the most favorable cases, and longer if deemed advisable. Any member of this society may be called to do this operation without preparation, instruments, or nurses, and I have no doubt you would meet all the requirements of the case possible under the circumstances. With a patient bleeding to death, you can not wait for anything. Where the surroundings and the condition of the patient will admit, an operator of known skill and courage should be procured.

**The Invasion of the "Masieur."**—We must beg our readers to keep a close eye upon the *masieur*. He is bearing down upon unshod humanity with a steady and relentless stride. He develops in the midst of us, he sails over from Germany and England to us, while, if there are any graduates of Heilgymnastik still left in Denmark, Sweden, or Norway, we should like to know it; for it has appeared to us, after some busy morning, that they have all called. Truly, the *masieur* is among us. He is a man of great resources. As his fraternity increases, he does not lose heart, or complain of competition, or seek protection from the State—he simply enlarges his field. In olden times the rubbing of a stiff knee with officinal linimentum saponis was the center and circumference of massage; soon, however, we learned how soothing was the emollient and theobromated hand upon the hyperesthetic skin and diseased muscle. The *masieur* became firmly established as the resourceful prop of hysteria and unfailing staff of morbid locomotion. But then the sinewy and insidious hand began to gather adventitious aids, and seek new worlds to conquer. Having organized its movements into a company of Gallic polysyllables, so that its manœuvres of *tapotement* and *pétrissage* and *effleurage* should not be mistaken for plain, every-day slap-slap, jab-jab, and thump-thump, it proceeded to attack all the several diseases and organs of the body. Adipose tissue in excess was made to disappear, while glandular tissue, if mammary, was rubbed to make it grow. Massage has now applied itself to diseases of the eye, and granular lids are, *quoad* the granulations, artistically rubbed off; it has invaded the mouth and throat, reducing hypertrophied tonsils, opening the Eustachian tubes, and curing catarrh and deafness. The abdominal viscera were the early and easy subjects for this now illustrious science. The colon's lax vermicular waves are tempestuously hastened, and the modest stream from the smaller bowel has scarcely bubbled through the ileo-cecal valve before it is rushed madly into the rectum. The pelvic organs have of late received the devoirs of this new art; and the uterus has been rubbed and stroked and pommeled, all in pure French terminology, until this martyr-viscus could not help but free itself from adhesions and congestions, and pillow itself gently on its original vesical cushion. Lastly, we learn that the heart is to have massage. The heart has been, we are told by poets, torn and bruised, and bled and broken; but it remains for modern science to see that it shall have *effleurage* and lomi-lomi. There are still a few things left for the *masieur*. Can he not apply *tapotement* to the brain, or, at least, to the cerebellum? Has he done justice to the kidneys? Might not the ovary receive a course of artistic jabbing before it is removed and bottled? When all fields are conquered, and every viscera springs responsive into blooming juvenescence beneath his learned touch, we recommend the *masieur* to Christian science.—*Med. Record.*

#### ANSWERS TO CORRESPONDENTS.

**No. 297.**—There are many excellent methods of embalming. The best are by injections into a large artery twenty-four hours after death, when muscular rigidity has disappeared. For temporary preservation,

Suequet's injection of sodium hyposulphite will answer; the preservative action lasts until all the hyposulphite has been converted into the sulphate. For permanent preservation, the method employed by Brunetti, of Padua, is perhaps to be preferred. Cold water is first injected until it returns perfectly clear (in from two to fifteen hours); alcohol is then injected for fifteen minutes; commercial sulphuric ether is then injected and allowed to remain from two to ten hours; a tepid watery solution (supposed to be from 15 to 20 per cent.) of tannin is then injected; finally, in from two to five hours more, the body is dried with a current of air at about 90° F., the drying process taking from an hour and a half to five hours. A less troublesome and reasonably satisfactory method is by injecting a mixture of a pint of alcohol and three quarts of a saturated solution of zinc chloride, the thoracic and abdominal cavities being treated with a solution of zinc chloride in stypic colloid.

**No. 298.**—Exalgine is a methyl derivative of acetanilide. It is freely soluble in water and in alcohol. It is closely allied to antipyrine in its physiological action, and is used as an anodyne, from six to twelve grains being generally given in the course of twenty-four hours. Single doses of seven grains and a half are said to have produced toxic symptoms.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

### EXHIBITION OF AN IMPROVED APPARATUS FOR THE THERAPEUTIC USE OF COMPRESSED AND RAREFIED AIR, WITH REMARKS ON

THE HOME-TREATMENT OF PULMONARY AFFECTIONS.\*

BY SOLOMON SOLIS-COHEN, A. M., M. D.,

PROFESSOR OF CLINICAL MEDICINE AND APPLIED THERAPEUTICS,  
PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE;  
CONSULTING PHYSICIAN TO THE JEWISH HOSPITAL, ETC.

THE apparatus which I have the honor to exhibit to the fellows of the college is primarily designed for use at the home of the patient, though the same features of construction which enable it to fulfill this purpose likewise recommend it for use at the physician's office; and by multiplying the number of delivery-tubes and introducing a motor and reservoir, it may be adapted for use in hospitals. In the "New York Medical Journal" for February 23, 1889, I have illustrated the arrangement of an apparatus for hospitals, permitting the treatment of seventy patients in the course of about two hours. The apparatus for inhalation of compressed air has been exhibited previously, though not before this body. But the apparatus for expiration into rarefied air has not yet been publicly described.

My attention had been called to the value of modifications of respiratory pressures in the treatment of pulmonary affections, and especially of phthisis, even before I became a student of medicine, by some rather remarkable recoveries ensuing upon such treatment in the practice of my brother. The apparatus which he employed was that of Waldenburg. A description of this instrument, by Dr. Pepper, and remarks upon its therapeutic employment by Dr. J. Solis-Cohen, may be found in the proceedings of the college (Feb. 2, 1876), "Transactions," third series, vol. ii.

Much of the success of this therapeutic measure depends upon its regular and continuous use. To insure this at such times as visits to the physician's office are impracticable, the apparatus must be placed in the patient's home. Waldenburg's apparatus is large and cumbersome. It is not continuous in action, its adjustment is troublesome, and its cost, fifteen years ago, was excessive. These considerations induced my brother to undertake some experiments with the view of providing a substitute which should be small, cheap, easily managed by a patient or nurse, and reliable as well as cleanly. He, however, abandoned the gasometer plan, and his efforts were not entirely successful. Taking the matter up where he had left off, I soon realized that the only available method of securing a certain, regular, and continuous pressure was to return to the gasometer; but I found that the desired reduction in size could be accomplished by using the gasometer as a regulator only, and not as a reservoir. This necessitated the introduction of another source of air supply; and as the simplest, cheapest,

and most practicable, I chose the foot-bellows of the dentist's blow-pipe. Any form of pump available under the particular conditions, or even city water pressure, might also be adapted; but the bellows is preferable under ordinary circumstances. This combination of foot-bellows and small gasometer solved the problem so far as the inhalation of compressed air is concerned. With the assistance of Mr. Charles Richardson an apparatus was constructed in 1883 which has been in continuous use ever since by others as well as by myself, and has given complete satisfaction. Though it has already been described in print,\* I may be pardoned for again exhibiting its construction, as several mechanical improvements have been introduced that have not yet been published.

It consists of a gasometer ("Compressed air," Fig. 1), of which the air chamber is eight inches in diameter and twenty-four inches high. The water chamber is pierced at the level of the base of the overflow tank (seven inches from the top) with a row of perforations, allowing the water to escape into the tank under pressure of air in the air cylinder. The air cylinder carries, two inches  $\frac{1}{2}$  from its open base, two shelves, one on each side, on which are placed ballast-weights for the purpose of lowering the center of gravity, and thus maintaining the steadiness of the apparatus. Both shelves and weights are perforated to avoid resistance of water. As the area of the top of the air chamber is just fifty square inches, atmospheric pressure upon it equals, in round numbers, 750 pounds. With the ballast upon its shelves, the cylinder weighs ten pounds, giving an excess pressure of  $\frac{1}{15}$  atmosphere. Weights are furnished in two sizes, in the shape of rectangular blocks of iron  $4\frac{1}{2}$  by 2 inches surface, and about  $\frac{1}{2}$  inch and 1 inch thick, respectively. The smaller ones are bored out to weigh  $1\frac{1}{4}$  pound each; the larger ones to weigh  $2\frac{1}{2}$  pounds each.

Being placed on top of the air chamber in successive pairs (one on each side, to preserve balance), they bring the pressure up to any desired amount not exceeding  $+\frac{1}{30}$  atmosphere. Thus:

Cylinder and bottom weights = 10 lbs. =  $+\frac{1}{15}$  atmosphere.  
 $2\frac{1}{2}$  lbs. (two small weights) additional =  $12\frac{1}{2}$  lbs. =  $+\frac{1}{60}$  atmosphere.  
 $2\frac{1}{2}$  lbs. (two small weights) additional = 15 lbs. =  $+\frac{1}{30}$  atmosphere.  
 $3\frac{3}{4}$  lbs. (one small weight and one large weight) additional =  $18\frac{1}{2}$  lbs.  
=  $+\frac{1}{40}$  atmosphere.  
 $6\frac{1}{4}$  lbs. (one small weight and two large weights) additional = 25 lbs.  
=  $+\frac{1}{30}$  atmosphere.

The air cylinder is furnished with two goose-necks, one (8) for the attachment of the tube (6, 7) from the bellows, conveying compressed air; the other (9) for attachment of the tube (10, 11) connected with the stop-cock (12, 13) and face-mask (14) or mouth-piece, through which the patient inhales. A perforation two inches in diameter is fitted with a screw cap carrying a hook on which a sponge may be placed, which is to be saturated with any volatile medicament (*e. g.*, terebene) that may be desired. The cap likewise contains a smaller perforation, into which an air-gauge may be fitted.

\* "N. Y. Med. Jour." Oct. 18, 1884, and other places.

† The shelves have been raised to avoid catching the weight of the escape-valve.

When the gauge is not in use this is closed with a rubber plug. Still another perforation in the top of the air chamber is fitted with a valve, which permits escape of air should too much be

cylinder to indicate cessation of pumping. By means of the automatic escape-valve we are enabled to introduce a continuously acting pump if desired.

As an additional precaution against splashing, the air chamber and overflow tank are each provided with a deflecting hood about an inch and a half wide, and inclined at an angle of forty-five degrees.

With these improvements over its original construction, being the gradual suggestions of six years' experience, the compressed-air apparatus is felt to be complete. There is no particular in which I find it deficient, or can now think of a change which would increase its mechanical convenience or therapeutic efficiency.\*

I have for some time been endeavoring to combine with it an apparatus for expiration into rarefied air—a procedure which has a certain limited degree of applicability, being sometimes employed alone, sometimes in combination with the inhalation of compressed air. There was no difficulty in constructing an apparatus merely for expiration into rarefied air. All that was necessary was to reverse the connection with the bellows, so that the latter would take air from the gasometer and deliver it into the room or the street, and to suspend the air chamber from a small pulley, counterpoising it with weights varied according to the desired negative pressure. The mechanical arrangement of pulleys and weights, the devices for adjusting the weights, the lowering of the outer water-tank (now a reservoir, and not for overflow), etc., are so obvious and so easily understood by looking at the instrument before us ("Rarefied air," Fig. 1) that description in detail is unnecessary. Mr. Metzger has made the various parts with his accustomed care, and has used a wire rope in preference to one of hemp. The difficulty lay

in the combination of the two gasometers into one instrument by means of a bellows which should, at the same stroke, compress air for delivery into one cylinder and rarefy air in order to exhaust the other cylinder. As we could not get any bellows manufacturer to construct this, Mr. Metzger at last made an experimental one with his own hands (see Fig. 1), and it answers the purpose perfectly. It is in reality two bellows, mounted back to back, on the same frame. The downward stroke of the lever compresses the upper bellows and expands the lower one. The recoil of the spring in the upper bellows expands that one and compresses the other. There is no communication between the two bellows. By means of a tube (2, 3) passing out of a window-board (1), the external opening being protected by wire gauze, the supply of air for inhalation is drawn from out of doors.

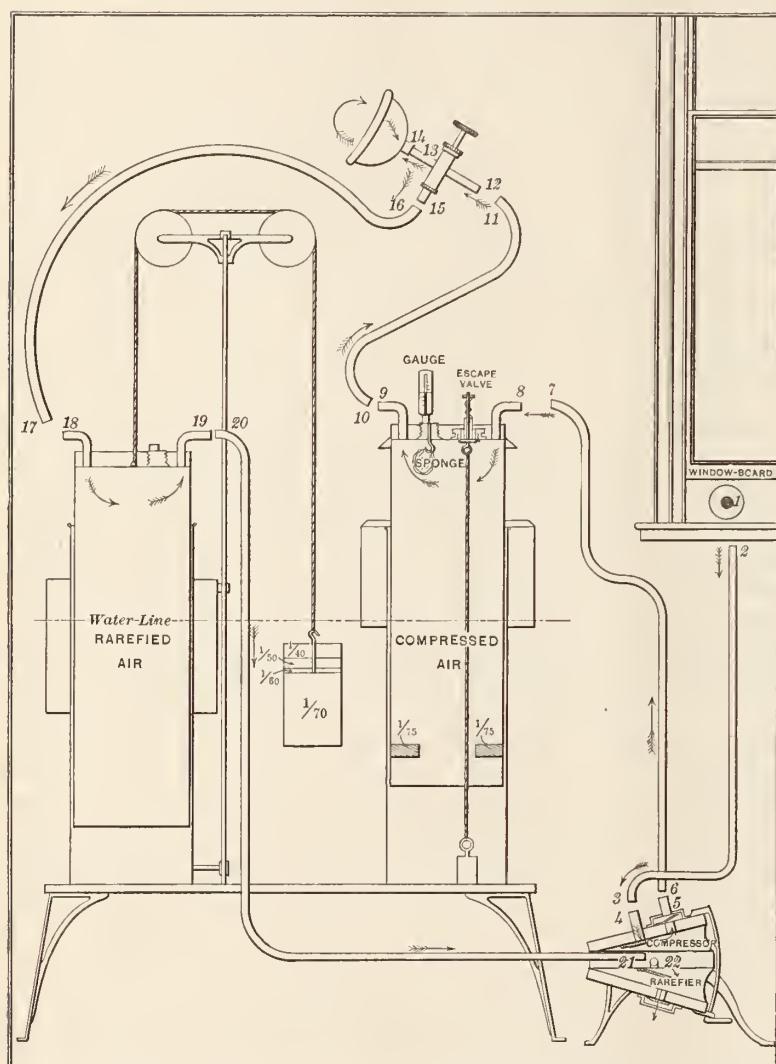

FIG. 1.—Explanation of figure. The parts are numbered in order of attachment, and in the direction of air-current; from the window to the mask through the compressed-air gasometer; and from the mask to the discharge pipe of the rarefying bellows through the rarefied-air gasometer. The discharge-pipe may also be connected with window if desired. The direction of air-current is indicated by the arrows.

sent over from the bellows. This valve, which is superior to my own arrangement for the same purpose, is the ingenious device of Mr. F. Metzger, of this city, who now makes the apparatus in every respect according to my instructions, and who has devoted much time and care to the details of construction in order to secure both strength and lightness. The escape valve is composed of two flat plates of brass, the upper perforated, the lower unperforated. They are held in apposition by a spring, and when in apposition no air escapes. The lower plate carries a chain, thirty-five inches long, which is attached to a weight which rests upon the floor of the water chamber. Should too much air enter the cylinder, lifting it too high, the plates are pulled apart, the air escapes through the perforated plate, and the cylinder falls to the proper level. This obviates any liability to splashing of water, which, before this attachment was made, would occur if attention was not paid to a line painted on the

\* My friend, Dr. D. D. Stewart, suggests that care be taken that the rubber tubes employed are not of the variety weighted with lead.

When both instruments are used together, as I show now, being brought into communication through the lungs of a patient by means of a double stop-cock connected with the face-mask or mouth-piece, the route for the air is as follows:

(a) From the street, (b) through the upper bellows, (c) to the compression gasometer, (d) thence to the lungs; (e) from the lungs (f) through the rarefaction gasometer (g) to the lower bellows, (h) which expels it into the room or into the street.

Apparatus for warming, drying, or moistening the inhaled air may be interposed at any desired point between the window and the patient.

The compression and rarefaction are made in the respective bellows. The gasometers act, to a certain extent, as reservoirs, but chiefly as intermediate regulating chambers, rising and falling to maintain a constant pressure in exact accordance with the weight placed upon them, and independent of the volume of air inhaled or exhaled, their available capacity being a little more than eight hundred cubic inches.

For purposes of observation, sufficiently accurate for clinical comparisons, though not for physiological data, the air chambers carry a scale of cubic inches, enabling us to see the approximate volume of air inhaled or exhaled at each respiration.

I have yet to describe the stop-cock by which the ingress or egress of air to or from the face-mask or mouth-piece is governed. It is modeled on the cornet-piston, and consists of a central barrel, carrying a hollow cylinder, controlled by a spring, and a horizontal tube, communicating freely with the central barrel. The face-mask or mouth-piece (14, Fig. 1) is connected with the proximal extremity (13) of the horizontal tube; the delivery tube of the compression gasometer (10, 11) with the distal extremity (12). The inner central cylinder contains two, or rather three, perforations. Two of these are opposite to each other, and, when brought in line with the horizontal tube, form with it a continuous channel. In this position air is allowed to pass from the compression apparatus through the mouth-piece or face-mask to the air-passages of the patient. The other perforation has no opposite fellow, and is on the side facing the mask or mouth-piece, so that when it is brought opposite the horizontal tube the air enters from the patient's lungs, and escapes through the inferior opening (15) in the central barrel. If it is desired to have exhalation made into rarefied air, this inferior extremity of the central barrel is connected (16, 17, 18) with the rarefaction gasometer. If the rarefaction apparatus only is to be used, the attachments to the compression gasometer are, of course, omitted.

If it is desired to have the patient exhale into compressed air, instead of connecting the stop-cock with the rarefaction gasometer, we can insert into this lower opening (15) an expiration resistance valve, as made for me by Messrs. Codman and Shurtleff, of Boston, and described in the "New York Medical Journal" for December 3, 1887.

If it is desired to have him inhale rarefied air, instead of connecting the stop-cock with the compressed-air appa-

ratus, we insert into the horizontal tube (12) an inspiration resistance valve.

The "resistance valves," which I have called by that name because they offer a resistance to the passage of air, are simply little cylinders containing ebonite valves controlled by spiral springs. The tension of the spring is regulated by screwing the cap of the cylinder, and a scale engraved upon the side gives its value in fractions of an atmosphere. The expiration valve is arranged to move toward the perforated distal end of the cylinder, thus allowing the expiration current to escape whenever the pressure of the expired air reaches the indicated figure. The valve of the inspiration cylinder is arranged to move from the perforated top of the cylinder, thus allowing the inspiration current to pass toward the patient whenever the rarefaction within the lung reaches the indicated figure. The two valves, suitably mounted in one instrument, may be used independently of the gasometers (Fig. 2).

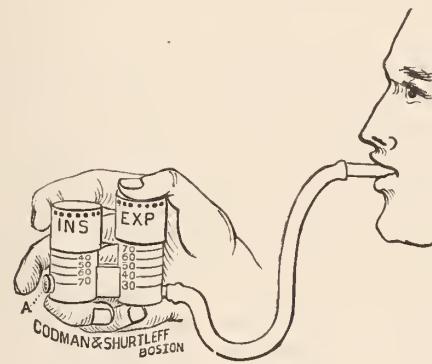

FIG. 2.

Thus, with these two gasometers, the double bellows, and a pair of resistance valves, we are able to obtain the mechanical satisfaction of all the conditions required for any of the following therapeutical expedients:

1. Inhalation of compressed air.
2. Inhalation of rarefied air.
3. Exhalation into compressed air.
4. Exhalation into rarefied air.
5. Inhalation of compressed air with exhalation into compressed air.
6. Inhalation of rarefied air with exhalation into rarefied air.
7. Inhalation of compressed air with exhalation into rarefied air.
