Abstract

Food packaging is an essential part of modern life. Any substances that migrate from packaging material into foods are viewed as indirect food additives. In addition to toxicological knowledge, it is important to know the amount of such indirect food additives expected to be present in the food during storage and processing. This program, sponsored by the Bureau of Foods of the Food and Drug Administration, is designed to provide theoretical models, a reliable data base and methodology for studying migration phenomena and can provide reasonable worst-case estimates for the concentrations of the indirect additives in foods. In this final report, we present the results of approximately 250 completed migration experiments based on radiotracer techniques on the migration of low molecular weight hydrocarbons and antioxidants from polyethylene, polypropylene, and ethylene-vinyl acetate copolymers. Results of a study for the determination of relative diffusion coefficients of several probe molecules in the polyethylene melt by inverse gas chromatography are also presented. Based on these studies, ethanol appears to be a far more reasonable food-oil stimulating solvent than n-heptane. Other pure or mixed triglycerides may also be considered as food-oil simulating solvents, however they may pose the same analytical difficulties associated with the use of the food oils themselves.

Keywords: antioxidants, diffusion, ethylene-vinyl acetate copolymers, food additives, food packaging, inverse gas chromatography, migration, oligomers, polyethylene, polypropylene, radiotracer.

Migration of Low Molecular Weight Additives in Polyolefins and Their Copolymers

List of Tables

I. Introduction

As in the proceeding decades, most foods available today are sold in packaged forms rather than in bulk for reasons of preservation, convenience and ease of distribution. The Bureau of Foods of the Food and Drug Administration has regulatory responsibility for the use of packaging materials in contact with food. Any substances that migrate from the food packaging materials into foods are considered to be indirect food additives. The regulatory decisions on the types of packaging materials suitable for use with various types of foods are based on: the indirect food additives that can be expected to migrate from the package into the food, ones knowledge of toxicology and the expected amount of migration during storage and usage. Since it is impossible to test every conceivable combination of polymer-migrant-food, this program at the National Bureau of Standards, sponsored by the Food and Drug Administration, is aimed at providing sound technical suggestions and reliable data to the Food and Drug Administration, and recommending theoretical or empirical estimation and extrapolation methods to yield at least a reasonable worst-case estimates for regulatory purposes. However, this report represents only the technical opinions of the authors as representatives of the National Bureau of Standards and should not be taken in any way as containing regulatory decisions or recommendations of the Bureau of Foods.

A large number of kinetic experiments were performed involving the migration of radioactive ^{14}C-labeled paraffinic oligomers (n-octadecane and n-dotriacontane) and an antioxidant (butylated-hydroxytoluene) from two different polyethylenes (high density or linear polyethylene and low density or branched polyethylene), isotactic polypropylene and two (ethylene-vinyl acetate) copolymers of relatively low vinyl acetate

content into various solvents including a variety of triglycerides, alcohols, hydrocarbons, and water at temperatures from room temperature to 60°C.

Among the correlations for various parameters, it was found that either the pure triglycerides (e.g. tributyrin and trioctanoin), mixed triglycerides, or anhydrous ethanol may successfully be employed as food-oil simulant in all cases studied. The degree of accelerating action of extracting migrants by n-heptane over that by the food oils is quantified.

Future works in the additive migration program should be mainly in the area of migration of additives from glassy polymers, where the diffusion coefficients are many orders of magnitude slower than those for the amorphous or semi-crystalline polymers above their glass transition temperatures.

Inverse gas chromatography (IGC) studies have been used to determine the relative diffusion coefficients of oligomers and antioxidants in polymers at temperatures above the glass transition region and in the supercooled-liquid or liquid phase. The determinations of the relative diffusion coefficients of several probe molecules in polyethylene are illustrated.

II. Experimental Details of Extraction Experiments

All scheduled experiments on the migration of additives from polyolefins (polyethylenes and polypropylenes) are now completed. In this report we present a complete summary of the polyolefin work, most of which has been reported in previous NBSIRs [1-6] on this subject, therefore, other than necessary descriptions to make this report self-explainatory, detailed discussions on each sub-category will not be repeated here.

As the copolymer work was started in mid-year and was just completed recently, rather detailed descriptions and discussions of it will be given in this report.

Migrations of low molecular weight additives moving from polymeric materials into surrounding liquid media under well stirred conditions were measured in this laboratory for the following combinations of base polymer, migrant, migrant concentration, solvent and temperature:

Polymers	Linear Polyethylene (LPE), SRM 1475
	Branched Polyethylene (BPE), SRM 1476
	Polypropylene (PP)
	Ethylene-5% Vinyl Acetate Copolymer
	Ethylene-13% Vinyl Acetate Copolymer
Migrants	n-Octadecane, n-$C_{18}H_{38}$
	n-Dotriacontane, n-$C_{32}H_{66}$
	BHT or 3,5-di-t-butyl-4-hydroxytoluene
Migrant Concentration	From 30 ppm to 10%
Solvents	Accelerating solvents: n-Heptane, n-Octadecane Fat and Oil Simulating Solvents: Corn Oil, Ethanol, n-Octanol, Tributyrin, Trioctanoin, HB307 Aqueous Solvents: Water, Ethanol-Water Mixtures
Temperatures	24, 30, 40, 60°C

The migrants are radiolabeled by carbon-14. The amount of radioactivity is determined by liquid scintillation counting techniques with detection limit less than 10 pCi.

Materials

The characteristics of the base polymers are listed in Table II-1 and II-2 and those of the base radioactive-labeled migrants are listed in Table II-3.

Sample Plaque Preparation

The following procedure for the mixing of additives in the polymer stock and the molding of the sample plaques was chosen. A large quantity of polyethylene powder stock was prepared from either the National Bureau of Standards-Standard Reference Material (NBS-SRM) 1475 or 1476 pellets by first dissolving it in hot toluene or xylene. Most of the polyethylene precipitates out upon cooling. The precipitate, together with the residue obtained by evaporating the solvent, was dried in a vacuum oven to remove the last trace of solvent.

A specific amount of labeled additive dissolved in a highly volatile solvent is mixed with a quantity of the polyethylene powder stock. The mixture, together with a number of glass beads which act as a ball mill, is then evaporated to dryness in a rotary evaporator under reduced pressure at relatively low temperatures. Further drying is carried out in a vacuum oven.

The mixture is then compression molded in a hydraulic press operated at about 180°C for oligomers and 165°C for BHT. Plaques of 125 mm x 125 mm or less are molded with brass or stainless steel shim stocks of appropriate thickness sandwiched between two sheets of Teflon or Teflon coated plates. Teflon surfaces are used to allow easy removal of the sample plaques without the use of, and subsequent contamination by, mold-release agents.

The isotactic polypropylene and (ethylene-vinyl acetate) copolymers were received in granular form from the suppliers. Therefore, they were used directly to form slurries with the migrants in solution as described above.

Special problems are encountered in the preparation of sample plaques with BHT as an additive. A much longer time is required to mix BHT with polymeric powder in a rotating flask with glass beads acting as a ball mill. Apparently BHT is relatively insoluble in the polymer even in the molten state, therefore, sample plaques made from such insufficiently mixed batches of powder mixtures yield autoradiographs of distinctively sharp regions of streaks and patches. Each molding at 185°C seems to "fix" an additional 15-20% of the available BHT, i.e. only 80% of the avialable BHT before the last molding may be extracted exhaustively even by n-heptane. Only 20% of original amount of BHT can be extracted from plaques remolded five times at 185°C. The residual BHT is combined with the polymer. This residual radioactivity stays in the polymeric precipitate, even after the plaques were dissolved in toluene at high temperatures. However, molding of well mixed batches of BHT and polymeric powder at 165°C seems to result in rather uniformly distributed sample plaques with less than 5% of BHT being combined with the polymer. The final fraction extracted from the original loading, M_f/M_o, by n-heptane, as listed in Tables in Section III, gives an indication of the unreacted fraction of BHT in those samples. Therefore the original loading M_o, is irrelevant and should be replaced by the remaining unreacted amount, M_f, for kinetic and partition calculations. There are further complications due to the volatility of BHT or its degraded components as detailed later in Section II.

Experimental Methods

Two extraction methods were used: (1) continuous extraction into a limited solvent volume and (2) discrete extraction into a simulated infinite solvent volume.

In method (1) an extraction vial of 25 ml volume with a Teflon valved cap is used. The 10 to 15 ml of solvent, in the vial will only contact glass walls and Teflon surfaces during normal experimental processes. A silicone plug is situated above the valve. A small area of the silicone rubber, less than 1 mm in diameter which is used as a septum for the hypodermic needle, is exposed to the solvent vapor. The polymer sample was sometimes surrounded by a nichrome or stainless steel screen to prevent it from sticking to another sample or to the walls, if the sample has lower density than the solvent.

The total amount extracted, at time t, M_t, is the sum of the amount of migrant in the solution at time t plus that were removed in previous aliquots,

$$M_t = C_{st}W_{st} + \sum_{i=1}^{t-1} C_{si}W_{ai}$$

where C_s, W_s and W_a represent the concentration of the migrant, total weight of the solution (including that of the aliquot for the determination of C_{st}) and the weight of the aliquot, respectively. At equilibrium the partition coefficient is estimated as the ratio of the concentrations in solvent and in polymer at equilibrium,

$$k = \frac{C_{s\infty}}{C_{p\infty}} = \frac{C_{s\infty}W_p}{M_o - M_\infty}$$

where M_o is the amount of migrant originally present in the polymer of weight W_p, and M_∞ is the total amount extracted at long times.

In method (2), the polymer sample is immersed in about 10 ml of extracting solvent in a typical 20 ml liquid scintillation counting vial. At specific times the sample is removed from the solvent, rinsed, and placed in another vial with fresh solvent to repeat the extraction process. The rinse is then combined with the previous extracting solvent. The total amount of migrant extracted at time t is simply the sum

of the migrant from all extracts:

$$M_t = \sum_{i=1}^{t} M_i$$

Method (1) is able to yield information about the equilibrium partition coefficient at an infinite extraction time. However, this method suffers from the rigid requirements of knowing accurately the weight or volume ratio of aliquot to total solution and accounting for materials lost during the sampling process for material balance purposes. As the extraction time increases, there is only a very small change in the concentration of extracted material in the solution, whereas the weighing or ratio error may persist. Therefore, the results for method (1) at long times or at high degree of extraction will show considerable scatter.

Method (2) is much simpler in operation, but simulates a condition of migration into infinite media. It is relatively free from aforementioned experimental difficulties. However, it should only be used for convenience where the migrant is highly soluble in or miscible with the solvent and thus the results of method (1) and method (2) are indistinguishable. It can neither be used to generate equilibrium partition information nor migration kinetics for cases where the migrant is sparingly soluble in the solvent.

A method often used in the literature consists of replenishing the amount of solution aliquot removed for testing with the same amount of fresh solvent, to keep the volume of solvent and exposed surface area ratio the same throughout the experiment. This method is a hybrid of method (1) and method (2), and thus suffers from the same drawbacks as those of method (2).

For both methods (1) and (2) mentioned above, the extraction vials are shaken inside a temperature controlled aluminum block on a shaking

table at a rate of about 200 reciprocations per minute.

In order to check the mass balance and variations in the migrant concentration, radioactivity of the residual low molecular weight species remaining in the polymeric sample is monitored by dissolving the sample in toluene at high temperatures after the extraction proceedure is ended. We have found that the single crystals or precipitates of polymer in the counting vial do not interfere with the counting efficiency beyond the normal uncertainty of the counting results.

Experimental Run Designation

The numerical representation of experimental run designations, PPSSTTN, are assigned as follows:

1) Least significant digit(N)--method of observation and repetition number.

2) Tens and Hundreds digits(TT)--temperature in °C.

3) Thousands and Ten Thousands digits(SS)--solvent code.

4) Hundred Thousands and Millions digits(PP)--sample code.

This coding scheme is described in more detail in Table II-4 and II-5.

Estimation of Diffusion Coefficient

One of the widely used solutions for the Fickian diffusion equations solved for the case of diffusion between a plane sheet p of thickness 2ℓ and a stirred liquid s of finite volume V_s, is presented by J. Crank[7]

$$\frac{M_t}{M_\infty} = 1 - \sum_{n=1}^{\infty} \frac{2\alpha(1+\alpha)}{1+\alpha+\alpha^2 q_n^2} \exp(-q_n^2 T) \qquad (1)$$

The solution for the non-zero positive roots, q_n, of

$$\tan q_n = -\alpha q_n$$

lies between $n\pi$ when $\alpha=0$ and $(n-1/2)\pi$ when $\alpha=\infty$. At $\alpha \ll 1$,

$$q_n \sim n/(1+\alpha).$$

For other values of α,

$$q_n \sim [n - \alpha/2(1+\alpha)]\pi$$

may be used as the starting value in a reiterative numerical computation.

Equation (1) converges rather slowly, at small value of T, thus a sufficient number of terms must be used to avoid premature termination of the computation. At $T << 1$, approximately $3^{(-\log_{10}T)}$ terms are required to reach a reasonable precision. The following approaches may be used to simplify the computational effort depending on the conditions and ranges of applications.

Simplified Computation

At small values of $\alpha(<<1)$, a master curve of the quantity $M_t/(1+\alpha)M_\infty$, which is equal to M_{pt}/M_{so} for absorption or $M_{st}/\alpha M_{po}$ for extraction, as a function of T/α^2 may be constructed from equation (1). However, by limiting the computations to $0.1>T>0.001$, the number of terms required may be limited to about 5 at $T\sim0.1$ and about 45 at $T\sim0.001$ for reasonable accuracy. The values of $M_t/(1+\alpha)M_\infty$ at small α, but at the same T/α^2, are equal to the values calculated for large α. The results of this selective computation deviates from the more rigorous and tedious computations by about 0.001% at $T\sim0.1$, and much less than 0.001% at lower T values.

The diffusion process may be divided into three regions of T:

Region I, $T<0.1$. The system is far from equilibrium, $M_t/(1+\alpha)M_\infty$ is a function of T/α^2 only.

Region II, $5>T>0.1$. The system is approaching equilibrium and detailed computation must be carried out for different α values (only 2 to 6 terms are required for equation (1) in this region). For $\alpha<<1$ and $T/\alpha^2>10^3$, $M_t/(1+\alpha)M_\infty = 1 - \alpha/(\pi T)^{1/2}$ before reaching equilibrium.

Region III, $T>5$. For all practical purposes, equilibrium has been reached with the deviation $\delta = 1-M_t/M_\infty \leq 10^{-T}$, where $M_\infty = M_{so}/(1+\alpha)$ for

the case of absorption and $M_\infty = M_{po}\alpha/(1+\alpha)$ for the case of extraction. For $\alpha<1$, equilibrium may be reached much earlier.

Computation for Migration into Infinite Media

When $\alpha\to\infty$, M_t/M_∞ approaches a limit, and equation (1) can be reduced to a function of T only:

$$M_t/M_\infty = 1 - 2 \sum_{n=1}^{\infty} \frac{1}{q_n^2} \exp(-q_n^2 T) \qquad (2)$$

where $q_n = (n-1/2)\pi$. For $T<0.1$, M_t/M_∞ is a linear function of $T^{1/2}$.

$$M_t/M_\infty = 2(T/\pi)^{1/2} = 1.128379\ T^{1/2} \qquad (3)$$

Deviations of equation (3) from equation (2) is less than 10^{-10} at $T<0.05$, about 10^{-6} at $T = 0.1$, about 5×10^{-4} at $T = 0.2$ and becomes much greater than 0.01 at $T = 0.3$ or higher.

Alternate Approximation

An alternative form of the solution[7]

$$M_t/M_\infty = (1+\alpha)\ [1 - e^{T/\alpha^2}\ \mathrm{erfc}(T^{1/2}/\alpha)], \qquad (4)$$

may be used in some cases and is relatively simple to compute. One of the rational approximations[8] for the error function yields the following

$$M_t/(1+\alpha)M_\infty = 1 - \sum_{n=1}^{5} a_n \tau^n + \varepsilon \qquad (5)$$

where $\tau=1/(1+0.3275911\ T^{1/2}/\alpha)$, $a_1=0.254829592$, $a_2=-0.28449636$, $a_3=1.42141374$, $a_4=-1.453152027$, $a_5=1.061405429$, and $|\varepsilon|<\omega 1.5 \times 10^{-7}$.

At $\alpha<<1$, results computed from equation (2) or (3) deviates less than 0.0001 from that of equation (1) at $T/\alpha^2<5$ or at $M_t/(1+\alpha)M_\infty<0.75$. Maximum deviation of 0.0035 occurs at $T/\alpha^2\sim500$ or at $M_t/(1+\alpha)M_\infty\sim0.97$. Therefore, equation (4) or (5) may be used to generate the master curve for equation (1) at $T<0.1$ (Region I). However equations (4) or (5) do not yeild any information about the region approaching equilbrium at larger values of α, and hence should be used with discretion.

By combining Equation (4) or (5) at T<0.1 (Region I) and Equation (1) at T>0.1 (Region II and III), computational requirements for the solution of the diffusion equation between a plane sheet and a well stirred liquid may be reduced to a minimum.

Diffusion coefficient at any point may be estimated from the above computation method by means of regression.

Effect of Swelling

The diffusion coefficients in the tables are calculated based on the original measured thickness of the sample, which is also given in the tables. The final sample is usually swollen with solvent. For volatile solvents, the absorbed solvent will leave the polymer soon after the sample is taken out of the extracting solvent. In these cases, the final sample weight is determined immediately after the surface of sample has been wiped free of the solvent. The dimensions of the final sample are generally not measured, however they may be estimated from the amount of solvent absorption by assuming an isotropic expansion. The diffusion coefficient may be adjusted to reflect the increase in the thickness as follows:

$$D = D_o \left(\frac{L}{L_o}\right)^2 = D_o \left(\frac{V}{V_o}\right)^{2/3}$$
$$= D_o \left[1 + \frac{\delta_f}{1-\delta_f} \cdot \frac{\rho_o}{\rho_s}\right]^{2/3}$$

where $\delta_f = (W_f - W_o)/W_f$. D, L, V, M and p are the diffusion coefficient, thickness, volume, weight and density respectively. The subscripts o, f, and s denote the original polymer, final polymer and solvent respectively. The sum of fractional weight increase δ_f and the fractional decrease in weight due to the migrant loss is given also in the table and indicates the weight percent of solvent content in the final sample. Therefore, the diffusion coefficients based on the final sample thickness

are increased from those based on the original thickness by approximately the same order of magnitude as the increases in weight.

III. Results of Polyolefin Extraction Experiments

The results of extraction experiments are summarized in Table III.1 through III.3 for the extraction of n-octadecane, n-dotriacontane and BHT by triglycerides, ethanol, n-octanol, ethanol/water mixtures, n-heptane, n-octadecane, and water.

The tables provide information on the test pieces as to their weight, thickness L, exposed area A, specific activity of polymer, amount extracted at the end of experiment M_f/M_o, the amount of solvent retained in the final sample and the observed maximum of the diffusion coefficient.

The value for M_f/M_o in the tables is the final fraction of total additives migrated at the end of the experiment. It may be either an equilibrium value or a non-equilibrium value after a long time (6 months to one year) lapse. In the case of BHT experiments, most of the M_f values for migration into good solvents denote the available fraction of BHT in the sample, which varies with the conditions underwhich the sample was prepared. Therefore, in calculating diffusion coefficients for samples containing BHT, an adjusted M_o is assigned to each sample according to the equilibrium (M_f/M_o) values observed in the good solvents. For the case of n-$C_{32}H_{66}$ in polypropylene or other samples which exhibit surface blooming of migrants, the total amount of migrant is also adjusted for the amount of migrant on the surface, before diffusion coefficients calculating from it.

Tables III-1 through III-3 summarize the experimental results arranged by migrant or additive and then according to the type of polymer, additive concentration, sample thickness, and, finally, solvents and temperature. In order to provide easy cross-references, Tables III-4

through III-6 summarize the experimental results which are arranged first by solvent and then by additive and other parameters.

The activation energies, E, calculated by a simple Arrhenius equation:

$$D = A \exp(-E/RT)$$

are given in Table III-7.

IV. Loss of BHT from Polymers in Ambient Atmosphere

ADL, Inc. had reported through private communications concerning the high volatility of BHT from their samples. When we examined our observed total BHT contents from various experiments over a 1 1/2 year period on a branched polyethylene sample, code 25, containing 45 ppm of BHT, we found a rather noticeable trend of decreasing radioactivities as a function of starting date of the experiment, Figure IV-1, although the sample plaque was always wrapped in aluminum foil except during short periods when pieces were cut from the plaque.

The volatility of BHT is further indicated by the following experiment. A piece of E-13% VA copolymer containing 60 ppm of BHT (sample code 32), 61 mg in weight with about 2 cm^2 of surface area, was placed in a sealed 20 ml vial. The bottom of the vial was kept at 30°C and the vial cap at 22-23°C. After 63 hours it was found that the aluminum cap liner had a radioactivity of 0.51% of the test piece and the glass wall of the vial had a radioactivity of 0.95% of the test piece. Thus in a relatively short period, 1.5% of the BHT was sublimed from the test piece at rather low temperatures in a closed vessel.

A further test was performed on both sample plaques 25 and 32. Four pieces were cut from each of the sample plaques. These four pieces were subjected to the following tests:

(A) The test piece was dissolved in o-xylene to check the current specific activity.

(B) The test piece was extracted immediately by ethanol at 60°C for three days. The residual specific activity and the activity of the extract were recorded.

(C) The test piece was suspended in a ventilation hood at room temperature for three days before procedure (B) was performed.

(D) The test piece was placed in a vial. Forced air was blown into the vial for three days at room temperature before procedure (B) was performed.

The results of these tests are presented in Table II-1. The test pieces A and B were used as controls. Apparently 30 to 50% BHT is lost from thin sheets of BPE or E-VA copolymer in mobile air at room temperature for three days. The specific activity of sample code 25, BHT in BPE, at the time of these tests was only 50% of the original specific activity of 2.8 μCi/g polymer, determined 16 months earlier.

These experiments and our prior experience indicate that: (1) the amount of additive remaining in the polymer after processing to produce plaques is a fraction of the additive mixed into the raw polymer, (2) for certain reactive additives, only a fraction of additive in the polymer may be extractable, the rest may be chemically bound to the polymer, (3) the total activity of the test pieces should be checked for each experiment not only to measure the uniformity of the additive concentration but also to measure the change in additive content as a function of time. Therefore reports which the results are normalized to the amount of additive supposely added to the polymer or to the total amount of additive present in the polymer when it was manufactured, without paying further attention to the amount of additive either reacted or lost, may yield seriously incorrect kinetics of migration.

Table IV-1

Sample Code	Test Piece	Specific Activities, μCi/g polymer Residue	Total	Percent of Original Activity (Average of A + B)
25 BHT in BPE	A	--	1.28	100
	B	0.042	1.30	100
	C	0.053	.93	72
	D	0.052	.89	69
32 BHT in E-13% VA	A	--	3.29	100
	B	0.077	3.45	100
	C	0.081	2.18	65
	D	0.068	1.49	44

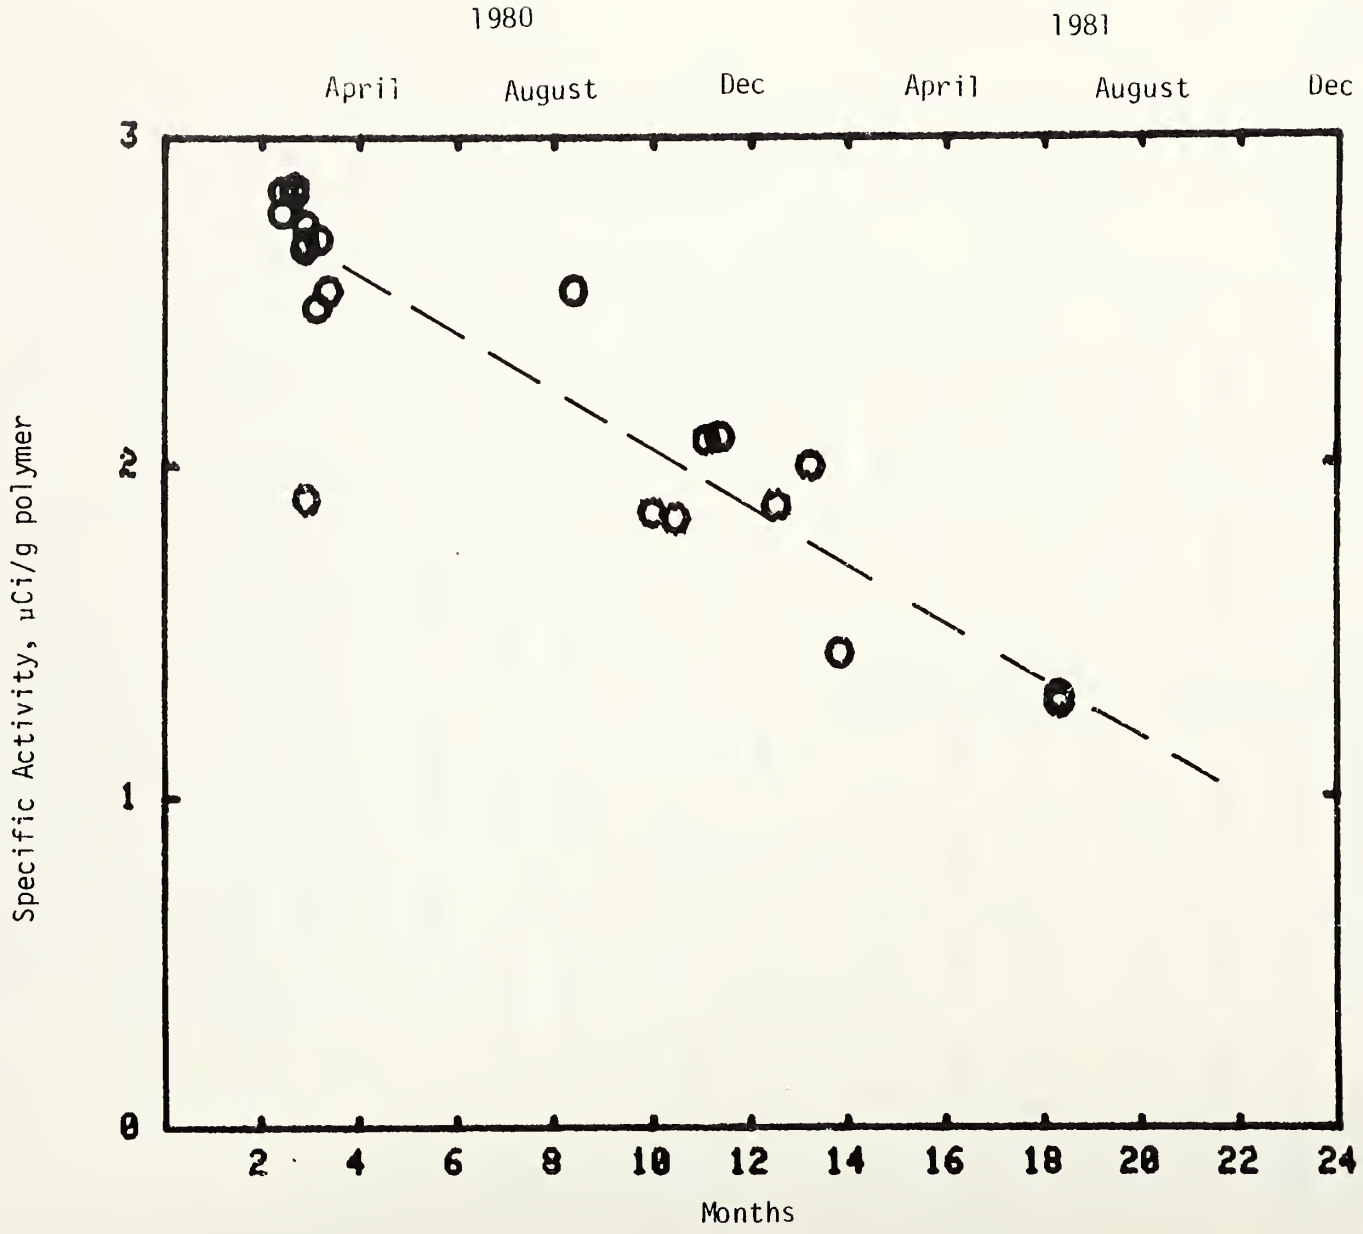

Figure IV-1

Loss of BHT from Sample 25, BHT/BPE

V. Migration of BHT from Ethylene-Vinyl Acetate Copolymers

Ethylene-vinyl acetate (E-VA) copolymers of relatively low vinyl acetate contents have been used in increasing quantities in recent years as food-contact polymer films. The migration of the antioxidant BHT from two copolymers having 5 and 13% vinyl acetate content into corn oil, anhydrous ethanol, 95% ethanol, water and n-heptane was observed with ^{14}C-labeled BHT. The characteristics of these polymers were shown earlier in Table I-2. The characteristics of the additive BHT were presented earlier in Table I-3. The sample plaques were prepared in similar manner to those of polyethylene and polypropylene samples described earlier, except that lower molding temperatures were used for the E-VA copolymers. The E-5% VA and E-13% VA samples were designated as plaque 31 and 32 with thickness of 0.027 and 0.068 cm and BHT contents of 9 and 57 PPM, respectively.

The results for individual extraction experiments are summarized in Table V-1. E-VA copolymers absorb a fair amount of solvents as shown in the table. The listed values are fractional weights of solvent contained in the final sample. Thus for experiment 3230600, the final sample contained n-heptane amounting to about 120% of the original weight of the polymer. The 12% corn oil content for sample 3210600 is higher than all other corn oil experiments.

The results of all extraction experiments for individual E-VA copolymers are shown graphically in Figures V-1.1 through V-1.4 for the migration of BHT from E-5% VA at 30 and 60°C, and from E-13% VA at 30 and 60°C, respectively. There are three illustrations for each figure, i.e., (A) M_t/M_o is plotted against t/L^2 in a log-log plot to indicate the migration behavior over several orders of magnitudes in both M_t/M_o and time, (B) M_t/M_o is plotted against $t^{1/2}/L$ for the short time region

to indicate the behavior observed during fast extractions, and (C) M_t/M_o is plotted against $t^{1/2}/L$ for the entire length of time of experiments.

From both Tables V-1 and Figures V-1, the residual BHT content in the 5% vinyl acetate copolymer samples, code 31, at the end of extration are seen to vary from 7 to 12%. It is estimated from graphical extrapolation that approximately 7-8% of the original BHT content is not extractable even by good solvents, such as n-heptane. Almost all of the BHT content in the 13% vinyl acetate copolymer is extractable. The 5% water content in 95% ethanol has no noticeable effect on the BHT extractability for the copolymers. No partitioning of BHT was observed between the copolymers and solvents such as n-heptane, corn oil, anhydrous ethanol and 95% ethanol, due to the near-complete of extraction of all available BHT from the copolymers by these solvents.

Figures V-2.1 through 5 show the migrational behavior of BHT from E-VA copolymers into various solvents, n-heptane, corn oil, ethanol, 95% ethanol and water. These illustrations offer comparisons of behavior among different E-VA copolymers and/or at different temperatures of extraction.

In a more concise comparison of this behavior, the apparent maximum diffusion coefficients of the swollen polymers are listed in Table V-2 together with the activation energies for diffusion. In all cases except water, the diffusion coefficient for the 13% vinyl acetate copolymer is about 2 to 3 times greater than that for the 5% copolymer. Increasing in the temperature from 30 to 60°C generally increases the diffusion coefficient by 10 to 20 fold, although the changes for the solvent n-heptane are only on order of 4 to 6.

The diffusion coefficients in 95% ethanol are only slightly less than those for anhydrous ethanol, about 10-15% less for 5% vinyl acetate copolymers and about 25-45% less for 13% copolymer. Both diffusion

coefficients for experiments in anhydrous ethanol and 95% ethanol are greater than those for corn oil by similar magnitudes.

The migrational behavior of BHT from the two E-VA copolymer into water is rather unusual, as can be seen in figure V-2.5. The log (M_t/M_o) versus log (t/L^2) representation in Figure V-2.5 is changed for Figures V-3.B and V-3-C into the more familiar M_t/M_o versus $t^{1/2}$ representation. Figure V-3-B is the short-time portion of Figure V-3-C which covered the entire time scale of experiment. These results indicate that the migration of BHT from E-VA copolymer into water occurs in two distinct stages, and that in contrast to the observations for other solvents, the diffusion coefficients of BHT from E-13% VA copolymer are slower than those from E-5% VA copolymer in the first stage. In the second stage the diffusion coefficients from E-13% VA are apparently approaching those from E-5% VA and can even surpass the latter when the time of experiment is lengthened to allow equilibrium extraction.

In the first stage, 10-50 hours, approximately 15% of the BHT from E-5% VA copolymer and about 1% of the BHT for E-13% VA copolymer, were extracted by water before the release of BHT levels off into a second stage behavior. It has not been determined whether the second stage of extraction, with its distinctly different diffusion coefficient, is due to the distribution of BHT in phase-separated regions of the copolymers or due to the reaction of water and BHT over prolonged periods.

Another plausible explantion for the two stage behavior would be surface blooming, or a very high migrant concentration near the surface layer, although the time lapse of 10 to 50 hours seems to be longer than usually needed to remove migrant from the surface or surface layer. By extending the second stage behavior to t=0, one may estimate from

Figure V-3-B that there might exist surface blooming of BHT amounts to about 7.5 and 11% for the E-5% VA copolymer and 0.6 and 0.57% for the E-13% VA copolymer, for 30 and 60°C experiments, respectively.

The diffusion coefficients presented in Table V-2 were calculated by first adjusting the original loading, M_0, to the available BHT, M_0^*, when necessary. The first stage diffusion coefficients were calculated based on the above mentioned percentages for M_∞/M_0^*. By substracting the first stage M_∞, normalizing and then applying equilibrium partitioning when applicable, the second stage difficient coefficients were estimated.

Equilibrium partitioning of BHT between the copolymers and solvents was observed only for the case of E-5% VA and water at 60°C. In all other experiments with water, a time lapse of six months was not long enough to establish an equilibrium conditions.

VI. IGC Determinations of the Relative Diffusion Coefficients of Several Probes in Linear Polyethylene

Inverse gas chromatography (IGC) studies on the determination of diffusion constants in polyethylene were reported in the previous annual report [1]. These findings indicate that while accurate absolute diffusivity measurements seem beyond the reach of the IGC method, the possibility exists for using the technique to rank the relative ease of diffusion of many probes in a given polymer. A calibration of a specific column can be accomplished by conducting experiments with a probe-polymer combination of known diffusivity to calculate the mean polymer layer thickness from the measured peak broadening. The same column can then be used under similar operating conditions to determine other probe diffusivities and a relative ranking of many probe diffusion coefficients can be established. Experiments on several series of compounds have been conducted and those for which the data analysis and reduction have been completed will be used to illustrate the procedure of relative diffusivity determinations. Preceding this discussion, however, will be: a review of the theory for determining absolute diffusion constants from IGC studies, a summary of results from polyethylene-octadecane experiments to be used in the relative diffusivity determinations, and a section giving experimental details on the relative diffusivity measurements.

A Review of Pertinent Theory for IGC Absolute Diffusivity Determinations

The probe or migrant injected onto a chromatographic column resides partly in the carrier gas and partially in the polymer or stationary phase during transit through the column. Diffusion of the probe vapor in the gas phase can occur parallel to the background flow of carrier gas sweeping the vapor through the column both in the direction of and opposed to the carrier flow. This longitudinal or axial gaseous diffusion process causes an increase

in width of the eluted peak over its initial injection distribution. An additional gas phase peak spreading mechanism originates in the multiplicity of path lengths possible around the packed support particles and leads to an associated broadened distribution of elution times. Peak spreading can also be attributed to diffusive processes in the stationary phase. If the carrier gas flow rate is very rapid, steady-state partitioning of the vapor between the gas and stationary phases cannot be established. The residence time in the stationary polymer phase is then influenced by both the diffusivity of the probe in the polymer and the distance in the stationary phase over which diffusion must occur, among other factors. The peak broadening processes discussed above are commonly quantified by the convenient construct of the height equivalent to a theoretical plate, H, which is related to the width at half-height, $w_{1/2}$, for an eluted Gaussian-shaped peak as follows:

$$H = \frac{L}{8 \ln(2)} \left(\frac{w_{1/2}}{t_R} \right)^2 \qquad (1)$$

where L is the column length, and t_R the retention time of the peak at the maximum. The determination of these quantities from a Gaussian-shaped experimental chromatogram with a peak standard deviation of σ is illustrated in the schematic of Figure VI-1.

An equation attributed to van Deemter et al. [2] is often used to relate H to the local carrier gas flow velocity, u, and is of the form:

$$H = A + B/u + Cu \qquad (2)$$

The A term arises from the number of possible gas paths through the column; B is from longitudinal diffusion of the probe in the carrier gas; and C originates from the resistance to mass transfer in the polymer or stationary

phase. The coefficients in equation 2 are defined as follows:

$$A = 4\lambda r \tag{3}$$

$$B = 2\gamma D_g \tag{4}$$

$$C = \frac{8\ s^2 k}{\pi^2\ D_s (1 + k)^2} \tag{5}$$

where λ is a measure of support packing irregularities, r the average support particle radius, γ a correction coefficient for constriction and tortuosity of the gas flow path in the column, D_g the probe diffusivity in the gas phase, s the effective thickness of the stationary phase film, D_s the diffusivity of the probe in the stationary phase, and k the column capacity factor commonly given as:

$$k = \frac{t_R - t_M}{t_M} \tag{6}$$

where t_M is the time taken to elute an unsorbed marker material from the column. Equation 2 indicates that, at large values of the flow rate, H will be proportional to the flow rate. The probe-polymer diffusion coefficient can then be determined from the constant of proportionality C by equation 5 if the effective film thickness is known. Equation 5 is not applicable for columns packed with glass bead support particles. In such cases of diffusion into a uniform stationary phase film on a solid surface, a similar relation for C applies:

$$C = \frac{2\ s^2 k}{3\ D_s (1 + k)^2} \tag{7}$$

While equation 2 gives a suitable explanation of peak spreading in some cases, other results have raised questions about its utility, particularly when significant gas phase diffusion can occur. These discrepancies indicate that the simplifications made by van Deemter in neglecting other mechanisms of diffusion are not valid for all systems. Giddings and coworkers [3] examined several modified forms of the van Deemter equation and found that none could account for the experimental results obtained on columns of varying length and outlet pressure.

An equation proposed by Jones [4] takes several additional sources of peak spreading into consideration: resistance to mass transfer in the gas phase normal to the carrier gas flow direction (D), carrier gas velocity distribution effects (E), and a correlation between these two processes (F). This equation is given as:

$$H = A + B/u + (C + D + E + F)u \tag{8}$$

where C is as in equation 7 and

$$D = \frac{C_D\, k^2\, g^2}{D_g(1 + k)^2} \tag{9}$$

$$E = \frac{4C_E\, r^2}{D_g} \tag{10}$$

$$F = \frac{4\theta(C_D C_E)^{1/2}\, k\, r\, g}{D_g(1 + k)} \tag{11}$$

g being the diffusion path length in the gas, θ the correlation coefficient between the D and E terms, and C_D and C_E geometric constants.

The radial diffusion D term was discounted by van Deemter and co-workers in the derivation of equation 2 because of the much greater magnitude of D_g compared to D_s. This simplification is valid for the thick liquid films used in their work, studies of columns with roughly 0.3 mass fraction stationary phase loading. The diffusion distances s and g are roughly comparable under these circumstances. If low column loadings which reduce s to about 0.01g are used, then the much larger probe diffusivity in the gas phase is overcome by the ease of mass transfer through the thinly-spread liquid phase and the D term cannot be ignored.

The E contribution to spreading arises from diffusion caused by differences in the velocity of the carrier gas in various parts of the column. Velocity differences can arise from both short and longer range channels formed by support packing irregularities and from trans-column effects caused by the influence of the tube walls. These effects are summarized by Giddings [5] who estimates approximate magnitudes for contributions of the many possible velocity gradients combined in the E term of equation 8.

While the first three terms in equation 8 are independent of one another, the D and E terms are not since molecules which have a lower average velocity will spend a smaller fraction of time in the gas phase and therefore not experience as great a percentage of gaseous diffusion as molecules with higher than average velocity. The total variance, σ_{ij}^2, of two such dependent contributors, σ_i^2 and σ_j^2, is given as:

$$\sigma_{ij}^2 = \sigma_i^2 + \sigma_j^2 + 2\theta_{ij}\sigma_i\sigma_j \qquad (12)$$

where the correlation coefficient between the two contributors is denoted as θ. The F term of equation 11 originates from the final term in the above relation and corresponds to the interaction between the D and E terms.

Giddings [6] has given an expression said to account for all known plate height terms contributing at least one percent of the total plate height for packed GC columns in the absence of interfacial adsorption as:

$$H = \sum_i \frac{1}{1/A_i + 1/E_i u} + \frac{B}{u} + \sum_i C_i u + Du + G \qquad (13)$$

The G term represents the contribution of column-wide velocity inequality effects, such as that arising from column coiling, and could alternatively be included in E. This equation is otherwise similar to equation 8 except for its omission of the interaction term F. A compilation of the C, D, and E coefficients expected to apply in various situations and a means of calculating their magnitude from measurable column parameters is given in reference [5].

The plate height equations discussed up to this point apply only to the peak spreading in a short region of the chromatographic column where the carrier velocity u is a constant local to that region. A final modification can be made to equation 8 or 13 to account for the variation in local carrier velocity along the column caused by the drop in pressure from column inlet to outlet. The effect of this correction is primarily on the liquid mass transfer term, as discussed by Dal Nogare and Juvet [7]. The final expression for the dependence of the experimentally accessible column average plate height, $\bar{H}$, on the carrier gas outlet velocity, u_o, is similar to equation 8 and is given as:

$$\bar{H} = A + \frac{B}{u_o} + \left(\frac{2p_o C}{p_i + p_o} + D + E + F + G \right) u_o \qquad (14)$$

where p_i and p_o are the column inlet and outlet pressure. The gas phase diffusivity found in equations 4, 9, 10, and 11 must also be restated at the outlet pressure of the column. The form of this modification is based on the relationship between the local column velocity and the average carrier gas velocity. The preceeding treatment assumes a distance average of this velocity. Other methods [3] involve the use of a pressure average velocity and yield a slightly different equation for $\bar{H}$ but agree reasonably well with equation 14 even at large values of the inlet pressure.

The magnitudes of coefficients in equation 14 and the configuration of the polymer film on the surface of the supporting beads can have a significant influence on the methods used in interpreting data derived from IGC determinations of diffusive peak broadening as discussed in the previous annual report. These effects will be reviewed briefly for the experimental determination of the diffusivity of normal octadecane in high density polyethylene considered there.

Summary of Previous Results for LPE-Octadecane

As discussed earlier, IGC determinations of diffusivity in the polymer phase are made from a study of probe peak broadening at varying carrier gas velocities; a schematic illustration of the results is shown in Figure VI-2. The local plate height and carrier velocity of equation 2 are commonly replaced by the measured average quantities in experimental determinations of column efficiency. Such $\bar{H}$ vs $\bar{u}$ plots for eight flow velocities in the flow rate region from about 10 to 100 cm/s yielded a slope C for column A of 7.05 ms with calculated standard deviation of 8.8 percent and 18.9 ms with calculated standard deviation of 7.4 percent for B. The van Deemter treatment provides for the calculation of the diffusivity of C_{18} in linear

polyethylene from these C values by equation 7 when the polymer film thickness in each column is known. Such a procedure is proper only if the other contributions to peak spreading discussed earlier are small when compared to that arising from polymer or stationary phase mass transfer. This assumption has been made in many previous studies of probe-polymer diffusion. However, if the other gas phase kinetic processes are operating to a significant extent then the limiting slope at high flow rate of Figure VI-1 should also reflect these contributions, as indicated by equations 8 and 14. It was important, therefore, to estimate the relative magnitude of the gas phase terms as compared to the stationary phase contribution to determine if such a simplified data analysis procedure could be applicable.

A further consideration is the nature of the carrier velocity on which the plate height depends. Equation 14 indicates that while the plate height contribution of the B, D, E, and F terms are directly or inversely proportional to the carrier outlet velocity u_o, the C term contribution to $\bar{H}$ depends on the average velocity. Consequently, the often-employed plot of $\bar{H}$ vs average carrier velocity suggested by equation 2 will not be linear at high flow velocity for any variant of velocity if both stationary and gas phase mass transfer effects are nonnegligible.

The estimated gas phase contributions to peak spreading were computed for both columns and compared to the limiting slope C calculated from the van Deemter equation least squares fit. It was evident that the peak spreading attributed to gas phase diffusion made a significant contribution to the overall kinetic broadening for column A. In instances of this nature, where gas phase diffusion terms make a significant contribution to peak spreading, difficulty can be encountered in deciding which are important and calculating their values. Alternatively, it is possible to resolve the gas and stationary

phase mass transfer contributions without directly estimating the magnitude of the gas phase terms. Purnell [8] has suggested a method which involves first determining A and B of equation 14 and employing these values to reduce the experimental $\bar{H}$ to the peak spreading arising only from mass transfer effects, $\bar{H}'$. In terms of an equation:

$$\bar{H}'/u_o = \left(\bar{H} - A - \frac{B}{u_o} \right) \Big/ u_o = \frac{2p_o}{p_i + p_o} C + D + E + F + G \qquad (15)$$

When the left-hand side of this equation is plotted against the pressure correction $2p_o/(p_i + p_o)$, a straight line with slope C and intercept (D + E + F + G) should be obtained. Evaluation of the constants A and B requires that experiments be conducted over a wide range of carrier gas flow velocities. Limited low velocity data often precludes experimental determination of these constants in many cases; however, they can be estimated from theoretical considerations and experimental results. The multipath A term defined in equation 3 has been determined to have a λ value between one half and unity in many cases [9] and a value of 0.5 was assumed here. The longitudinal diffusion B term most often has a γ value near one [9] and unity was utilized in the determinations. These values were used to calculate the A and B terms of equation 19 and a fit of $\bar{H}'/u_o$ against the pressure correction term gave a linear least squares line with a slope of 16.4 ms and calculated standard deviation of 5.5 percent for column A and 21.9 ms with calculated standard deviation of 6.6 percent for B. These results are compared to the van Deemter fit slopes in Table VI-1 on the following page. The smaller standard deviations of the Purnell method slopes compared to the corresponding values for the van Deemter fit discussed earlier indicated the better applicability of the Purnell method. The C value obtained by this method for column A was more

Table VI-1

Comparison of the C Coefficient Determined by Two Methods for LPE-Octadecane at 150 °C

Column Code	Column Loading (Mass Fraction Polymer)	$C_{van\ Deemter}$ (Eq. 2)	$C_{Purnell}$ (Eq. 15)
A	6.10×10^{-4}	7.05 ms	16.4 ms
B	5.71×10^{-3}	18.9 ms	21.9 ms

than twice that obtained from the van Deemter analysis. This was attributed to the latter's combination of the effects of polymer and gas phase mass transfer in a nonlinear manner, which can be noted by comparing the C term appearing in equation 2 to its complement in equation 14, the expression in parenthesis. For the case of column A where the gas phase terms contributed significantly to the peak broadening, the van Deemter equation-based analysis underestimated the magnitude of C. Gas phase mass transfer effects for column B contributed only slightly to the total broadening and this was reflected in the similar results of the two methods for determining C which differed by only 15 percent, as indicated in Table VI-1.

While the method of determining the polymer phase mass transfer contribution can be important under certain column conditions, the most significant parameter which affected the diffusivity determination was the distance over which diffusion occurred. This distance is commonly identified with the effective film thickness s of equation 7. It is often assumed that the stationary phase is distributed as a uniform thin film over the entire surface of the spherical glass bead column packing. The effective film thickness for this geometry can be calculated from the expression:

$$s = \frac{M_s}{4\pi r^2 N \rho_s} \qquad (16)$$

where M_s is the mass of polymer phase in the column, N the number of support particles in the column, and ρ_s the polymer density. Such a configuration requires a high amount of stationary phase surface area, however, and a geometry in which the stationary phase is confined by capillary forces into annular regions around the contact points between support particle spheres has been advocated as a means of minimizing the exposed stationary phase surface area. This geometry has been observed for both low molecular weight [6] and polymeric [10] stationary phases coated onto glass bead supports and is illustrated schematically in Figure VI-3. A stationary phase film may also be present on surfaces where the beads are not in contact, as indicated in the inset. Its thickness, however, should be much less than that of the stationary phase in the region of adjacent support beads.

The different diffusion path lengths expected for the two extremely different polymer distributions described above can exert a significant influence on determinations of polymer-probe diffusivity by IGC. Giddings [11] has compared the contribution to peak spreading expected from a hypothetical support coated with two regions, a thin film of uniformly adsorbed stationary phase and a second region where the liquid stationary phase collects at the support contact points. He concludes that for glass bead supports at mass fraction loadings up to about 0.015, the bulk of the stationary phase is present at the bead contact points and controls the plate height performance by virtue of its greater thickness. An equation has been proposed [12] to relate C to measurable column parameters for this geometry and is as follows:

$$C = \frac{r^2 k}{3\, D_s (1 + k)^2} \left(\frac{m_s \rho}{18.75 \rho_s} \right)^{1/2} \qquad (17)$$

where ρ is the density of the support particles and m_s the mass fraction of polymer phase in the column. This treatment assumes that the spherical support particles pack randomly and are surrounded by 6.25 nearest neighbors. The relation for C is similar in form to equation 7. If the differing variables are combined into an explicit expression for s in terms of the particle size, the following relation is obtained:

$$s = \left(\frac{m_s \rho}{18.75 \rho_s} \right)^{1/4} \frac{r}{2\sqrt{5}} \qquad (18)$$

This equation provides for the calculation of a value of s which, when substituted into equation 7, yields a result for C identical to the C term determined by equation 17.

A computation of s by these methods was useful for comparing the effective film thicknesses of the two stationary phase arrangements considered. The average film thicknesses calculated in the above manner for a polymer stationary phase collected at bead contact points were much greater than the thicknesses corresponding to the uniform layer geometry, as can be noted from the following table.

Table VI-2

Effective Layer Thicknesses for Columns with Differing Polymer Phase Geometry

Column Code	Effective Layer Thickness, s(μm)	
	Uniform Thin Surface Film (Eq. 16)	Annular Film at Contact Points (Eq. 18)
A	0.043	5.58
B	0.404	9.77

Both equations 7 and 17 were used to calcualte the diffusion coefficient of octadecane in HDPE. For column A assuming a thin uniform film, D_s was calculated from the C coefficient obtained with the Purnell treatment by substituting equation 16 into equation 7; a result of 3.8×10^{-11} cm^2/s was obtained. Assuming a geometry where the polymer collects at the bead contact points for column A, D_s was calculated according to equation 17 and a value of 6.4×10^{-7} cm^2/s determined. These results and the corresponding values for column B are summarized in Table VI-3 below.

Table VI-3

Influence of Film Geometry on the Diffusion Coefficient of Octadecane in Linear Polyethylene at 150 °C

Column Code	Diffusion Coefficient ($cm^2 \cdot s^{-1}$) Uniform Thin Surface Film (Eqs. 7 and 16)	Annular Film at Contact Points (Eq. 17)
A	3.8×10^{-11}	6.4×10^{-7}
B	4.1×10^{-10}	2.4×10^{-7}

It was evident that the uniform thin film geometry assumption led to unreasonably low values of the diffusion coefficient. In addition, an order of magnitude discrepancy existed between results for the two columns. The assumption of a collection of the polymer stationary phase at bead contact points yielded diffusion coefficients of reasonable magnitude for the temperature of the experiment and column-to-column agreement within a factor of three. This threefold difference in the diffusivity results may be attributed to the effects of differing probe concentrations in the polymer phase of the two columns.

Diffusivity values are often quite sensitive to the concentration of the diffusing species, depending approximately either linearly or exponentially

on concentration [13]. In these IGC determinations the probe concentration in the polymer film varied both along the column length due to increasing peak broadening with transit time and with the depth of penetration into the polymer film expected from Fickean diffusion. The diffusivity determined was therefore a concentration-averaged value over all column conditions. The actual concentration of octadecane in the polyethylene film was estimated to range from 0.01 to 1.5 percent by mass for column A and from 0.001 to 0.16 percent by mass for column B. The diffusion coefficient calculated from the column B results corresponded to probe concentrations about an order of magnitude lower than for column A. This could account for the lower value of probe diffusivity determined with column B. For either a linear or exponential dependence of the diffusion coefficient on concentration, the diffusivity should be less at lower diffusant concentrations, as found here. A determination of the functional relationship of the diffusivity on diffusant concentration was not possible, however, because of the variation in probe concentration along the column length and the limited amount of data available.

Limited data are available in the literature on diffusion of the higher alkanes in LPE; however, studies of similar diffusants, linear aliphatic esters with 25 to 45 backbone units, have been conducted by Klein and Briscoe [14]. Extrapolating their experimental results to an 18 unit chain leads to an expected diffusion coefficient of 5×10^{-6} cm^2/s in linear polyethylene at 152 °C. This result is about an order of magnitude greater than the IGC determinations for a polymer film collected at the support bead contact points.

The distribution of film thickness also plays an important role in determining the magnitude of the diffusivity. The previous calculations

assumed that the film thickness was constant. In an actual column, however, the film thickness would be expected to be distributed about the mean values employed here. An alternate form of equation 7 can be used to estimate the effects of different film thicknesses [15]. The equation is:

$$D_s = \frac{k}{C(1 + k)^2} \sum_i q_i x_i s_i^2 \qquad (19)$$

where q_i is a configuration factor and x_i the volume fraction per unit column volume of stationary phase segments with thickness s_i. Assuming a uniform configuration factor and holding x_i constant gives:

$$D_s = \frac{kqx}{C(1 + k)^2} \sum_i s_i^2 = Z \sum_i s_i^2 \qquad (20)$$

which reduces to:

$$D_s = Zs^2 \qquad (21)$$

for a uniform film of thickness s. For a distribution with an equal volume of film 0.1s and 10s in thickness:

$$D_s' = Z\,[5(0.1s)^2 + 0.05(10s)^2] = 5.05\ Zs^2 \qquad (22)$$

This distribution, resulting from the same volume of stationary phase present in the uniform thickness case, leads to a diffusivity value five times larger than that corresponding to a uniformly distributed film. Table VI-4 summarizes the effects of different thickness distributions on the diffusion coefficient D_s' compared to that expected from a uniform film of thickness s, D_s. All the geometries considered require the same volume of stationary phase per unit column volume and have an average thickness of s. It is evident from these examples that thick sections of the polymer film

Table VI-4

Effect of Thickness Distribution on Diffusivity in the Polymer Phase

Thin Section Depth	Thick Section Depth	D_s'/D_s
0.50s	2s	1.25
0.25s	4s	2.13
0.10s	10s	5.05
0.02s	50s	25.01
0.01s	100s	50.01

can exert a disproportionate influence and lead to a considerable increase in the polymer-probe diffusion coefficient when compared to the value calculated for an IGC experiment with an assumed ideal polymer layer of uniform thickness. An experimentally difficult determination of the variability of the polymer film in the IGC column would be necessary in order to correct the calculated diffusivity values for the actual polymer layer nonuniformity.

Experimental Details

The column used throughout the relative diffusivity study was prepared from glass support beads coated with a layer of the linear polyethylene (LPE) NBS SRM 1475 and packed into a 6.35 mm outer diameter stainless steel tube, as described in the previous annual report [1]. After installation in the gas chromatograph, a final drying and column conditioning step was carried out by purging with dry, deoxygenated helium followed by heating to 150 °C for a 24-hour period. The column used is identical to column B in the previous annual report and contains 5.71×10^{-3} mass fraction of LPE. It was chosen because of the relatively small contribution which gas phase mass transfer made to the overall peak spreading when compared to column A of that report.

Several alkane probes and an antioxidant were employed as diffusants and are listed in the table below [16]. All were dissolved in hexane (Burdick and Jackson Labs.) to give solutions of about 0.02, 0.2, and 2.0 percent by mass.

Table VI-5

Probes Employed in an IGC Study of Relative Diffusivity in LPE

Probe	Code	Source
n-octadecane	C_{18}	Supelco
n-hexadecane	C_{16}	Aldrich Chemical
2-methylpentadecane	$2MeC_{15}$	Alfa Products
2,2,4,4,6,8,8-heptamethylnonane	$7MeC_9$	Aldrich Chemical
n-tridecane	C_{13}	American Petroleum Institute
1,3-di-tert-butyl-2-hydroxy-5-methylbenzene	BHT	Polysciences

Approximately 1 µl of each solution was injected into the flash vaporization injector of a gas chromatograph, maintained at 180 °C. The column oven was held at 150 °C ± 0.3 °C throughout. The eluted peaks were monitored with a flame ionization detector (FID) held at 190 °C, whose signal at 10^{-10} A/mV sensitivity was fed to an electronic integrator connected to a strip chart recorder and to a high acquisition speed recorder-plotter. The former setup was employed to time the peak maxima to within 0.01 min and for manual measurements of the chart width at half maximum at chart speeds up to 1 cm/s. Typical results are shown in Figure VI-4.

The rapid collection capabilities of the high speed recorder-plotter allowed the FID output to be sampled at 10 ms intervals, facilitating analysis

of the marker and solvent peaks. A typical trace is shown in Figure VI-5 for five repeated determinations. Data collection was triggered upon injection of the methane and hexane vapor sample and the time to the methane peak maximum, assumed to have k = 0, was employed to determine t_M of equation 6 and to calculate the column average linear flow velocity, $\bar{u}$, from the expression:

$$\bar{u} = L/t_M \tag{23}$$

The quantity of interest, the column outlet velocity, was then calculated from $\bar{u}$ as follows:

$$u_o = \frac{2\bar{u}}{3}\left[\frac{(p_i/p_o)^3 - 1}{(p_i/p_o)^2 - 1}\right]. \tag{24}$$

Column inlet and outlet pressures were monitored with calibrated pressure gauges of appropriate range. The outlet pressure was very near to atmospheric in all cases. The helium carrier gas volumetric flow rate was measured with a soap film flow meter, when necessary. The data were collected over a corrected flow rate range of about 1 to 5 ml/s.

The first derivative of a chromatographic peak with respect to time can be used to aid in determinations of the maximum height and peak widths indicated in Figure VI-1. At a point where the chromatogram is at a maximum, the first derivative will be zero while the second derivative is negative. Determination of the first derivative zero point is illustrated with curve B of Figure VI-6, the first derivative of curve A obtained by experiment. The inflection points of the chromatogram are also readily indicated by maxima or minima in the derivative curve. The magnitude of the derivative at this point gives the slope of a tangent to the peak. The ratio of the absolute values of the derivative maximum and minimum gives a measure of peak symmetry.

For the purposes of this study, a symmetric peak is defined as that having a front to rear tangent slope ratio of 1 ± 0.2. The highly asymmetric peaks that result from excessive probe concentrations or adsorption, two of the many factors which can cause deviations from Henry's law in the chromatographic column, are not amenable to analysis by the methods outlined here for Gaussian-shaped peaks. The time period between maximum and minimum of the derivative curve can be measured easily and is equal to twice the standard deviation of the peak, as illustrated in Figures VI-1 and VI-6. The above procedure was used to collect information on the center position, standard deviation, and symmetry of the eluted diffusant peaks.

Relative Diffusivity Determinations

As noted earlier, the probes listed in Table VI-5 were studied in the same LPE-containing column. This allows the diffusivity of one probe in LPE to be compared to that of another, irrespective of the method of any calculation of the absolute diffusivity of the probes in the polymer. The experimental data acquired for tridecane in LPE is given in Table VI-6 and can be used to give an indication of typical values of the various parameters utilized in these determinations. The variables p_i, p_o, and t_M are used in the calculation of u_c by equations 23 and 24. The plate height is determined from $w_{1/2}$ and t_R with equation 1 or from w_i and t_R by the following expression:

$$H = \frac{L}{4}\left(\frac{w_i}{t_R}\right)^2 \qquad (25)$$

When values of A and B are available, the plot suggested by equation 15 can be constructed from the data of Table VI-6. The previous annual report [1] contains a more detailed example of the calculation of these two constants from equations 3 and 4 than the abbreviated discussion given here. The values used in calculating $\bar{H}'/u_o$ are given in a footnote to Table VI-6.

Table VI-6

Experimental Data for an IGC Diffusivity Study of Tridecane in Linear Polyethylene at 150 °C

Pressure (Torr)		Time to Maximum (s)		Peak Width (s)		Outlet Velocity	Plate Height	Ordinate	Abscissa
P_i	P_o	t_M	t_R	$w_{1/2}$	w_i	u_o(cm/s)	$\bar{H}$ (cm)	$\bar{H}'/u_o$,(ms)*	$2p_o/(p_i+p_o)$
3160	745.9	4.23	54.6	8.68	7.34	108.2	0.705	6.31	0.3819
2590	745.0	5.29	69.0	9.79	8.34	72.2	0.562	7.44	0.4468
2103	743.4	6.94	90.6	11.10	9.45	46.0	0.419	8.49	0.5224
1827	744.6	8.43	111.0	12.15	10.29	33.6	0.335	8.95	0.5790
1577	745.2	10.78	141.0	13.73	11.68	23.3	0.265	9.56	0.6417

*The following values were used in the calculation of $\bar{H}'/u_o$: L = 154.9 cm, A = 0.0165 cm, B = 0.585 cm^2/s

Plots of $\bar{H}'/u_o$ against the $2p_o/(p_i + p_o)$ term are shown for five diffusants in Figure VI-7. The slopes of these plots provide a value for the C constant needed in a diffusivity determination. These C values are listed in Table VI-7, accompanied by the corresponding value of k for each

Table VI-7

Relative Diffusivity Results for Several Alkanes and BHT in LPE at 150 °C

Probe	C (ms)±σ(%)	k±σ(%)	D_{Probe}	$D_{Probe}/D_{C_{18}}$	D ($10^7 \cdot cm^2/s$)
C_{18}	21.9± 7	119 ±3	0.38 Y	1	2.4
C_{16}	7.8±14	60.9±1	2.05 Y	5.4	13
$2MeC_{15}$	8.7±12	49.0±1	2.25 Y	6.0	14
$7MeC_9$	18 ±11	12.8±1	3.74 Y	9.9	24
C_{13}	12 ± 9	12.1±1	5.74 Y	15.2	36
BHT	9.9±11	32.4±2	2.94 Y	7.8	19

probe as calculated from the data of Table VI-6 by equation 6. This information can then be used to determine a value for the relative diffusivity by the following procedure. Equation 17 can be rearranged to collect all the variables used only to characterize the polymer packing into one term and solved for the diffusivity. The following expression results when this is done:

$$D_s = \frac{k}{C(1 + k)^2} \left(\frac{r^4 m_s \rho}{168.75\ \rho_s} \right)^{1/2} \qquad (26)$$

The first term in the above equation contains the variables which characterize the interactions between the probe and polymer while the square room term consists of variables which describe polymer layer and support

particle characteristics only. These latter variables are constant throughout all determinations with this particular column and this collection of parameters can be abbreviated as the constant Y. The following version of equation 26 is consequently obtained:

$$D_s = \frac{k}{C(1 + k)^2} \cdot Y \qquad (27)$$

This equation was used to determine the probe diffusivity values given in the fourth column of Table VI-7. If one of the probes is selected as a reference, in this instance octadecane, the diffusivity of a probe in the polymer relative to the diffusivity of the reference probe in that polymer can be obtained from a ratio of the respective results from equation 27. These values are given in the fifth column of Table VI-7.

An alternate determination of the relative diffusivity might be based on equation 7. In this instance the following expression would be obtained for D_s:

$$D_s = \frac{k}{C(1 + k)^2} \cdot \frac{2s^2}{3} = \frac{k}{C(1 + k)^2} \cdot Y' \qquad (28)$$

Equations 27 and 28 are identical except for the constants Y and Y', which are derived from different collections of parameters used to describe the distribution of the polymer phase on the support. The numerical front-factor for Y' is identical to that given for Y in column four of Table VI-7 since it depends only on the values of C and k, which are the same for either method. The relative diffusivity results would also be identical as the Y or Y' constant is eliminated by the ratioing method used to obtain this quantity.

An absolute diffusion constant for each probe in the polymer can readily be obtained from the relative diffusivity values if an absolute diffusion coeffi-

cient for any of the probes in that polymer exists. Taking the previously cited value in Table VI-3 for column B of 2.4×10^{-7} cm^2/s for octadecane in LPE at 150 °C as accurate, the absolute diffusivities in column six of Table VI-7 were otained by multiplying the relative diffusion coefficients of column five by this factor.

Future Results

Results on lower molecular weight alkanes, principally isomers of octane and normal decane and tridecane, at temperatures below the LPE melting point will be given in a later report. They will allow a more rigorous evaluation of the IGC relative diffusivity technique as many more absolute diffusivity determinations have been conducted with these compounds. Independent values for the absolute diffusion coefficient of tridecane in LPE will then be available at two temperatures, one below and one above the polymer melting point. By using an appropriate activation energy to extrapolate one of the results and making allowances for the expected effects of polymer crystallinity on the diffusion coefficient, a direct comparison of the two results will be possible. Unfortunately, it is not possible to study the alkanes from octane to octadecane at a single temperature due to the great differences in volatility among these compounds. This necessitates the temperature extrapolation for a common probe described above as a means of connecting the two bodies of data collected at different temperatures and allowing for a critical evaluation of the method. Additional results for BHT at lower temperatures will also be provided.

VII. A Simplified Migration Decision Tree

One of the most important parameters in indirect food additive regulation is the maximum allowable concentration or a critical concentration of the species of concern in food, C^*. This value is based upon toxicological studies and from the fractional amount of total food consumed, that would be in contact with the packaging material of concern.

Acceptable migration would be the case in which an upper bound level of migration for the maximum time and temperature for storage and usage, based upon either actual tests of sound estimations, is less than the critical or threshold level.

To this end, we have exemplified and simplified our decision tree described earlier (NBSIR 79-1779) as a flow chart shwon in Figure VII-1.

1. Load Limited Migration

In the ultimate case, all the migrant of concern moves from the packaging material into food. The concentration of the migrant in food is:

$$C = \frac{V_p C_o}{V_s}$$

where C_o is the original concentration of the migrant in the packaging material, V_p and V_s are the volumes of the packaging material and food or solvent respectively. Migration is acceptable if this concentration is less than the critical concentration, C^*.

In general, 10 g food is considered in contact with 1 in^2 (6.45 cm^2) of the packaging material (CRF Title 21, Part 21, Part 177). In other words, by approximating the density of foods as 1 gcm^{-3}, the ratio of the volumes of the packaging material to food V_p/V_s is 0.645 ℓ where ℓ is the thickness of the packaging material in cm. Commonly this ratio is less than 1:40 or the thickness of the packaging material is less than 0.04 cm.

Therefore, the migration level is acceptable if the following conditions are met:

$$C_o < \frac{V_s}{V_p} C^* \qquad \text{for all cases,}$$

or

$$C_o < \frac{1.53}{\ell} C^* \qquad \text{if no less than 10 g of food is in contact with 6.45 } cm^2 \text{ of packaging material,}$$

or

$$C_o < 40C^* . \qquad \text{If } V_p \text{ is less than 1/40 of } V_s.$$

2. Solubility Limited Migration

For the case in which the loading of the migrant of concern is greater than the above limit, the saturation solubility C_{sat} of the migrant in the particular type of food or food simulant is examined in order to find out whether the saturation solubility is less than the critical concentration. Special attention should be given to cases where surfactant or emulsification action may tend to increase the actual migrant concentration in food beyond the saturation concentration. The migration level is acceptabe if

$$C_{sat} < C^*.$$

3. Partition Limited Migration

If both the loading and the solubility exceed the limiting threshold, then the partitioning of the migrant between the packaging material and the food or the simulant should be examined. The partition coefficient k is defined as the quotient of the activities, a, of the migrant in the food and in the polymer at equilibrium. It may also be approximated by the ratio of the solubilities in the solvent and in the polymer,

$$k = \frac{1}{K} = \frac{a_s}{a_p} \simeq \frac{C_{sat}}{C_{p,sat}}$$

By defining α as the ratio of the amount of migrant in the solvent, M_∞, versus that in the polymer, $M_{p\infty}$, at equilibrium

$$\alpha = \frac{M_\infty}{M_{p\infty}} = \frac{V_s}{V_p} k = \frac{V_s C_\infty}{V_p C_{p\infty}},$$

then the final fraction of original amount of additive migrated,

$$\frac{M_\infty}{M_0} = \frac{\alpha}{1 + \alpha}$$

where M_0 is the original loading of migrant in the polymer. For the final concentration in food or solvent to be less than the threshold,

$$C_\infty = \frac{M_\infty}{V_s} < C^*,$$

or

$$\frac{\alpha}{1 + \alpha} \frac{V_p}{V_s} C_0 < C^*,$$

it requires that

$$C_0 < \left(\frac{V_s}{V_p} + K \right) C^*.$$

Thus step 1 is just a special case of step 3.

In the case that the partition coefficient or the saturation concentration of the migrant in the polymer is unknown or difficult to determine, the partition coefficient may be assigned a value as in our previous reports (NBSIR 79-1598 and 79-1779)

$$\ell nk = \ell nC_{sat} + X_p^{\infty} + 1 = \ell nC_{sat} + 2$$

In general, X_p^{∞} is in the range of 0 to 2. Thus

$$k < 20\ C_{sat}.$$

This assigns a solubility of $C_{p,sat}$ of > 0.05. Therefore the requirement is simplified as,

$$C_o < (K + 40)\ C^*,$$

or

$$C_o < \frac{1}{20C_{sat}} + 40 \quad C^*$$

However, this simplification is applicable only when the saturated solubility in the food or solvent is relatively low and the solubility in the polymer relatively high.

4. Diffusion Limited Migration

When the equilibrium properties such as the additive loading in the polymer, the solubility of the additive in the solvent, and the partitioning of the additive between the polymer and solvent all yield too high a final concentration of the additive in the food or the solvent beyond the threshold concentration C^*, then it is necessary to find out kinetically whether, under the particular storage condition and in the limited storage time, the amount of the additive migrated would produce an additive concentration in the solvent less than that of the threshold limit. The kinetics of migration depends upon additive, polymer, and solvent combinations, as well as effects of temperature and stirring. The combination of additive, polymer, and solvent or food is the most important factor influencing the diffusion coefficient. This diffusion coefficient is also dependent upon temperature, with an activation

energy in the order of 10-20 kcal/mol for polymers in the rubbery state. A further relatively minor influence in comparison to the above factors may be observed due to the changes in the degrees of crystallinity and molecular weights of the polymer. Stirring speeds up the approach of an equilibrium condition.

If the migration is kinetically limited, i.e. much less than half of additive is migrated, then we are only interested in the short time behavior; otherwise, the estimation of total migration from step 1 would be sufficient.

For a single-sided extraction, at t when $M_t/M_\infty < 0.5$, we may apply the simple equation

$$\frac{M_t}{M_\infty} = 2\left(\frac{Dt}{\pi}\right)^{1/2}\frac{1}{\ell}$$

In other words

$$\frac{M_t}{A} = 2\left(\frac{Dt}{\pi}\right)^{1/2} C_o,$$

or

$$C_t = 2\left(\frac{Dt}{\pi}\right)^{1/2}\frac{A}{V_s} C_o,$$

where ℓ is the thickness of the film and A is the area of contact. For an upper limit, D is assigned the value of the diffusion coefficient measured on the polymer swollen by the solvent concerned. In the upper bound case, all migrants are assumed to be able to migrate from the polymer into solvent, i.e., $M_\infty = M_o = V_p C_o$. If partitioning exists, M_∞ should be reduced from M_o according to that described in step 3.

By assuming a storage time, t, of 1 year (3.15×10^7 s) and a container thickness of 0.04 cm (calculated from a food to container contact area of 10 g/in^2 and a container to food weight ratio of 1:40), one may obtain

$$M_t/M_\infty \cong 1.6 \times 10^5 D^{1/2},$$

or

$$M_t/A \cong 6300 D^{1/2} C_o,$$

or

$$C_t \cong 4100\ D^{1/2} C_o.$$

For $M_t/M_\infty = 0.5$, a diffusion coefficient of $D = 10^{-11}\ cm^2 s^{-1}$ is required to meet the threshold limit. Therfore, with the above mentioned storage conditions, only in the cases where D is less $10^{-11}\ cm^2 s^{-1}$ will diffusion limited migration be important enough to be considered. Otherwise equilibrium conditions should be used for estimation. For thinner packaging materials, D should be even less or at less than $6.2 \times 10^{-9} \ell^2 cm^2 s^{-1}$ in order for the kinetic criteria for migration to apply.

For polyolefins, the glass transition temperature is lower than -20 °C. Hence, the semicrystalline solid polymers are, in general, utilized in the condition of mixed rubbery (amorhpous portion) and crystalline states. It is usually assumed that the additive migration occurs in the amorphous region. The diffusion coefficients of migrant for the rubbery state are generally many orders of magnitude higher than those for the glassy state. For oligomers up to $n\text{-}C_{32}H_{66}$ and anti-oxidant molecules such as BHT, the apparent diffusion coefficients into either corn oil, triglycerides or ethanol are near or greater than $10^{-11} cm^2 s^{-1}$ above 30 °C. The influence of solvent, temperature, and crystallinity on the diffusion coefficients of BHT in polyethylene have been summarized earlier in this report. Therefore, for polyolefins, the diffusion limited case exists for these migrants and solvents only at a storage temperature lower than ambient, or at a much shorter storage time (a 10-fold reduction in the amount migrated requires a 100-fold reduction in time), or for a very thick container. The diffusion limited case may also exist for extraction with poor solvents for the migrant. However, in the case with poor solvents, the solubility limit or partition limit requirements may often suffice.

Fig. VII-1. A Simplified Additive Migration Decision Flow Chart

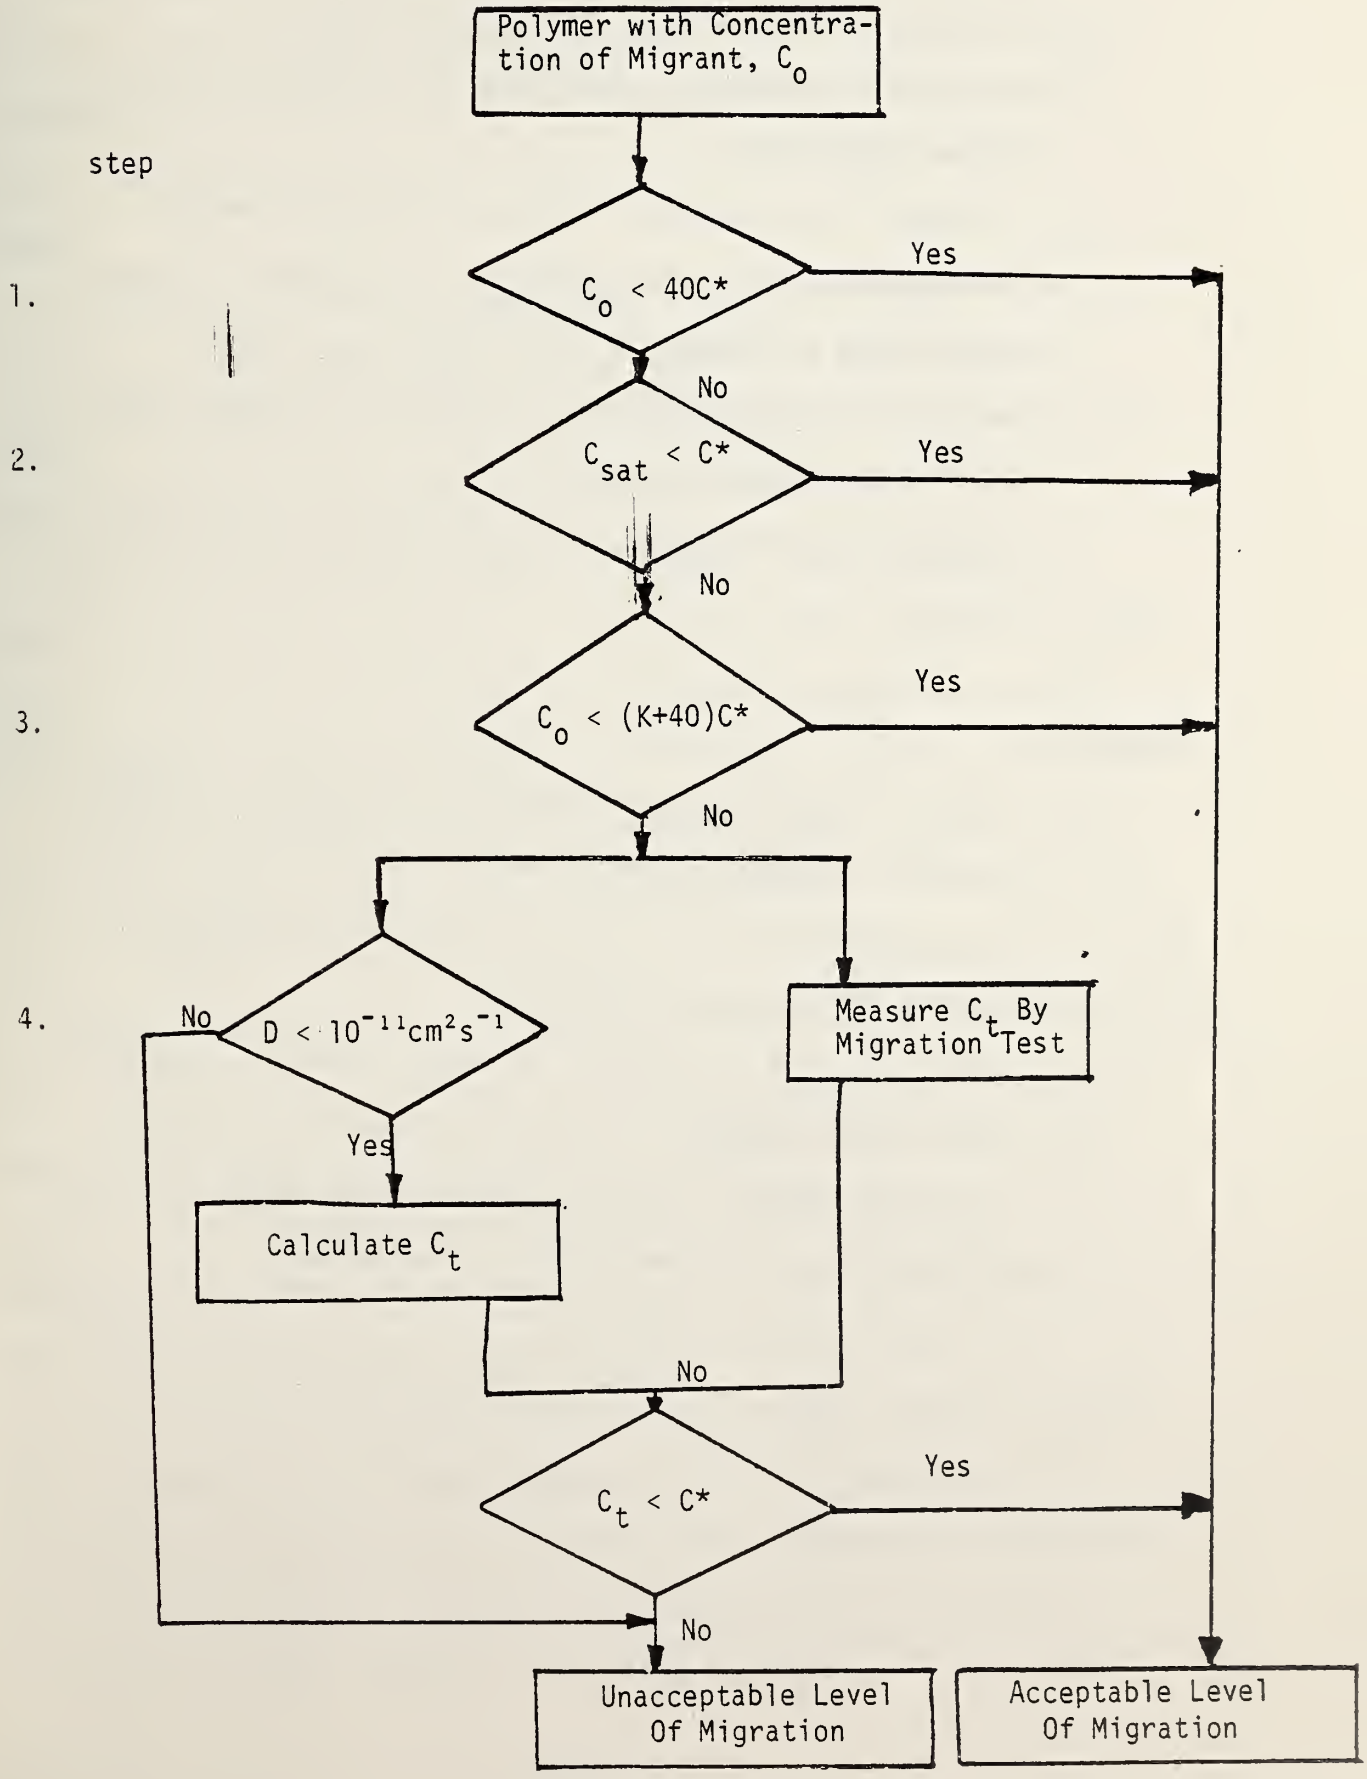

Figure VII-1. (Continued)

Glossary:

C_o - Original concentration of migrant in polymer.

C* - Critical or acceptable concentration of migrant in food or solvent of concern.

C_{sat} - Solubility of migrant in food or solvent of concern.

K - Distribution or partition coefficient of migrant in polymer and in food or solvent at equilibrium, C_{poly}/C_{solv}.

D - Apparent diffusion coefficient of migrant in polymer chain by food or solvent of concern.

C_t - Concentration of migrant in food or solvent after contact time t.

Notes:

1. This flow chart is based upon the assumption of a volume ratio of packaging material/food of 1:40 or 10 g of food are in contact with 1 in^2 or 6.45 cm^2 of packing material. Consult text for other conditions.
2. Along the decision or branching points, move to the next step if the parameter in the particular step is unknown or not determined, the particular step may be skipped and the criteria of the next step will be tested.

VIII. Simulating Solvents

Within the limited temperature range of food utilization and storage, solvent is the single most important parameter effecting both the amount of migrant extractable and the diffusion coefficient of the migrant, acting through its solubilities in and its swelling action upon the polymer.

By correlating diffusion coefficients in other solvents to that in one of the solvents, e.g. ethanol, while keeping all other parameters constant, it is possible to reduce the large spread of diffusion coefficients of the order of 10^8 to within a factor of 5 or less.

For partitioning or low solubility solvents, the correlations depend not only on the solvent but also on the migrant and/or the polymer. However, for solvents having moderate solubilities toward the migrant, the correlation seems to be independent of migrant, polymer or temperature.

The most significant correlations are those found for pure triglycerides and ethanol as food oil simulants and that for the accelerating solvent, n-heptane. As shown in Figure VIII-I, the diffusion coefficients of migrants (n-octadecane, n-dotriacontane or BHT) moving from polyolefins (LPE, BPE, PP) or E-VA copolymers into either tributyrin, trioctanoin or synthetic triglyceride mixture HB307 at either 30 or 60 °C are almost the same as the corresponding diffusion coefficient in corn oil. The diffusion coefficients in the pure triglycerides are slightly higher than that in corn oil with a ratio of D(pure triglycerides)/D(corn oil) less than 1.5 over most of the range studied. Ethanol seems to behave almost identically to the lower members of pure triglycerides in its extraction behavior as shown in Figure VIII-2. However the correlation for the data of ethanol extractions shows more scatter than that for triglycerides within a factor of less than 3 or less.

From the above observations, either ethanol or low members of pure triglycerides may be used successfully for most occasions as food oil simulants, regardless of dissimilarities in viscosities, solvation power for the migrants, and swelling power for the polymers.

The accelerating action of n-heptane over that of food oil has long been recognized. The amount extractable by food oil was sometimes considered to be 1/5 of that by n-heptane. However we found that no constant factor will describe this accelerating action. Beside the differences in solubilities and in partition coefficents, the accelerating power of n-heptane is clearly demonstrated in Figure VIII-3, where diffusion coefficients in n-heptane and in triglycerides (including corn oil) are plotted against those in ethanol for identical test samples and conditions. Regardless of polymer, migrant and temperature, the accerating power is greater at low diffusion coefficients than that at high diffusion coefficients. While, at D(ethanol) around 10^{-7} cm^2s^{-1}, accelerating power is greater at low diffusion coefficients than that at 1000 at D(ethanol) around 10^{-11} or $10^{-12}cm^2s^{-1}$.

The accelerating action of n-heptane compared to that of ethanol (and that of triglycerides), coupled with the differences in solubilities of oligomers of polyolefins, has dramatic effects on the total extractables of polyolefins. We, therefore, subjected large quantities (50 g) of the raw polymer stocks of SRM 1475 (LPE) and SRM 1476 (LPE) to extraction by 500 ml of ethanol n-heptane at 70 °C for 160 days with occasional shaking. By assigning a minimum diffusion coefficient of about 10^{-9} cm^2s^{-1} for n-$C_{32}H_{66}$ and a pellet radius of 0.1 cm, the effective time $T = Dt/\ell^2$ is 1.4. Thus according to the generalized solution for the diffusion equation, the extraction should be at least 95% complete. The results of the 160-day extractions are listed in

Table VIII-I. For each polymer, about 6 to 8 times as much of polymer fraction was extracted by n-heptane than by ethanol.

The extracts were then subjected to gel permeation or size exclusion chromatographic analysis by Roger C. Snyder of FDA to find out their molecular weight distributions, as summarized in Table VIII-2 and shown in Figure VIII-4 for linear polyethylene SRM 1475 extracts, respectively. The molecular weight scales were calibrated by means of analyzing five NBS polyethylene standard reference materials, three n-alkanes (C_{10}, C_{20}, C_{44}) and test mixtures containing known amounts of n-alkanes from C_6 to C_{44}. The molecular weight scale for branched polyethylene is only approximately correct, however it should be sufficient for comparison purposes.

The extracts from the linear polyethylene show rather normal symmetrical distributions with peaks of molecular weight centering at about 300 for ethanol and at about 800 for n-heptane extracts. Such results are expected from the practice of molecular weight fractionation by solvents of different solubility power. On the low molecular weight side, e.g., n-$C_{18}H_{38}$, there is a large enough solubility or even total miscibility of the oligomer fraction in both solvents, such that almost all of the low molecular weight fraction will be dissolved by the extraction processes, cf. labels A in Figures VIII-4 and VIII-5. As molecular weight becomes higher, e.g., n-$C_{32}H_{66}$, the solubility in the solvent, especially in ethanol, decreases which causes a partitioning of the particular component between the polymer and the extracting solvent to occur, cf. labels B in Figures VIII-4 and VIII-5. The partitioning of n-$C_{32}H_{66}$ has been confirmed by extraction experiments with ethanol. The diffusion coefficients for larger molecules also drop significantly. Thus the combination of the effects of solubility, partitioning and diffusion created the shape of the molecular weight distribution curve beyond the peak molecular weight extracted.

A similar comparison for branched polyethylene is seen in Figure VIII-5. The skewed curves are most likely due to the incorrectness of the size versus molecular weight calibration which was based on n-paraffins and linear polyethylene fractions. The peak of apparent molecular weight extracted is about 350 for ethanol and about 3200 for n-heptane extracts.

Therefore, n-heptane can not only accelerate the diffusion process but also remove high molecular species of oligomers that may be hardly present in ethanol or triglyceride extracts.

IX. Summary of Conclusions

* Maximum amount of extractables depends on the original migrant concentration in the polymer, the solubilities and the partition of the migrant in solvent and in polymer.
* Migration behavior is mainly Fickian.
* Diffusion coefficient may be increased by absorption of the solvent or swelling of the polymer by the solvent.
* Activation energies for the change of diffusion coefficient as a function of temperature generally lie between 40 and 200 kJ mol^{-1}. In general, the activation energy is lower at higher diffusion coefficients.
* Lower members of pure triglycerides may be used to simulate the extraction behavior of corn oil in oligomers and anti-oxidants, such as BHT, from polyolefins.
* Anhydrous ethanol may also be considered as food-oil simulant.
* Accelerating action of n-heptane over that of food-oils or oil simulates is more pronounced at lower diffusion coefficients.
* n-Heptane will remove high molecular weight fractions of oligomers which may hardly be present in food oil or oil simulants.
* Diffusion coefficient increases with increased oligomer content.
* Increase of amorphous content in a polyolefin produces a corresponding change in diffusion coefficient.
* The following is the ranking of the importance of the parameters effecting the diffusion coefficient of a migrant from polymer matrix into surrounding media:

Solvent > Temperature (limited range) > Swelling
> Migrant Concentration > Amorphous content.

11. ABSTRACT (A 200-word or less factual summary of most significant information. If document includes a significant bibliography or literature survey, mention it here)

Food packaging is an inseparable part of modern life. Any substance that migrates from the packaging material into foods is viewed as indirect food additives. In connection with toxicological knowledge, it is important to know the amount of such indirect food additives expected to be present in the food during storage and processing. This program, sponsored by the Bureau of Foods of the Food and Drug Administration is to provide theoretical models, reliable data base, methodology to study the migration phenomena and to provide reasonable worst-case estimates for the concentrations of the indirect additives in food. In this final report we present the results of approximately 250 completed migration experiments based on radiotracer techniques on the migration of low molecular weight hydrocarbons and antioxidants from polyethylene, polypropylene and ethylene-vinyl acetate copolymers. Results of a study for the determination of relative diffusion coefficients of several probe molecules in the polyethylene melt by inverse gas chromatography are also presented. Based on these studies, ethanol appears to be a far more reasonable food-oil stimulating solvent than n-heptane. Other pure or mixed triglycerides may also be considered as food-oil simulating solvents, however they may pose the same analytical difficulties as that of the food oil itself.

12. KEY WORDS (Six to twelve entries; alphabetical order; capitalize only proper names; and separate key words by semicolons)

antioxidants; diffusion; ethylene-vinyl acetate copolymers; food packaging; inverse gas chromatography; migration; oligomers; polyethylene; polypropylene; radiotracer
