## **Abstract**

The empirical literature on compensating wage differentials has a mixed history. While there have been some successes, much of this literature finds weak support for the theory of equalizing differences. We argue that it is dispersion in total job values or “job dispersion” that leads to biased compensating wage differential estimates. We begin by demonstrating how job dispersion can lead to biased hedonic estimates. Then we take a partial equilibrium on-the-job search model with utility from non-wage job characteristics, structurally estimate it and then simulate a dataset. Using our simulated dataset, we conduct a detailed analysis of the sources of bias in hedonic wage estimates. While worker heterogeneity and job dynamics are important sources of job dispersion, a significant proportion of the variation in jobs can only be explained by the inherent randomness of job offers.

Keywords: compensating wage differential, theory of equalizing differences, revealed preference, on-the-job search

*JEL* codes: J3, J42, J64

# 1 Introduction

Equally able workers in a frictionless labor market earn wages that equalize differences in the value of non-wage job characteristics between different jobs (Smith, 1776; Rosen, 1986). The argument is simple and compelling but empirical support for the theory is weak. For example, Brown (1980) summarized existing results at that time, and found that compensating wage differential estimates “provided rather limited support for the theory [of equalizing differences]” and that the most common explanation is inadequate control for unobserved worker ability. Using the National Longitudinal Survey Young Men’s sample, he then showed that even controlling for individual characteristics, compensating wage differential estimates are “often wrong signed or insignificant.”

More recently, Hwang *et al.* (1998) showed that if the value of non-wage job characteristics are correlated with the total value of jobs then a cross-sectional compensating wage differential regression results in biased marginal-willingness-to-pay (MWP) estimates. They use an equilibrium search model where employers select both the wage and the amenity level to demonstrate that low cost providers of amenities offer higher amenity levels and higher total job values (wage plus the value of the non-wage amenity). They further demonstrate that their model can result in a positive correlation between offered wages and amenity levels. Thus in their framework with endogenous job amenities, a traditional regression estimate can even yield a “wrong-signed” marginal-willingness-to-pay.

While unobserved heterogeneity in worker ability and correlation between amenities and total job value can certainly contribute to biased compensating wage differential estimates, we argue that the root cause is dispersion in total job values, or “job dispersion” for short. Indeed, unobserved heterogeneity and amenity correlation contribute to biased compensating wage differential estimates by increasing job dispersion.

Not surprisingly, job dispersion is closely related to the extensive literature on wage dispersion (for a few examples, see Brown and Medoff, 1989; Dunlop, 1957; Groshen, 1991). For instance, in any model with frictions where wages are dispersed, total job values or jobs are dispersed as well. Thus job dispersion is quite general to labor markets with frictions (e.g., Albrecht and Vroman, 1998; Burdett and Mortensen, 1998; Bhaskar and To, 2003).

We begin by illustrating how job dispersion can lead to inaccurate com-

compensating wage differential estimates and then sketch a simple model of imperfect competition to demonstrate how job dispersion can arise naturally in non-competitive labor markets. We then take a job search framework<sup>1</sup> to analyze job dispersion and its impact on estimated compensating wage differentials. In order to avoid potential problems with excluded job characteristics,<sup>2</sup> we bundle of all relevant job characteristics into “non-wage utility.” Indeed, many job characteristics are intangible, unobserved or heterogeneously valued (Bhaskar and To, 1999; Bhaskar *et al.*, 2002) and it would be impossible to accurately capture all of them. Moreover, with choice over just two dimensions (wages and non-wage utility), we are able to precisely focus on the interaction between search frictions and biased compensating wage differential estimates.

We estimate a partial equilibrium search model and use the estimated parameters to simulate a steady-state cross section dataset. But rather than model search over several non-wage job characteristics (e.g., Bonhomme and Jolivet, 2009), we consider the total utility from all non-wage job characteristics. In particular, we use our simulated dataset to conduct a detailed analysis to understand the sources of bias in standard compensating wage differential regressions. Our compensating wage differential estimates have the correct sign but are moderately to severely biased vis the true MWP. Fundamentally, this bias arises because for a worker moving out of unemployment, almost all acceptable jobs offer total utilities that are strictly greater than an unemployed worker’s reservation utility. In other words, jobs are dispersed.

Furthermore, employed workers’ reservation utilities are given by the utilities at their current jobs. Since the total utilities in workers’ first jobs out of unemployment are dispersed, reservation utilities for employed workers are also dispersed. This dispersion in reservation utilities further increases the cross-sectional dispersion of jobs. For example, the average utility for workers in their second job out of unemployment is greater than the average utility for workers in their first job out of unemployment, etc.

The earlier literature on compensating wage differentials has focused on

---

<sup>1</sup>We focus on job search because it has been well-studied in numerous empirical applications (Eckstein and van den Berg, 2007).

<sup>2</sup>In frictionless labor markets, compensating differential wage regressions will yield biased estimates of the marginal-willingness-to-pay if included job characteristics are correlated with excluded job characteristics. For example, if jobs with high risk of injury tend to offer health insurance then estimating wages on health insurance without also accounting for risk of injury would tend to undervalue health insurance.

heterogeneous ability as the primary explanation for the weak empirical support for the theory of compensating wage differentials. Our analysis suggests that this focus is not unwarranted since much of the bias in compensating wage differential estimates can be attributed to heterogeneous worker ability. Nevertheless, although worker heterogeneity can increase job dispersion, it is not necessary for biased compensating wage differential estimates. Indeed, under ideal circumstances, 33 percent of cross-sectional job dispersion in our simulated dataset can only be due to the inherent dispersion of job offers.

In the following section, we illustrate the basic intuition for why job dispersion results in inaccurate MWP estimates and then sketch a simple theoretical model in which job dispersion arises naturally. Next, we lay out a partial equilibrium model of on-the-job search with preferences for non-wage job characteristics in Section 3. Then in Section 4, we discuss the dataset used to estimate our partial equilibrium model and in Section 5 we discuss our econometric methodology and some important identification issues. In Section 6 we present our parameter estimates and in Section 7 we analyze the estimation of compensating differentials using simulated datasets. Section 8 concludes.

## 2 General Framework

Take the simplest case where equally able workers have the common utility function:<sup>3</sup>

$$U_i = U(w_k, \boldsymbol{\xi}_{ik}) \tag{1}$$

where  $w_k$  is the wage offered by employer  $k$  and  $\boldsymbol{\xi}_{ik}$  is a vector of non-wage job characteristics for worker  $i$  at employer  $k$ . As far as the workers' job choice decisions are concerned,  $U_i$  perfectly summarizes all of the information embodied in  $w_k$  and  $\boldsymbol{\xi}_{ik}$ . Since total utility, not its individual components, determine job choice, for all intents and purposes,  $U_i$  is the job.

Under the theory of equalizing differences,  $U_i = U^*$  for all  $i$  so that there is no job dispersion and:

$$U(w_k, \boldsymbol{\xi}_{ik}) \equiv U^*. \tag{2}$$

---

<sup>3</sup>Rosen (1986) allows for heterogeneous worker preferences and compensating wage differentials equalize total job utility for the marginal worker.

Solving for  $w_k$  yields:<sup>4</sup>

$$w_k = U^{-1}(U^*, \xi_{ik}) \quad (3)$$

so that in a frictionless labor market, the relationship between wages and non-wage job characteristics is deterministic.

The compensating wage differential literature attempts to estimate this relationship in order to arrive at a value for the MWP for various non-wage job characteristics. For example, a common specification is:

$$w_k = \alpha + \beta \xi_{ik} + e_{ik} \quad (4)$$

where the estimated coefficient,  $\hat{\beta}_l$ , is interpreted as the marginal-willingness-to-pay for job characteristic  $l$ . If  $\beta_l < 0$  then job characteristic  $l$  is a “good” and if  $\beta_l > 0$  then characteristic  $l$  is a “bad.”

However, if jobs are dispersed then total utility,  $U_i$ , will not be identical across jobs or workers. In this case, a regression equation such as (4) is incorrectly specified and can lead to poor MWP estimates. The notion that job values or jobs can be dispersed is quite general and can arise in a variety of theoretical models.

## An Example

Consider a simple Hotelling labor market as described in Bhaskar *et al.* (2002). Equally able workers are uniformly distributed along the  $[0, 1]$  interval with two employers, 0 and 1, located at either end. Workers pay a “transportation cost” of  $t$  per unit of distance to go to work so that a worker located at  $i$  pays  $ti$  to work for employer 0 and  $t(1-i)$  to work for employer 1. In this case the distance to work,  $\xi_{i0} = i$  or  $\xi_{i1} = 1-i$ , is a negative job characteristic and the known MWP for  $\xi$  is positive and equal to  $t$ . Worker utility is the wage net of transportation costs or  $U(w_k, \xi_{ik}) = w_k - t\xi_{ik}$ . Figure 1 shows two examples where the downward and upward sloping line segments represent the consumer’s total utility. The marginal worker who is indifferent between working for employers 0 and 1 is located at  $i^*$ . The workers located at 0 and 1 work for employers 0 and 1 and pay no transportation costs. As workers travel farther to work, they pay higher transportation costs and get lower utility.

If employers are equally productive and cannot wage discriminate, then they pay the same wage and evenly split the labor market (Figure 1a). Even

---

<sup>4</sup>Assuming that  $U$  is increasing in  $w_k$  ensures that  $U$  is invertible.

Figure 1: Hotelling job values

though wages are identical, jobs ( $U_i = w_k - t\xi_{ik}$ ) are dispersed. A standard compensating wage differential estimate of the marginal-willingness-to-pay for commuting distance yields  $\hat{\beta} = 0$ , even though the true MWP in the model is equal to  $t$ .

The simple hotelling model also generates biased hedonic estimates of the MWP in the more general case where employers differ in productivity. For example, if employer 1 is more productive than employer zero, it offers a higher wage rate ( $w_1 > w_0$ ) and employs a larger share of the labor market (Figure 1b). On average, workers employed at firm 0 travel shorter distances than those working for firm 1, so wages are positively correlated with commuting distance. As a result of this positive correlation, estimating a compensating wage differential equation by OLS yields an estimated MWP with the correct sign (i.e.,  $\hat{\beta} > 0$ ). However, this estimate is strictly bounded

above by the true MWP of  $t$ .<sup>5</sup> This simple duopsony analysis extends to more general models of oligopsony (Bhaskar and To, 2003).

While this example succinctly illustrates the basic intuition of how job dispersion leads to attenuated MWP estimates, for the remainder of this paper, we elaborate on compensating wage differentials and job dispersion using a partial equilibrium search framework. A search model’s explicit dynamics play a key role in the degree of job dispersion observed in cross-section.

### 3 The Search Model: Wages and Non-Wage Utility

This section presents the search model used to study compensating differentials in a labor market with frictions. The model is set in discrete time. Agents maximize the discounted sum of expected utility over an infinite time horizon in a stationary environment. In each time period, individuals occupy one of two states: employment or unemployment.<sup>6</sup>

#### 3.1 Preferences and the Total Value of a Job

The utility received by an employed agent is determined by the log-wage,  $w$ , and the match-specific non-wage utility flow,  $\xi$ . The one-period utility from employment is

$$U(w, \xi) = w + \xi$$

where both  $w$  and  $\xi$  are specific to a particular match between a worker and employer, and are constant for the duration of the match. A job offer consists of a random draw from the distribution  $F(w, \xi)$ , which is a primitive of the model. Since  $w$  and  $\xi$  are additively separable in the utility function, it is convenient to define the agent’s decision problem in terms of total utility,  $w + \xi$ , where  $U(w, \xi) \equiv U$  and  $U$  is distributed as  $H(U)$ .<sup>7</sup>

---

<sup>5</sup>It can be shown that the “best” possible OLS compensating wage differential estimate is  $\hat{\beta} = \frac{t}{2}$  which occurs when equilibrium wages are such that  $i^* = \frac{3 \pm \sqrt{3}}{6}$ . Moreover, as  $i^* \rightarrow 0$  or  $i^* \rightarrow \frac{1}{2}$ ,  $\hat{\beta} \rightarrow 0$ .

<sup>6</sup>Following the majority of the search literature, the model does not distinguish between unemployment and non-participation in the labor market.

<sup>7</sup>In particular,  $H(U) = \int_{-\infty}^{\infty} F_{w|\xi}(U - \xi | \xi) f_{\xi}(\xi) d\xi$  where  $F_{w|\xi}$  is the conditional cumulative wage distribution and  $f_{\xi}$  is the unconditional probability density function

The non-wage match value,  $\xi$ , captures the net value of all the non-wage job characteristics associated with a particular job to a specific worker. These characteristics include employer provided benefits (health insurance), tangible job characteristics (commuting time), and intangible job characteristics (friendliness of co-workers). The non-wage match value represents the worker's personal valuation of a job, so in addition to capturing variation in non-wage characteristics across jobs, it also reflects heterogeneity in preferences for job characteristics across workers.

For our purposes, there are two primary advantages to aggregating the value of all non-wage job characteristics into a single index. First, this approach avoids the potential bias that could result from focusing on a small number of observable characteristics while ignoring other relevant, but unobserved, job characteristics. As discussed in Rosen (1986), the theory of equalizing differences applies to the wage and the total non-wage value of a job. However, it will not necessarily apply if some job characteristics are excluded. Second, it is likely that workers have heterogeneous preferences over the employer provided benefits and tangible and intangible job characteristics that differentiate jobs.

### 3.2 Unemployed Search

Unemployed agents search for jobs, which arrive randomly with probability  $\lambda_u$ . The discounted expected value of lifetime utility for an unemployed agent is

$$V^u = b + \delta[\lambda_u E \max\{V^u, V^e(U')\} + (1 - \lambda_u)V^u], \quad (5)$$

where  $b$  represents log-unemployment-benefits, and  $\delta$  is the discount factor. The term  $V^e(U')$  represents the expected discounted value of lifetime utility for an agent employed in a job with utility level  $U'$ .

### 3.3 On-the-job Search

In each time period, with probability  $\lambda_e$  an employed agent receives a job offer from an outside firm. The worker may accept the job offer, or reject it and continue working for his current employer. Job matches end with exogenous

---

for  $\xi$ .

probability  $\lambda_l$ . When a job ends for this reason, the worker becomes unemployed. With probability  $\lambda_{le}$ , a worker's current job exogenously ends and he receives a job offer from a new employer in the same time period. When this happens, the worker can accept the new offer, or become unemployed. Finally, with probability  $(1 - \lambda_e - \lambda_l - \lambda_{le})$  the job does not end exogenously and no new offers are received, so the worker remains in his current job.

The discounted expected value of lifetime utility for a worker who is currently employed in a job with utility level  $U$  is

$$V^e(U) = U + \delta[\lambda_e E \max\{V^e(U), V^e(U')\} + \lambda_l V^u + \lambda_{le} E \max\{V^u, V^e(U')\} + (1 - \lambda_e - \lambda_l - \lambda_{le})V^e(U)]. \quad (6)$$

The first bracketed term in equation (6),  $\lambda_e E \max\{V^e(U), V^e(U')\}$ , represents the expected value of the best option available in the next time period for an employed individual who receives a job offer from a new employer.<sup>8</sup> The second bracketed term,  $\lambda_l V^u$ , corresponds to the case where a job exogenously ends and the worker is forced to enter unemployment. The third bracketed term,  $\lambda_{le} E \max\{V^u, V^e(U')\}$ , represents the case where the worker is laid-off but also receives a job offer from a new employer. The final bracketed term represents the case where the worker is neither laid-off nor receives an outside job offer.

### 3.4 Optimal Job Search and Job Dispersion

The optimal search strategies for unemployed and employed workers can be expressed in terms of reservation utilities, which are analogous to reservation wages in a standard income maximizing search model. A utility maximizing unemployed worker will accept any job offer with a one-period utility flow greater than the reservation level,  $U^*$  (Appendix A presents the formal derivation of  $U^*$ ). The reservation utility search strategy implies that the distribution of accepted job offers generated by the model is truncated from below at  $U^*$ . Since unemployed agents in the model will choose to work in any job that offers utility level  $U > U^*$ , subject to the constraints imposed by search frictions, pairs of accepted job offers  $(w, \xi)$  do not directly reveal the marginal willingness to pay for non-wage job characteristics. Section 7 expands on this point in considerable detail by using simulated data from

---

<sup>8</sup>The value function reflects the fact that in this model it is never optimal for a worker to quit a job and enter unemployment.

the estimated model to examine the performance of a standard compensating wage differential regression in our dynamic model of the labor market.

Employed agents in the model also adopt a reservation utility rule when evaluating outside job offers. In this stationary search environment, optimal decisions for employed agents are based on comparisons of one-period utility flows. When an employed worker receives an offer from an outside firm but does not experience an exogenous job ending, a simple reservation utility strategy is optimal. Since  $V^e(U)$  is increasing in  $U$ , the rule is to accept the offer if it provides greater utility than the current job ( $U' > U$ ), and reject the offer otherwise ( $U' \leq U$ ). As a result, workers climb a “utility ladder” as they voluntarily move between jobs. Workers make optimal tradeoffs between wages and non-wage utility, but these decisions are constrained by search frictions.

If a worker’s job exogenously ends and he receives a new job offer at the same time, which occurs with probability  $\lambda_{le}$ , the situation is identical to the one faced by an unemployed agent who receives a new job offer. As a result, he will choose to accept or reject the offer based on the unemployed reservation utility level  $U^*$ . In the remainder of the paper, we will refer to direct job-to-job transitions that occur as the result of a simultaneous layoff and job offer as “involuntary” transitions between employers. This terminology reflects the fact that although a direct job-to-job transition occurs, the worker’s previous job ended involuntarily (exogenously). For agents in the model, voluntary and involuntary transitions are fundamentally different types of job mobility. When a voluntary job-to-job transition occurs, utility increases ( $U' > U$ ). In contrast, when an involuntary transition occurs, the new job offer is preferable to unemployment ( $U' > U^*$ ), but it may offer lower utility than the previous job which exogenously ended ( $U' < U$ ).

### 3.5 Heterogeneity in Worker Ability

A primary concern of the existing empirical hedonic wage literature is the effect of heterogeneity in worker ability on estimates of compensating wage differentials (Brown, 1980). For example, Rosen (1986) contends that unobserved worker ability is the primary reason that low paying jobs tend to be the “worst” jobs. Using a competitive framework, Hwang *et al.* (1992) and Han and Yamaguchi (2012) show that unobserved worker productivity can significantly bias compensating wage differential estimates.

Hedonic studies tend to include as many worker characteristics as possible

but nevertheless it is well known that wage regressions leave a large fraction of variation in wages unexplained. Instead, we minimize worker heterogeneity by selecting a relatively homogeneous sample and in addition allowing for unobserved worker heterogeneity.

We control for heterogeneity in worker ability by allowing the mean of the wage offer distribution,  $\mu_w$ , to vary across the population. In addition, we also allow the mean of the distribution of match specific utility flows,  $\mu_\xi$ , to vary across the population. To the best of our knowledge, this is the first study of hedonic wages that allows for the possibility that workers search for jobs in an environment where the mean quality of non-wage job offers varies across workers.

To model worker heterogeneity, we follow Keane and Wolpin (1997) and a large subsequent literature, and assume that the joint distribution of unobserved heterogeneity is a mixture of discrete types. Assume that there are  $J$  types of people in the economy, and let  $\pi_j$  represent the proportion of type  $j$  in the population. The parameters of the distribution of unobserved heterogeneity,  $\{\mu_w(j), \mu_\xi(j), \pi_j\}_{j=1}^J$ , are estimated jointly along with the other parameters of the model.

One important feature of the discrete mixture distribution is that it allows for a wide range of possible correlations between the mean wage offer and non-wage utility offer faced by workers.<sup>9</sup> For example, if  $\mu_w(j)$  and  $\mu_\xi(j)$  are positively correlated, then high ability workers tend to receive good (high  $w$  and high  $\xi$ ) job offers. Arguments can be made for either positive (health insurance) or negative (risk of injury) correlation between  $w$  and  $\xi$  and our discrete mixture distribution provides a great deal of flexibility to match the correlation across our relatively homogeneous population.

## 4 Data

We use the 1997 rather than the venerable 1979 cohort of the NLSY to estimate our model for two reasons. First, the NLSY97 is more representative of current labor market conditions. Second, the NLSY97 design team incorporated lessons from the NLSY79 and has a more consistent methodology (Pergamit *et al.*, 2001).

---

<sup>9</sup>However, it is important to note that we do not impose any particular correlation between  $\mu_w$  and  $\mu_\xi$ . The estimated values of the parameters  $\{\mu_w(j), \mu_\xi(j), \pi_j\}_{j=1}^J$  determine whether or not the correlation is positive or negative.

The NLSY97 is a nationally representative sample of 8,984 individuals who were between the ages of 12 and 16 on December 31, 1996. Interviews have been conducted annually since 1997. The NLSY97 collects extensive information about labor market behavior and educational experiences which provide the information needed to study the transition from schooling to employment, early career mobility between employers, and the associated dynamics of wages. Individuals enter the estimation sample when they stop attending high school. The information from the annual interviews is used to construct a weekly employment record for each respondent.

We select a particular subset of the NLSY97 in order to minimize unnecessary complications in estimating our model. Women are excluded for the usual reason of avoiding the difficulties associated with modeling female labor force participation. Similarly, in order to avoid issues relating to household search, men who are ever married during the sample period are excluded. Moreover, we use data from interviews up to the 2006 interview and we select workers who have never attended college because low-skilled workers with little work experience can be expected to have little or no bargaining power and hence conform best to our wage-posting model. Thus we focus on young, unmarried, low-skilled men who are at the beginning of their careers. As is standard in the empirical search literature, individuals who ever serve in the military or are self employed are excluded from the sample. Since the maximum age that an individual could reach during the sample period is only 26 years, our results should be viewed as applying to young workers who tend to be quite mobile during this early phase of their career. Whether the results generalize to older workers, or different cohorts of workers, is an open question.

The NLSY97 provides a weekly employment record for each respondent which is aggregated into a monthly<sup>10</sup> labor force history for the purposes of estimation. First, each individual is classified as unemployed or employed full time for each month depending on whether more weeks were spent employed or unemployed during the month.<sup>11</sup> Next, employed individuals are assigned a monthly employer based on the employer that the worker spent the most weeks working for during the month. The monthly wage is the one associated with the monthly employer. The monthly employment record con-

---

<sup>10</sup>For tie-breaking purposes, we use a 5-week month.

<sup>11</sup>Non-participation and unemployment are considered to be the same state for the purposes of aggregating the data. Full time employment is considered to be jobs that involve at least twenty hours of work per week.

tains a complete record of employment durations, direct transitions between employers that occur without an intervening spell of unemployment, transitions into unemployment, and the growth in wages resulting from mobility between employers.

Since the importance of non-wage job characteristics is identified in part by job-to-job transitions, we are careful to differentiate between those that are voluntary and those that are not. To identify involuntary job-to-job transitions we use the stated reason that a worker left their job. We consider “layoffs,” “plant closings,” “end of a temporary or seasonal job,” “discharged or fired” or “program ended” to be involuntary. While these data may be somewhat noisy, we are reassured by the summary statistics which show that direct transitions we classify as strictly involuntary are more likely to result in a wage decline (Table 1). In addition, on average, workers who make involuntary transitions between employers experience nearly a 2 percent decline in wages. In contrast, wages increase on average by 8 percent at all transitions between employers.

The final issue worthy of discussion regarding the data is the treatment of within-job variation in wages. In the NLSY97, when a job persists across survey interviews, which occur approximately one year apart, a new measurement of the wage is taken. If a job does not last across interview years, only the initial measurement of the wage is available. In principle, it would be possible to allow for within-job variation in wages using these data. However, as discussed by Flinn (2002), jobs with observed wage changes are not a random sample from the population, so there are difficult selection issues which must be confronted when estimating an on-the-job wage process using these data. Even more importantly for our purposes, since the NLSY97 is still a relatively short panel, the majority of jobs do not persist across survey years. For these jobs, it is impossible to observe on-the-job wage growth. More specifically, we only observe a single wage for 72 percent of all jobs in our data. In addition, for our estimation sample we are unable to reject the null hypothesis that mean wage growth is zero within job spells.<sup>12</sup> Given these features of the data, there is little hope of precisely estimating an on-the-job wage growth process. As a result, we restrict wages to be constant within job spells for the purposes of estimation. When multiple wages are

---

<sup>12</sup>More specifically, we are unable to reject the null hypothesis that the mean of wage growth equals zero at the 5% level. Mean wage growth is computed using the first and last wage present for each job in the NLSY estimation sample.

reported for a particular job, we use the first reported wage as the wage for the entire job spell. Moreover, for our application, with our focus on young, unskilled workers during a highly mobile stage of their career, constant wages within jobs does not seem unrealistic.

## 4.1 Descriptive Statistics

This section highlights the key characteristics of the data used to estimate the importance of non-wage job characteristics in determining employment outcomes. It is convenient to describe the labor market histories in the data and the data generated by the search model in terms of employment cycles, as in Wolpin (1992). An employment cycle begins with unemployment and includes all of the following employment spells that occur without an intervening unemployment spell. When an individual enters unemployment, a new cycle begins. In the remainder of the paper, whenever a job is referred to by number, it represents the position of the job within an employment cycle.

Table 1 shows the means and standard deviations of key variables from the sample of the NLSY97 used in this analysis. There are 980 individuals in the data who remain in the sample for an average of 54.2 months, and these people experience an average of 2.88 employment cycles. The top section of the table shows that as individuals move between employers within an employment cycle, the average wage and employment duration increase.<sup>13</sup> The middle section of the table shows that although mean wages increase as individuals move directly between jobs, conditional on switching employers without an intervening unemployment spell there is a 36 percent chance that an individual reports a lower wage at his new job.<sup>14</sup> For individuals who report that the direct transition between employers was involuntary, the mean wage change is negative and the probability of a wage decrease rises to 46 percent. Measurement error in wages certainly accounts for some fraction of the observed wage decreases at voluntary transitions between employers. However, the prevalence of these wage decreases and the increased probability of observing a wage decline at an involuntary transition both suggest a role

---

<sup>13</sup>Statistics are not reported for more than three jobs within a cycle because only a very small number of people have four or more consecutive jobs without entering unemployment.

<sup>14</sup>This number is consistent with existing estimates of the fraction of direct employer-to-employer transitions that involve a wage decrease. Bowlus and Neumann (2006) report that 40 percent of direct transitions involve a wage decrease in the NLSY79.

Table 1: Descriptive Statistics: NLSY97 Data

	Job Number within Cycle		
	Job 1	Job 2	Job 3
Mean log-wage	1.979	2.038	2.061
Standard deviation of log-wage	0.425	0.458	0.457
Mean employment spell duration*	8.939	9.271	9.738
Number of observations	2614	940	382
	Type of Employer Switch		
	All	Involuntary	
Pr(wage decrease) at job-to-job move	0.364	0.460	
Mean $\Delta w$ at job-to-job switch <sup>†</sup>	0.081	-0.017	
Median $\Delta w$ at job-to-job switch	0.074	0.00	
Mean $\Delta w$ at job-to-job switch $ \Delta w > 0$	0.359	0.322	
Median $\Delta w$ at job-to-job switch $ \Delta w > 0$	0.231	0.211	
Mean $\Delta w$ at job-to-job switch $ \Delta w < 0$	-0.327	-0.345	
Median $\Delta w$ at job-to-job switch $ \Delta w < 0$	-0.163	-0.206	
All Jobs			
Mean unemployment spell duration	5.908		
Mean number of cycles per person <sup>‡</sup>	2.878		
Std. dev. of number of cycles per person	1.793		
Mean total work experience at end of sample period <sup>§</sup>	40.01		
Fraction of job-to-job transitions that are involuntary	0.151		
Number of people	980		
Mean number of months in sample per person	54.153		

Notes: \*All durations are measured in months.

<sup>†</sup> $\Delta w$  represents the change in the wage at a job-to-job transition.

<sup>‡</sup>An employment cycle begins with the first job after an unemployment spell, and includes all subsequent jobs that begin without an intervening unemployment spell.

<sup>§</sup>This is the across-person mean of total work experience in the final time period. The final time period is either the end of the sample time frame, or the final time period before an observation is truncated due to missing data.

for non-wage job characteristics in determining mobility between jobs.

## 5 Estimation

The parameters of the model are estimated by simulated minimum distance (SMD). This section begins by specifying the distributional assumptions about the job offer distribution, measurement error in wages, unemployment benefits, and the discount factor needed to estimate the model. Then it explains how the simulated data is generated, describes the estimation algorithm and discusses identification.

### 5.1 Distributional Assumptions and Exogenous Parameters

#### The Job Offer Distribution and Measurement Error in Wages

Estimating the model requires specifying the distribution  $F(w, \xi)$ . As we noted at the end of Section 3.5, our discrete mixture distribution allows for correlation between log-wage offers and match-specific utility flows across the population. Thus we assume for each type that they are independent. Moreover, it is necessary to make parametric assumptions over  $F(w, \xi)$ ; we assume that they are normally distributed so that,

$$\begin{aligned} F_j(w, \xi) &\sim \Omega_j(w)\Psi_j(\xi) \\ \Omega_j(w) &\sim N(\mu_w(j), \sigma_w) \\ \Psi_j(\xi) &\sim N(\mu_\xi(j), \sigma_\xi), \end{aligned}$$

where  $j$  indicates that these distributions vary over the  $J$  discrete types of agents in the model.

Wages in typical sources of microeconomic data are measured with error (see Bound *et al.* (2001) for a comprehensive survey). We account for measurement error by assuming that the relationship between the log-wage observed in the data and the true log-wage is  $w^o = w + \varepsilon$ , where  $w^o$  is the observed log-wage,  $w$  is the true log-wage, and  $\varepsilon \sim N(0, \sigma_\varepsilon)$  represents measurement error in wages that is independent of the true wage.<sup>15</sup> Based

---

<sup>15</sup>Accounting for measurement error in this way is standard in the search literature. See, for example, Stern (1989), Wolpin (1992), and Eckstein *et al.* (2009).

on existing estimates of the extent of measurement error in wages, we set  $\sigma_\varepsilon = 0.15$ .

## Unemployment Benefits and the Discount Factor

Many papers in the search and dynamic labor supply literature have found that the discount factor is either not identified, or is in practice very difficult to estimate. Following these papers, we set the monthly discount factor to  $\delta = 0.998$ . Finally, estimating the model requires choosing a value for  $b$ , the amount of unemployment benefits. The unemployment insurance system in the U.S. is quite complicated, and the details of the program such as eligibility requirements, maximum duration of benefits, and the generosity of benefits varies widely across States (see Kletzer and Rosen, 2006). Kletzer and Rosen also documents that the average replacement rate for UI benefits across the U.S. was 0.36 during the years 1975-2004. Given the complexity of the UI program, we adopt the following stylized model of unemployment benefits,  $b(j) = \ln(0.35 \times e^{\mu_w(j)})$ . This specification allows unemployment benefits to vary across types, so that agents with higher expected wages receive higher unemployment benefits.

## 5.2 Data Simulation

As discussed in Section 3, the optimal decision rules for the dynamic optimization problem can be described using simple static comparisons of one-period utility flows. It is straightforward to simulate data from the model using these optimal decision rules without numerically solving for the value functions that characterize the optimization problem.

The first step when simulating the model is to randomly assign each individual in the data to one of the  $J$  discrete types that make up the population distribution of unobserved heterogeneity. Next, a simulated career is formed for each individual in the NLSY97 estimation sample by randomly generating job offers and exogenous job endings, and then assigning simulated choices for each time period based on the reservation value decision rules. Computing the reservation utility levels for each type,  $\{U^*(j)\}_{j=1}^J$ , requires numerically solving Equation (A3). The number of time periods that each simulated person appears in the simulated data is censored to match the corresponding person in the NLSY97 data. Measurement error is added to

the simulated accepted wage data based on the assumed measurement error process.

### 5.3 Simulated Minimum Distance Estimation

Simulated minimum distance estimation finds the vector of structural parameters that minimizes the weighted difference between vectors of statistics estimated using two different data sets: the NLSY97 data, and simulated data from the model. We use the terminology simulated minimum distance to make it clear that during estimation we match moments from the data (as in the simulated method of moments) and the parameters of an auxiliary model (as in indirect inference).<sup>16</sup> In this application, the auxiliary parameters are the parameters of a reduced form wage regression. In the remainder of the paper, for brevity of notation we refer to all of the statistics from the data that are matched during estimation as moments.

Let  $\theta = \{\sigma_w, \sigma_\xi, \lambda_u, \lambda_l, \lambda_e, \lambda_{le}\} \cup \{\mu_w(j), \mu_\xi(j), \pi_j\}_{j=1}^J$  represent the parameter vector that must be estimated. The search model is used to simulate  $S$  artificial datasets, where each simulated dataset contains a randomly generated employment history for each individual in the sample. The simulated and actual data are each summarized by  $K$  moments. The SMD estimate of the structural parameters minimizes the weighted difference between the simulated and sample moments. Let  $m_k$  represent the  $k$ th moment in the data, and let  $m_k^S(\theta)$  represent the  $k$ th simulated moment, where the superscript  $S$  denotes averaging across the  $S$  artificial datasets. The vector of differences between the simulated and actual moments is  $g(\theta)' = [m_1 - m_1^S(\theta), \dots, m_K - m_K^S(\theta)]$ , and the simulated minimum distance estimate of  $\theta$  minimizes the following objective function,

$$\Phi(\theta) = g(\theta)'Wg(\theta), \tag{7}$$

where  $W$  is a weighting matrix. We use a diagonal weighting matrix during estimation, where each diagonal element is the inverse of the variance of the corresponding moment. We estimate  $W$  using a nonparametric bootstrap with 300,000 replications. Bootstrapping the matrix  $W$  is convenient because it is not necessary to update the weighting matrix during estimation. Parameter estimates are obtained by minimizing the objective function

---

<sup>16</sup>See Stern (1997) for a survey of simulation based estimation, and Smith (1993) for the development of indirect inference. Recent examples of papers that use this approach to estimating search models include Eckstein *et al.* (2009) and Yamaguchi (2010).

shown in equation (7) using simulated annealing.<sup>17</sup> Simulated moments are averaged over  $S = 25$  simulated datasets. The standard errors are computed using a nonparametric bootstrap using 900 draws from the NLSY97 data.

## 5.4 Choice of Moments and Identification

This section discusses the moments targeted during estimation and provides a discussion of how they identify the parameters of the structural model. Table B1 lists the 51 moments from the NLSY97 that are used to estimate the model. This section begins by describing how the wage offer distribution and non-wage utility offer distribution are identified. Next, it demonstrates how the distribution of person-specific unobserved heterogeneity is identified. The section concludes by turning to a discussion of how the transition parameters ( $\lambda$ 's) are identified. Throughout this section, we provide examples of how different parameters impact the moments used in estimation to illustrate identification. We do not attempt to provide an exhaustive summary of the effect of each parameter on every simulated moment.

### Identifying the Wage and Non-Wage Offer Distributions

As is standard in the structural search literature, and described in Section 5.1, we must assume a parametric functional form for the job offer distribution,  $F(w, \xi)$ .<sup>18</sup> For clarity of exposition, we initially abstract away from person-specific unobserved heterogeneity when discussing identification of the job offer distribution. Following this discussion, we explain how the distribution of unobserved heterogeneity is identified.

The mean and standard deviation of the wage offer distribution are identified by moments that describe accepted wages and wage growth from mobility. More specifically, our simulated minimum distance estimation procedure attempts to match the mean and standard deviation of accepted wages, and the mean employment spell duration for the first three employment spells (Panel 1 of Table B1). Recall that employers within a cycle represent a

---

<sup>17</sup>See Goffe *et al.* (1994) for a discussion of the simulated annealing algorithm and FORTRAN source code to implement the algorithm. The primary advantage of this algorithm is that it is a global search algorithm that can escape local optima.

<sup>18</sup>The major difference between our paper and existing work is that we must specify the distribution of  $\xi$  in addition to the wage distribution.

sequence of direct transitions between employers that occur without an intervening spell of unemployment, so mean wages conditional on employer number also provide information about wage growth from job search. As discussed in Barlevy (2008), wage gains from mobility provide useful identifying information about the wage offer distribution. Also, the increase in the average employment duration as workers move between jobs reflects improvements in job match values from on-the-job search.

The extent of variation in non-wage utility,  $\sigma_\xi$ , is identified by moments which summarize the relative importance of wages and non-wage utility in determining job mobility. In particular, moments relating to wage changes in job-to-job transitions are particularly informative about the magnitude of  $\sigma_\xi$  (Panel 3 of Table B1). For example, the proportion of voluntary job-to-job transitions in the simulated data that involve a wage decrease responds strongly to changes in  $\sigma_\xi$ . When  $\sigma_\xi = 0$ , the only explanation for the relatively large number of observed wage decreases at job-to-job transitions in the NLSY97 data is measurement error in wages which for our application has been fixed to  $\sigma_\varepsilon = 0.15$ . As  $\sigma_\xi$  increases away from zero, the model generates an increasing number of voluntary transitions where workers are willing to accept lower wages in exchange for higher non-wage utility.

### Identifying the Distribution of Unobserved Heterogeneity

In many cases, the intuition behind identification of the parameters  $\{\mu_w(j), \mu_\xi(j), \pi_j\}_{j=1}^2$  closely parallels simpler panel data models of wages and employment durations. For example, the within-person covariance in wages (moment 46) helps identify the person-specific component of wages, just as it would in a simpler panel data model of wages. When there is no heterogeneity in  $\mu_w$  across people, the model generates a within-person covariance of zero between wages on employers that are separated by unemployment spells. The mean non-wage utility offer is identified by the combination of moments that summarize employment durations and unemployment durations. As the  $\mu_\xi(j)$  parameters increase, jobs on average offer higher utility relative to employment, so unemployment spells tend to be shorter. The variation in  $\mu_\xi$  across people is identified by moments that summarize the variation in unemployment durations across people (moments 38, 41)

Finally, it remains to discuss the identification of the covariance between the mean person-specific wage and non-wage offers. Given the assumed discrete distribution of unobserved heterogeneity, and allowing for  $J = 2$

types of people, this covariance term is  $\text{cov}(\mu_w, \mu_\xi) = \sum_{j=1}^2 \pi_j \mu_w(j) \mu_\xi(j) - [\sum_{j=1}^2 \pi_j \mu_w(j)][\sum_{j=1}^2 \pi_j \mu_\xi(j)]$ . This covariance is identified by the covariance between the first wage observed after unemployment and the unemployment duration (moment 47), and the within-person covariance between the average wage and the fraction of months spent unemployed (moment 49).

## Identifying Transition Parameters

We now discuss how the transition rate parameters  $\{\lambda_u, \lambda_l, \lambda_e, \lambda_{le}\}$  are identified.

The layoff rate,  $\lambda_l$ , is identified non-parametrically by the empirical transition rate from employment into unemployment (moment 11 in Table B1). The job offer arrival rate,  $\lambda_e$ , is identified by moments that describe job-to-job transitions.<sup>19</sup> Within the model, the probability of a job-to-job transition for a worker employed in a job with utility  $U$  is  $\lambda_e \Pr(U' > U)$ . Taking the parametric distribution  $H(U)$  as given,  $\lambda_e$  is identified by moments that describe the frequency of job-to-job transitions, such as the empirical job-to-job transition rate (moment 12), and the average number of voluntary transitions that a worker makes over his career (moment 13).<sup>20</sup>

The probability that a layoff occurs in the same period is represented in the model by the parameter  $\lambda_{le}$ . As discussed in Section 4, we use data from the NLSY97 on the reason that jobs end to distinguish between voluntary and involuntary direct transitions between employers. If an individual reports that a job ends involuntarily, and he moves to a new job without experiencing an intervening spell of unemployment, then a simultaneous exogenous job ending and accepted outside offer has occurred. The probability that this type of transition occurs is  $\lambda_{le} \Pr(U' > U^*)$ . Taking  $H(U)$  and  $U^*$  as given, the fraction of direct job-to-job transitions in the data that are involuntary (moment 33) identifies  $\lambda_{le}$ .

It remains to discuss identification of the arrival rate of job offers for the

---

<sup>19</sup>We follow the search literature in assuming that job-to-job mobility is restricted by randomness in offer arrivals, but there is no direct monetary or non-monetary job switching cost.

<sup>20</sup>As discussed in French and Taber (2011), non-parametric identification of  $\lambda_e$  requires exclusion restrictions in the form of observable variables that affect  $\lambda_e$  but do not affect  $\Pr(U' > U)$ . In our model and with these data, there are no obvious candidates for exclusion restrictions. Unfortunately, information on rejected job offers, which would provide direct information about  $\lambda_e$ , is not available in the NLSY97.

unemployed,  $\lambda_u$ . The reservation utility level for the unemployed is defined by Equation (A3) where the transition rate out of unemployment is  $\lambda_u \Pr(U' > U^*)$ . Note that  $U^*$  is not a primitive of the model – it is determined by optimal job search behavior. During estimation, as discussed in section 5.1, we fix the monthly discount rate to  $\delta = .998$  and set  $b = \ln(0.35 \times e^{\mu_w})$ . It is clear from equation (A3) that  $\lambda_u$  will impact the unemployment durations generated by the model, so  $\lambda_u$  is identified by the moments that summarize the unemployment duration distribution (moments 10, 18-20).

## 6 Parameter Estimates

This section discusses the estimated parameters for the search model with non-wage job characteristics. In general, the model does a good job of fitting the data (Table B1) but in the interest of space we do not discuss this in further detail.

Our discussion begins with an examination of the importance of wages and non-wage utility and the magnitude of search frictions implied by the estimates. The discussion concludes by quantifying the importance of person-specific unobserved heterogeneity.

### 6.1 Job Offers and Labor Market Frictions

The parameter estimates are shown in Table 2. The estimate of the standard deviation of wage offers ( $\sigma_w$ ) is 0.4052. Interestingly, the estimate of  $\sigma_\xi = 0.3942$  indicates that a worker faces approximately the same amount of variation in non-wage utility across job matches as in wages. The relatively large amount of variation in non-wage utility across job matches indicates that non-wage considerations are an important factor as workers evaluate job offers. In other words, focusing only on wages, as is commonly done in the on-the-job search literature, misses a significant determinant of worker search behavior and total utility. This result is clearly demonstrated by examining simulated data generated from the estimated model (summary statistics are given in Table 3). In these data, non-wage utility accounts for nearly 50 percent of the utility gains from voluntary transitions (mean  $\Delta w$ /mean  $\Delta \xi$ ).

Job dispersion due to search frictions is easily demonstrated by examining a scatterplot of accepted wages and non-wage utility and a histogram of total

Table 2: Parameter Estimates

Parameter	Notation	Estimate
Stand. dev. of wage offer	$\sigma_w$	0.4052 (0.0066)
Stand. dev. of non-wage match	$\sigma_\xi$	0.3942 (0.0113)
Pr(offer while unemployed)	$\lambda_u$	0.9655 (0.0509)
Pr(layoff)	$\lambda_l$	0.0430 (0.0072)
Pr(offer while employed)	$\lambda_e$	0.6295 (0.0103)
Pr(offer and layoff)	$\lambda_{le}$	0.0427 (0.0026)
<u>Type 1</u>		
Mean wage offer	$\mu_w(1)$	0.8875 (0.0574)
Mean non-wage utility offer	$\mu_\xi(1)$	-1.9882 (0.0430)
Reservation utility*	$U^*(1)$	-0.1333 (0.0592)
Pr(type 1)	$\pi_1$	0.2497 (0.0261)
<u>Type 2</u>		
Mean wage	$\mu_w(2)$	1.6328 (0.0144)
Mean non-wage utility offer	$\mu_\xi(2)$	-1.3820 (0.0154)
Reservation utility*	$U^*(2)$	0.7117 (0.0230)
Pr(type 2)	$\pi_2$	0.7503 (0.0261)

\*The reservation utility levels are computed by solving Equation (A3) at the estimated parameters.

(a) Scatter plot

(b) Histogram of  $w + \xi$

utility (Figure 2) where for clarity we focus on the first accepted job offer after unemployment for Type 2 workers.<sup>21</sup> Not only are wages and non-wage utilities dispersed (Figure 2a) but total job values or “jobs” are also widely dispersed (Figure 2b). As we discussed in Section 2 and as we will illustrate in the following section, job dispersion results in severely biased estimates of the marginal-willingness-to-pay. Furthermore, as workers move up the “utility ladder,” jobs can become further dispersed.

The four transition parameters ( $\lambda$ 's) determine the magnitude of frictions in the labor market. Recall that the model is estimated using monthly data, so all parameters are monthly arrival rates. The estimated offer arrival probability for unemployed agents is close to one ( $\lambda_u = 0.9655$ ), and the estimated job offer arrival rate for employed workers is approximately 60 percent lower ( $\lambda_e = 0.6295$ ). An employed agent faces approximately a 4 percent chance of exogenously losing his job in each month and being forced into unemployment ( $\lambda_l = 0.0430$ ). Similarly, an employed worker has approximately a 4 percent chance of losing his job, but simultaneously receiving a new job offer that gives him the option of avoiding unemployment ( $\lambda_{le} = 0.0427$ ).

## 6.2 Person-Specific Unobserved Heterogeneity

As discussed earlier in the paper, the extent of person-specific unobserved heterogeneity in the model is determined by the estimated values of the parameters  $\{\mu_w(j), \mu_\xi(j), \pi_j\}_{j=1}^2$ . The most common type of person in the economy makes up three-quarters of the population ( $\pi_2 = 0.7503$ ), and has an expected wage offer of  $\mu_w(2) = 1.6392$  and expect to receive a non-wage utility offer of  $\mu_\xi(2) = -1.3820$ . Recall that the non-wage utility flow from employment is measured relative to the value of unemployment, so the fact that this parameter estimate is negative simply indicates that on average these workers get disutility from working. The remaining one-quarter of the population consists of Type 1 workers. Relative to Type 2 workers, this segment of the population has lower labor market ability, and receives worse job offers (both wage and non-wage). More specifically, the expected wage offer for a Type 1 worker is approximately half as large as that of a Type 2 worker ( $\mu_w(1) = 0.8875$  vs  $\mu_w(2) = 1.6392$ ). Clearly, the estimates indicate

---

<sup>21</sup>Section 6.2 describes the differences in labor market outcomes between Type 1 and Type 2 workers. Section 7 provides a detailed analysis of how job-to-job mobility impacts accepted job offers.

that there is substantial unobserved heterogeneity in this sub-sample from the NLSY97.

The most straightforward way to quantify the importance of person-specific unobserved heterogeneity is by comparing simulated outcomes for the two types of workers. It is apparent from Table 3 that unobserved heterogeneity results in large difference in outcomes between Type 1 and 2 workers, not only for wages and non-wage utility but also employment and unemployment durations and for lifetime utility. As we will show, although controlling for worker ability reduces the bias observed in MWP estimates, it will not completely eliminate it. Indeed, regressing  $w + \xi$  on a type dummy reveals that worker type can only explain about 59.2 percent of the variation in job utility. That is, even controlling for worker ability, 40.8 percent of the variation in total utility remains unexplained.

Finally, as discussed in Section 3.5, worker heterogeneity in mean wage and non-wage match values can give rise to correlation across the population. Given our estimates, this correlation is 0.339. Since it can be argued that some characteristics are positively correlated (health insurance benefits) while others are negatively correlated (risk of injury), this does not seem unreasonable.

## 7 Estimating Compensating Wage Differentials

In our model, the marginal-willingness-to-pay for  $\xi$  is known and fixed at  $-1$ . With this in mind, we can use our model to better understand the sources of job dispersion in a search framework and to illustrate how the various sources of job dispersion lead to biased hedonic compensating wage differential estimates. To do so, we estimate several variants of the following hedonic wage equation:

$$w_i = \alpha + \beta\xi_i + \gamma \times \text{type dummies} + \kappa \times \text{job dummies} + e$$

where  $\beta$  represents the marginal willingness to pay for non-wage job characteristics. At its most inclusive, this specification controls for worker heterogeneity and job dynamics through worker job numbers within employment cycles.

The standard, naïve wage hedonic with no controls for ability or job dynamics yields an extremely biased MWP of  $\hat{\beta} = -0.22$ . Controlling for

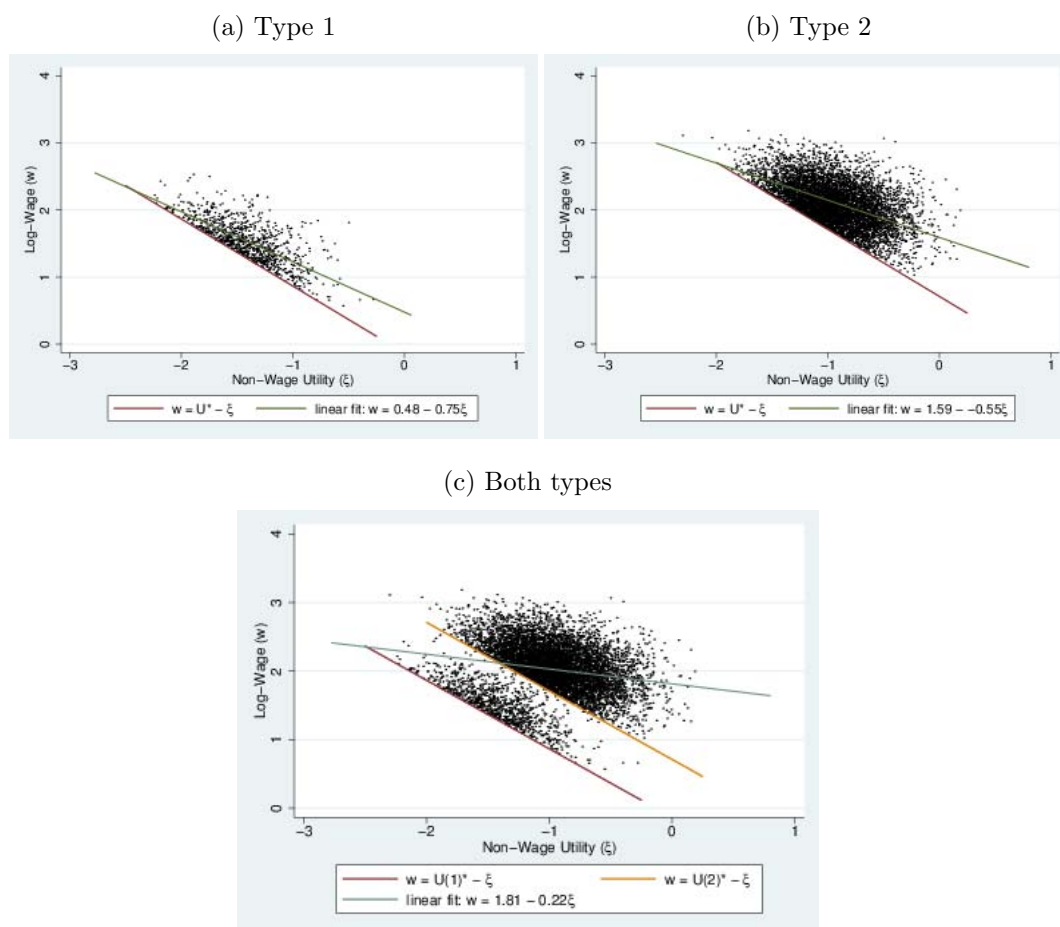

worker type using dummy variables yields a greatly improved but still significantly biased MWP estimate of  $-0.58$ . Fully controlling for worker type by allowing MWP estimates to vary by type yields estimates of  $-0.75$  for Type 1 workers and  $-0.55$  for Type 2 workers.

Figure 3 decomposes the effects of job dispersion and worker heterogeneity on hedonic MWP estimates. This figure plots accepted wages and non-wage utilities in the simulated data separately for each type (Figures 3a and 3b), and pooled across both types (Figure 3c). Figures 3a and 3b show that conditional on type, there is a considerable amount of job dispersion in the simulated data because accepted jobs are truncated from below at the reservation utility level ( $w + \xi > U^*$ ). As a result, hedonic estimates of the MWP are attenuated from the true value of  $-1$  that was used to generate the simulated data. It is important to note that the estimates shown in this figure represent, in some respects, a best case scenario for the simple hedonic regression approach. These regressions allow the econometrician to have perfect information about worker type, so he is able to fully control for heterogeneity by estimating separate regressions for each type. In contrast, empirical applications typically rely on imperfectly measured, and undoubtedly incomplete, proxies for worker heterogeneity. These results show that even in this optimistic scenario where the econometrician is able to eliminate bias due to worker heterogeneity, job dispersion leads to seriously biased estimates of the MWP.

Figure 3c plots accepted jobs for both types of worker, the reservation utility frontiers ( $U^* = w + \xi$ ) for each type, and a fitted hedonic regression line which assumes that worker type is not observed by the econometrician. In this scenario, MWP estimates will suffer from bias due to both dispersion in job offers and unobserved worker heterogeneity. The plotted regression line in this figure illustrates how failing to control for unobserved differences between workers leads to a severe downward bias in the estimated MWP. Simply put, because Type 2 workers tend to accept jobs that offer higher total utility than Type 1 workers, the relationship between accepted values of  $w$  and  $\xi$  uncovered by a naïve specification of a hedonic regression bears little resemblance to the true MWP of workers in the model.

The dynamics of our search model also contributes to the dispersion in jobs (see summary statistics for jobs 1, 2 and 3 from Table 3). Controlling for job number within an employment cycle but excluding ability controls yields a moderately improved MWP estimate of  $-0.28$  (vis  $-0.22$ ). Finally, controlling for both type and job number the MWP estimate is still signifi-

Figure 3: Worker heterogeneity and bias

cantly biased at  $-0.61$ . This specification is able to explain only about 55.5 percent of the variation in wages.<sup>22</sup>

Note that it is the dispersion of both wage and non-wage utility offers that introduces a tradeoff between wages and non-wage utility and therefore generates some measure of success in our compensating wage differential estimates. Without variation in both dimensions, MWP estimates may bear no resemblance to underlying worker preferences. To see this, consider a model where there is no variation in wage offers ( $\sigma_w = 0$ ) or no variation non-wage utility offers ( $\sigma_\xi = 0$ ). In this case, it is clear that MWP estimates will be degenerate (i.e., 0 or  $\infty$ ) if worker ability is controlled for. If worker ability is not controlled for, hedonic regressions using simulated data yield positive MWP estimates of 0.16 or 0.59.

With a few exceptions (Gronberg and Reed, 1994; Hwang *et al.*, 1998; Bonhomme and Jolivet, 2009), the literature on compensating wage differentials has focused on unobserved worker ability as the reason for weak support for the theory (Brown, 1980; Hwang *et al.*, 1992; Han and Yamaguchi, 2012). To some extent, this focus on unobserved ability is warranted but nevertheless, there are further, important sources of job dispersion due to job dynamics and search frictions.

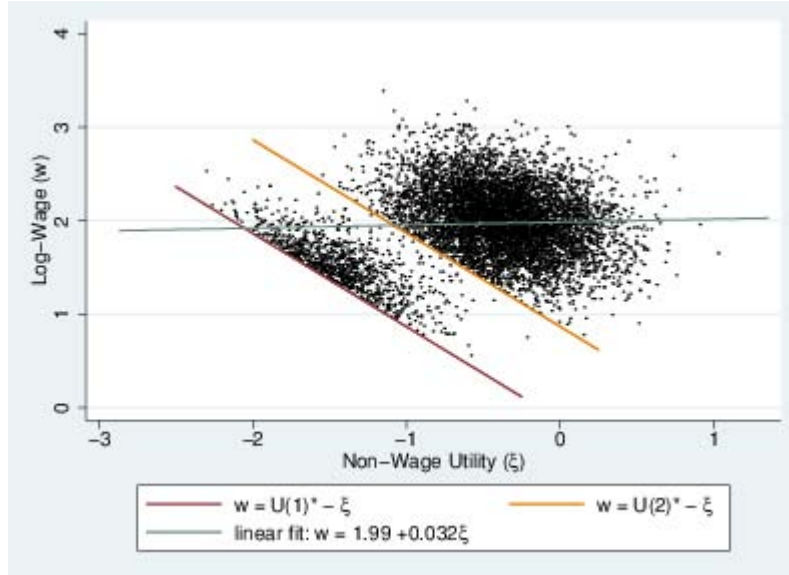

In general, when frictions are an important feature of the labor market, compensating wage differential estimates will be biased. Our findings are similar to those of Bonhomme and Jolivet (2009) where they estimate a partial equilibrium version of Hwang *et al.* (1998) with several non-wage job characteristics. They find strong preferences for amenities but little evidence of compensating differentials in their simulated data. Our aggregate approach with choice over just two dimensions draws a clear picture of precisely how search frictions interact to bias compensating wage differential estimates. Our biased compensating wage differential estimates arise because frictions imply that acceptable jobs typically provide utility greater than the reservation level. This job dispersion does not depend on but is exacerbated by heterogeneity in worker ability and job dynamics.

Since these biases are due to job dispersion (i.e.,  $\text{var}(U_i) > 0$ ), it is useful to examine the sources of job dispersion. In our discussion thus far, we have discussed worker ability and job-to-job mobility as sources of job dispersion. But job-to-job mobility, while observable to the practitioner, is an imperfect

---

<sup>22</sup>This can only be marginally improved by allowing for interactions in explanatory variables.

Figure 4: Worker heterogeneity and wrong signed MWP

proxy for the dispersion of worker reservation utilities due to job dynamics. As the modelers, we perfectly observe reservation utilities,  $U_i^{**}$ :  $U_i^{**} = U^*$  for the first job out of unemployment and  $U_i^{**} = w_i(-1) + \xi_i(-1)$  for all other jobs where  $w_i(-1)$  and  $\xi_i(-1)$  are the worker's prior wage and non-wage utility. Regressing  $U_i$  on type dummies and  $U_i^{**}$ , we find that only about 67 percent of the job dispersion observable to us as modelers can be explained by ability differences and dispersion in reservation utilities. Thus, the remaining 33 percent can only be due to frictions resulting from the inherent dispersion of job offers.

Unlike some of the compensating wage differential literature, our marginal willingness to pay estimates using our simulated dataset all have the correct sign. Using a counterfactual experiment, we examine how increasing worker heterogeneity can yield MWP estimates with the wrong sign.

## Worker heterogeneity

As we discussed earlier, using degenerate examples of our model, worker heterogeneity is sufficient to generate MWP estimates with the wrong sign. We

now show that a more moderate perturbation of our estimated parameters is sufficient to generate wrong-signed MWP estimates. Consider a model where the mean non-wage utility for Type 2 workers is changed from  $\mu_\xi(2) = -1.382$  to  $\mu_\xi(2) = -0.75$  but all other parameters remain the same. As a result of the increase in mean non-wage utility offers Type 2 workers optimally increase their reservation utility from  $U^*(2) = 0.7117$  to  $U^*(2) = 0.8682$ . Wages and non-wage utility for Type 2 workers shift to the northeast resulting in a positive estimated willingness-to-pay (see Figure 4). The hedonic wage regression without ability controls yields a simulated dataset with an estimated MWP of 0.0320 and a standard error of 0.0004.

## 8 Concluding remarks

In a frictionless and competitive labor market, equally able workers must receive the same total compensation and the estimated wage differential for a job attribute will equal the workers' willingness-to-pay for that attribute. Unfortunately, evidence in support of the theory is weak (Brown, 1980). In contrast, in labor markets with frictions, total job values or "jobs" are dispersed and total utility will in general exceed a worker's reservation utility so that different, equally-able workers will receive different compensation packages, biasing estimates of compensating wage differentials.

In this paper we explore the links between job dispersion and the often weak evidence for compensating wage differentials. We begin by estimating an on-the-job search model which allows workers to search across jobs based on both wages and job-specific non-wage utility flows. The importance of non-wage utility is revealed through voluntary job-to-job moves, wage changes at transitions, and job durations. Since not accounting for worker ability is a common explanation for the frequent failure of compensating wage differential estimates, we control for worker heterogeneity.

Using a simulated data set based on our model and parameter estimates, we show that job dispersion leads to severely biased compensating wage differential estimates. Job dispersion is exacerbated by differences in worker ability and in an on-the-job search framework, by dispersion in reservation wages and controlling for these sources of job dispersion ameliorates the bias. Nevertheless, MWP estimates still have a downward bias of nearly 40 percent. Indeed, estimating total utility on worker type and the reservation utility reveals that 33 percent of job dispersion must be due to frictions inherent in

the dispersion of job offers.

## Appendix

### A Derivation of Reservation Utility

The reservation utility level for unemployed agents,  $U^*$ , solves  $V^e(U) = V^u$ . To derive  $U^*$ , we must first rearrange (6) and (5) so that common terms can be collected when evaluated at  $U = U^*$ . Subtracting  $\delta V^e(U)$  from both sides of (6):

$$(1 - \delta)V^e(U) = U + \delta[\lambda_e E \max\{0, V^e(U') - V^e(U)\} + \lambda_l(V^u - V^e(U)) \\ + \lambda_{le} E \max\{V^u - V^e(U), V^e(U') - V^e(U)\}].$$

Evaluating this at  $U = U^*$ :

$$(1 - \delta)V^e(U^*) = U^* + \delta \left[ \lambda_e \int_{U^*}^{\infty} [V^e(U') - V^u] dH(U') + \lambda_{le} \int_{U^*}^{\infty} [V^e(U') - V^u] dH(U') \right] \\ = U^* + \delta(\lambda_e + \lambda_{le}) \int_{U^*}^{\infty} [V^e(U') - V^u] dH(U') \tag{A1}$$

Similarly, subtracting  $\delta V^u$  from both sides of (5),

$$(1 - \delta)V^u = b + \delta\lambda_u E \max\{0, V^e(U') - V^u\} \\ = b + \delta\lambda_u \int_{U^*}^{\infty} [V^e(U') - V^u] dH(U'). \tag{A2}$$

Evaluating at  $U = U^*$ , we can equate (A1) and (A2), integrate by parts and solve to get:

$$\begin{aligned}
 U^* &= b + \delta[\lambda_u - (\lambda_e + \lambda_{le})] \int_{U^*}^{\infty} [V^e(U') - V^u] dH(U') \\
 &= b + \delta[\lambda_u - (\lambda_e + \lambda_{le})] \int_{U^*}^{\infty} V^{e'}(U') [1 - H(U)] dU' \\
 &= b + \delta[\lambda_u - (\lambda_e + \lambda_{le})] \int_{U^*}^{\infty} \frac{1 - H(U')}{(1 - \delta) + \delta\{\lambda_e[1 - H(U')] + \lambda_l + \lambda_{le}\}} dU'.
 \end{aligned}
 \tag{A3}$$

When  $\lambda_u > \lambda_e + \lambda_{le}$  (the probability of receiving an offer while unemployed is greater than that when employed), an unemployed worker's reservation wage exceeds the one-period utility flow from unemployment.

## B Estimation Moments

Table B1: Moments of the NLSY97 Data and Simulated Data

Moment #	Description	Data	Simulated
Cycle Moments (Panel 1)			
1	Mean log-wage (employer 1)	1.9791	1.9469
2	Std. dev. of log-wage (employer 1)	0.4249	0.3942
3	Mean employment spell duration (employer 1)	8.9392	8.5086
4	Mean log-wage (employer 2)	2.0377	2.0690
5	Std. dev. of log-wage (employer 2)	0.4582	0.3767
6	Mean employment spell duration (employer 2)	9.2713	9.3163
7	Mean log-wage (employer 3)	2.0608	2.1142
8	Std. dev. of log-wage (employer 3)	0.4572	0.3553
9	Mean employment spell duration (employer 3)	9.7382	8.9228
Transition and Duration Moments (Panel 2)			
10	mean unemp. spell duration	5.9087	5.5116
11	Pr(transition into unemp.)	0.0469	0.0563
12	Pr(job-to-job transition)	0.0364	0.0426
13	mean total number of voluntary job-to-job transitions	1.4510	1.4497
14	mean total number of involuntary job-to-job transitions	0.2571	0.2704
